Incorporated

# INFORMATION FOR CONTRIBUTORS

## Manuscripts

Send manuscripts to Elmer Hutchisson, Case School of Applied Science, Cleveland 6, Ohio.

Papers must be in English, **typewritten double spaced** with wide margins on a durable white paper, preferably lettersize. **The original copy,** not the carbon, should be submitted.

For general style, spellings, abbreviations, and form, recent issues of this journal should be consulted.

## Abstracts

**An abstract must accompany each article.** It should be adequate as an *index* and as a *summary.* As an index it should give all subjects, major and minor, concerning which new information is presented. As a summary it should give the conclusions of the article and all numerical results of general interest.

## Mathematical Expressions

Make all expressions clear to the typesetter. Identify in the margin of the manuscript Greek letters and unusual symbols.

Use fractional exponents instead of root signs.

**Avoid complicated exponents and subscripts.** Should it be necessary to repeat a complicated expression a number of times it should be represented by some convenient symbol.

The solidus (/) should be used wherever possible for fractions.

## References

References should appear as footnotes, numbered consecutively, and arranged thus:

[1] A. B. Smith, Phys. Rev. 41, 852 (1932).

[2] G. R. Harrison, *Atoms in Action* (William Morrow & Company, New York, 1939), first edition, p. 30.

## Figures and Tables

**A separate sheet listing captions for all figures must accompany manuscript.** Each table should have a caption. These in all cases should be complete in themselves so as to make the data intelligible to the reader without reference to the text. Each figure and table should be cited in sequence in the text.

## Line Drawings and Photographs

Plan figures for approximately one-half reduction. Wherever possible arrange figures so that after reduction they will not be wider than **three inches. Lettering must be large enough to be readable after reduction.**

**Line drawings must be made with black India ink on white paper or tracing cloth. Coordinate paper is not desirable, but if used must be blue-lined and all coordinates to be reproduced drawn with India ink.**

Drawings which cannot be used will be returned to the author.

Photographs should show clear black and white contrasts.

Avoid round and oval photographs.

## Alterations

**Take great care that each manuscript is typographically accurate.** A limited number of alterations in proof is unavoidable, but the cost of making extensive alterations after the article has been set in type will be charged to the author.

Proof and all correspondence concerning papers in the process of publication should be addressed to the Publications Manager, American Institute of Physics, 57 East 55 Street, New York 22, New York.

# INFORMATION FOR SUBSCRIBERS

The JOURNAL OF APPLIED PHYSICS is devoted to physics in its role as the science basic to other natural sciences and to the arts and industries. Previous to 1937 this publication was known as PHYSICS. It aims to be of service not only in physical laboratories, but also in the laboratories of industrial, chemical, geological, geophysical, meteorological, radio, and similar concerns. The JOURNAL OF APPLIED PHYSICS publishes editorials, news of physicists, and reviews, as well as technical papers of applied physics.

**Subscriptions** and orders for back numbers should be addressed to the American Institute of Physics, 57 East 55 Street, New York 22, N. Y.

### SUBSCRIPTION PRICE

# European Electron Induction Accelerators

BY HERMAN F. KAISER
*U. S. Naval Research Laboratory, Washington, D. C.*

Betatrons, induction electron accelerators for the production of high energy $X$-radiation, were under development in Germany during the war and to a limited extent at present. This work is reviewed for the most part and details are given on the constructional features of 6- to 15-million volt betatrons and on the theory and design of 15- and 200-million volt betatrons. The smaller units, especially the Siemen's 6 Mv, are quite successful and more advanced than comparable American units. While no large machines were actually built, the projected 200-Mv Wideroe design introduces new features of value. Betatron patent ideas are reviewed.

## I. HISTORY OF BETATRON DEVELOPMENT ON THE CONTINENT

THE first published work on electron induction acceleration to appear in Europe was the doctoral dissertation of Rolf Wideroe[1] of 1927 which was published as a paper[2] the following year. It is known, however, that a patent application for an electron induction accelerator was filed in Germany by J. Slepian (Westinghouse) soon after the filing of an application[3] in the United States in April, 1922. Because of a misunderstanding of the principles involved by a Dr. Smidt of the German Patent office who persisted in quoting the text of Abraham and Becker in support of his contention that it was impossible to both accelerate and guide an electron by a magnetic field at one and the same time, it was not granted until 1928. Whether or not Wideroe had knowledge of this patent is not known. At the same time experiments were being carried out by Breit and Tuve[4] at the Carnegie Institute in Washington which it is now known were correct in principle and might have been successful if pursued further. In 1929 a work by E. T. S. Walton,[5] following a suggestion by Lord, Rutherford, appeared in England. In this he discovered independently the flux conditions announced by Wideroe and made a further contribution on the theory of the magnetic fields required for assurance of a stable orbit. Successful experimental results unfortunately were not obtained.

Developments on the continent have been based on Wideroe's work and on the Steenbeck patents of 1937[6] in which the necessary conditions of Wideroe are set forth and supplemented

by the condition for producing axial stability by curvature of the guide field flux—a condition which was discovered independently in the United States by Breit and Tuve and later by Lawrence and Livingston for the cyclotron. An induction accelerator was built and tried by Steenbeck, who recorded production of 1.8-Mev radiation. Following Kerst's[7] publication of successful production of 2.5-Mev radiation at intensities of 15–100 milligrams of radiation, Steenbeck published a belated note on his work in 1943,[8] describing results obtained in 1935 and 1936.

The work of Kerst was a great incentive to the continental workers interested in this field, particularly Steenbeck and Wideroe. During the war the latter was the more active in this work, but Steenbeck set into action further work on this subject by Siemens Reiniger. Wideroe and the group that came to be associated with him in the wartime German betatron work were not in sympathy with the Nazi cause but were induced to continue such work for scientific and other considerations.

An unpublished investigation[9] interrupted by the war was carried out by James L. Tuck working in collaboration with L. Szilard at the Clarendon Laboratory in Oxford. It is now known that this investigation came very near to success.

The betatron development was carried out by three separate groups. One was the Megavolt Versuchsanstalt (MVA) or Megavolt Research Association which worked under the guidance of Dr. Wideroe. Siemens and the A.E.G. also had betatron projects. MVA laid plans for 15-, 30-, and a 200-Mv accelerators. The first was begun early in 1944 and brought to successful completion in the fall of the same year. The second was merely tentative. The design of the 200 Mv was prompted by news that the General Electric Company (U.S.A.) was constructing a 100-Mv betatron. The design of the 200-Mv accelerator was completed about this time and the construction work was turned over to the Brown-Boveri firm in Heidelberg. Occupation in Germany, however, came before any construction work could be begun.

The basic ideas underlying the design of the 15- and 200-Mv induction accelerators were published by Wideroe in two papers.[10] These discuss the special problems involved such as the axial and radial stabilization by properly designed guiding fields, injection and extraction of electrons, the useful load of the apparatus, the maximum electron filling of the acceleration chamber, dependence on injection voltage, use of auxiliary lens systems especially for high radiation energies, the effects of gas molecules, technical transformer construction for high energy production and finally the fields of application of the betatron; cancer treatment, radiography, and nuclear physics.

In collaboration with the design work of Wideroe, a considerable amount of theoretical work was carried out by Touschek which was known to have been of invaluable aid in the development of the 15-Mv accelerator. Further theoretical work has been done by Touschek on the starting of electrons in the accelerator. Some of this work is along the lines initiated by Kerst and Serber[11] whose work was known to Touschek. Recent work of his, it is believed, may give an explanation of the discrepancy between the Kerst-Serber theory and experimental results.

The wartime betatron work of the Siemens Reiniger firm was based on the work of Steenbeck whose 1940 patent is mentioned above. An American license for its use by the General Electric Company was requested from Siemens shortly before the outbreak of war in 1941. The results published by Kerst[11] renewed an interest which had lagged and in 1942 (December) designs were under way for construction of an electron induction accelerator. Dr. Steenbeck gave the basic specifications which were incorporated into a design at Siemens and discussed in a conference on December 15, 1942 held together with Dr. Ganswindt, Dr. Kurt Bischoff, Dr. J. Patzeld, and Dr. Konrad Gund all of Siemens. At this time was also discussed a design of Dr. Gund in which he proposed an accelerator with a fixed magnetic guide field, surrounding an alternating magnetic field passing through a central core, a

scheme originating from a paper of W. W. Jasinsky[12] in which the field-radius conditions are erroneously set forth. These are corrected in the design mentioned and several other ideas set forth. A patent application was filed by Siemens in July 1942[13] covering these and also premagnetization or bias field operation. Ideas for operation with biased fields were also evolved by Kerst at about this time.[14]

From the design worked out in the above conference and later meetings a successful 6-Mv betatron operating on 550 cycles was developed. A more detailed description of this unit will be given later.

## II. ACTIVITIES OF THE MEGAVOLT RESEARCH ASSOCIATION (MVA)

### A. Description of the 15-Mv Induction Electron Accelerator

*General Considerations*

Theoretical curves of the absorption coefficient as a function of electron energy have a minimum which lie between 3–10 Mev for most metals. A peak energy of 15 Mev was, therefore, chosen to bring the effective energy in the neighborhood of 7–8 Mev. (It has since been shown that 20 Mev satisfies these requirements better.) A theoretical sixfold increase in the range of radiographic thicknesses was expected. It was also desired to use the betatron for medical purposes but not too much was expected except for an improvement in the depth dose condition due to a lowered absorption coefficient. The desirability was recognized of using the betatron for the production of high energy electron beams in which the dissipation of energy by absorption in human tissue may be localized more effectively. This problem was under consideration but no practical results had been realized.

*Constructional Details, Core*

The radius of the electron equilibrium orbit was chosen as $r=14$ cm. The diameter of the induction pole was chosen as 220 mm (11-cm radius) and the air gap in the poles was made 2 cm. The average separation of the guide poles was chosen as 6 cm and the contour of the guide pole faces was determined from magnetic measurements and from measurements made by means of the electrolytic trough. This process was continued until the guide field had the properties required. The guide poles were so arranged with respect to the remainder of the apparatus that, as a result of the saturation of the guide field, the latter does not increase in proportion to the accelerating field from a certain point in the cycle onwards. This type of construction has some obvious advantages. The space between the acceleration pole and guide poles allows the use of flux biasing windings. It also has the advantage that no orbit expansion equipment is required, the electron striking the target upon saturation of the guide field and this without the attendant loss of energy which is present when the electron has to spiral into a smaller radius to strike a target. It may be noted, however, that this feature may still be obtained in Kersts' form of construction in which acceleration and guide fields arise from the same pole piece by a special reduction of the amount of iron at the edge of the pole piece. The approximate data for the main components (which are slightly above the initial estimates of Dr. Wideroe) are:

| | | |
|---|---|---|
| Iron weight | 1000 kg | 2200 lb. |
| Copper weight | 200 kg | 440 lb. |
| Total losses | 2.5 kw at 50 cycles | |
| Dead load | 250 kva | |
| Driving voltage | 6 kv | |

The details of core and pole assembly are shown in Fig. 1. The yoke is constructed from laminated iron of thickness equivalent to 29-gauge, 0.014-inch stock of approximately ½ watt per pound core loss (10,000 lines and 60 cycles). The lamination stack is not divided, i.e., no provision is made for cooling the core by means of air ducts. It was found that the heating was not excessive. The vertical members of the yoke, in contrast to American design, extend the full height of the apparatus, and the horizontal members are held between these by a special arrangement of clamping frames. This produces four vertical "shim" gaps. On the upper side these have means for adjustment of the height and level of the upper transverse member (yoke). This part carries the accelerating pole by means of six bolts circularly arranged. By means of a supporting ring, it also carries the guide pole and

FIG. 1. View of 15-Mev betatron at Wrist.

coil boxes. The yoke laminations are clamped by transverse bolts through insulating tubes.

### *Acceleration Chamber*

Glass acceleration chambers were made by the glass-blowing laboratory of the C. H. F. Müller firm. These have an approximately elliptical cross section. The inside walls are coated with graphite or silver coatings and the tubes have either two or three radial openings with stems on the periphery for evacuation or for mounting the electron injection assembly. Vacuum was produced by an oil diffusion pump backed by a three-stage mercury diffusion pump with a liquid air trap separating the two. The mercury diffusion pump was backed in turn by a rotary oil pump. This unnecessary complication of pumps was caused by the scarcity of available and usable equipment.

The vacuum was measured by means of a Phillips vacuum meter placed between the two diffusion pumps and by means of an ionization gauge sealed to the acceleration chamber on the injection stem. It was noted that operation was not possible at pressures above $10^{-5}$ mm Hg and steady yields were obtained only at $10^{-6}$-mm pressure.

The electron gun or injector is shown in Fig. 2 and follows in principle the design introduced by Kerst. It consists of a tungsten filament (oxide coated electron sources were also used) surrounded by a semi-cylindrical Wehnelt or Faraday cage and of two anode plates insulated from each other. The cage serves, on application of a potential between itself and the filament, to concentrate the electron stream. The split anode, on the two halves of which different potentials could be applied has, ignoring for a moment the necessary acceleration of electrons, a purpose similar to that of the deflection plates of a cathode-ray tube. It is thus possible by applying various potentials to these plates to give the electrons various initial projection angles in the plane of the orbit. The necessary correction of the electron beam in the vertical direction is obtained by a small rotation of the whole injector system or stem on its ground glass joint. A small bar of tungsten is fastened to the innermost anode plate with its long axis vertical to serve as a target for x-ray production.

The filament is heated continuously. The injection voltage is applied only for a short time at the beginning of the acceleration period by means of a special arrangement to be described below, partly to charge the entire injector structure to as high a voltage as possible and partly to avoid filling the electron accelerator chamber with stray electrons.

### *Connections*

Figure 3 shows the entire diagram of connections. Alternating current of 6 kv is generated by a regulating transformer and supplied to the driving circuit in which the dead load of the circuit is compensated by a capacitor bank, the

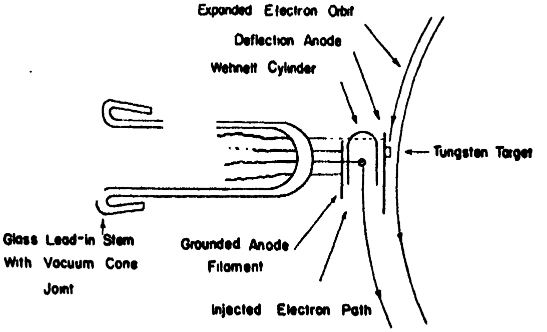

FIG. 2. Electron injector gun for 15-Mev betatron (schematic).

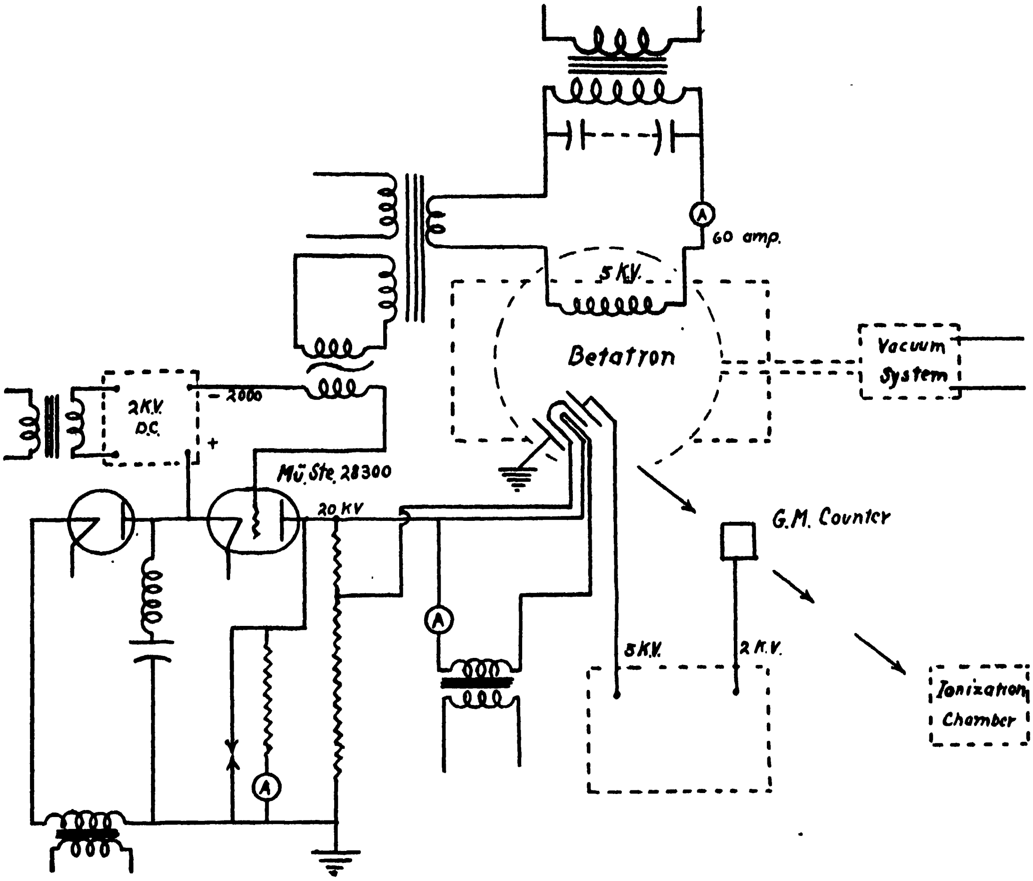

FIG. 3. Diagram of connections for 15-Mev betatron.

capacity of which may be varied between limits. The injection voltage is produced by H.V. equipment from which the potential may be applied at the proper instant near the beginning of the acceleration period by means of a special grid controlled high voltage rectifier tube. The driving circuit of the betatron passes through a small utility transformer which in turn operates a peaking transformer for the production of a sharp positive pulse to remove momentarily the large negative potential on the grid of the control valve. In earlier experiments, a mechanical contactor driven by a synchronous motor was used to apply the tripping pulse but this gave much trouble due to fouling of contacts. The circuit diagram also shows a 5-kv constant potential circuit used for applying the deflection voltages to the split anode, the innermost plate of which is connected together with the acceleration chamber coating to ground.

*Operation*

In the early stages of operation radiation is detected by means of a counter tube which of course becomes useless when the machine is brought into adjustment and radiation of considerable intensity is produced. Ionization chambers are then used and depended upon for measurement of the radiation intensity. With shielding the counter tube may still be used for indicating the point in the cycle at which radiation is emitted directly upon an oscilloscope in which the horizontal or time base is supplied by the a.c. driving voltage.

In operation the vacuum is checked, the driving circuit is energized, and the phase of the injection pulse is determined and corrected by means of the phase shifting device. On starting the counter and cathode-ray tube, a radiation output is generally observed. By rotation of the ground glass joint of the injector, by application of a suitable deflector voltage, by changing the position of the acceleration chamber in the machine, and also by adjustment of the air gap in the guide field it is possible to gradually bring about an optimum yield. Then by keeping these variables constant quite reproducible results could be depended upon which were then only influenced by the vacuum conditions.

To check the quality of the radiation produced, various methods were resorted to: (a) observation of the output radiation pulse on the oscilloscope allowed an estimate of the time of acceleration of the electrons and a deduction of their maximum energy which in general was around 13–15 Mev, (b) absorption measurements on the radiation which, however, are somewhat uncertain because of the shallow minimum in the absorption *versus* energy curve, (c) rapid dying out of radiation intensity on reducing the amplitude of the exciting current, and (d) production of artificial radioactivity by irradiation of various materials. These phenomena are especially pronounced in the case of copper and silver.

After the expected quality of radiation had been established, attention was directed to improving the intensity of the radiation. It was hoped to attain a maximum electron filling of the acceleration chamber such as could be expected from the following formula deduced by Wideroe for the effect of space charge*:

$$i=\frac{4\pi n^3(\Delta r)^3(1-n)f^2rB_{\max}}{c^2(-dr)}\text{ amp.}$$

$\Delta r$: radial oscillation amplitude,
$dr$: change in $\Delta r$,

in which $r$ is the radius of the orbit, $n$ the exponent in field-radio relation, $f$ the frequency, $B_{\max}$ the maximum guide field strength, and the other quantities their usual significance. This formula indicates a value which is usually about ten times that observed experimentally. In operation yields ranging from 30 grams to 1 kilogram radium equivalent were obtained. It was believed that this discrepancy is caused by the release of gases by bombardment of the walls of the acceleration chamber and that better results could be obtained only by use of baked out and sealed-off acceleration chambers.

### *Program for Further Development*

The program of the Megavolt Versuchsanstalt as described in June 1945 was: (a) further work to increase the radiation yield of the 15-Mev betatron and (b) to build as soon as possible a duplicate of this equipment for use in medical research to allow the first unit to be used solely for technical development. This was, of course, the wartime program. At present scientific research is strictly limited by the military government of the occupational forces.

Under (a) it was planned to make further experiments on acceleration chambers fitted with electron lens systems which might, in view of the greater stabilization forces made available by their use, bring about an increase in radiation output intensity. It was also planned to study the tangential electron injection technique of Wideroe once more because of the possible advantage accruing from the absence of an injector structure in the acceleration chamber; also to study the problem of releasing a beam of electrons from the apparatus, a subject of considerable importance.

Another intention was the design and construction of a 30-Mev unit for use in nuclear research. This project was to have been undertaken at an early date and some of the design calculations had been made along with those for the 15-Mev betatron.

It was felt that an apparatus of equal size but operating on the premagnetization scheme of Wideroe would be useful in testing such questions as to whether or not the final energy of the accelerator would be affected by the radiation damping as predicted by Iwanenko and Pomerantschuk.[15]

A final project was the design and construction of a 200-Mev accelerator using the premagnetization scheme. This will be described below.

## B. Description of the 200-Mev Induction Electron Accelerator

### *Preliminary Considerations*

The design of the 200-Mev betatron was the outgrowth of some preliminary design work carried out by Wideroe for a 100-Mev unit.[10] This was based on his experience with the con-

---

* A brief derivation is given in Appendix I.

[15] Phys. Rev. 65, 43 (1944).

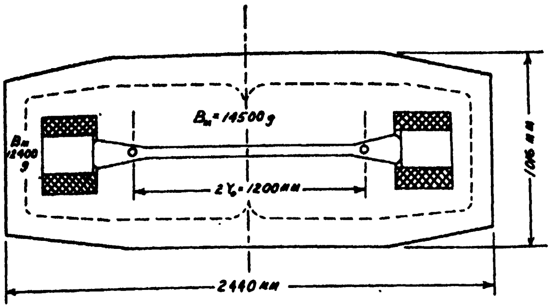

FIG. 4. Design for a 100-Mev betatron.

struction of large transformers by the Brown-Boveri firm with which he was associated. An economical design for transformer construction used by this firm consists of a radial construction in which the radial laminations are welded at the top and bottom. In this type of construction an exactly circularly shaped iron section is obtained and the required guide pole shapes are easily designed and adapted. The necessary cooling ducts are likewise easily incorporated into the core. The minimum amount of iron is used if the yoke is continuous as in a shell transformer. This lends itself to a rugged construction having a small yoke height and large cooling surface. It also offers a certain amount of radiation protection by shielding the acceleration chamber, access to which is obtained by apertures cut into the yoke.

A preliminary design for a 100-Mev unit is shown in Fig. 4. Here yoke, core, and iron return form a common iron unit constructed from radial laminations. By removal of the ten-ton upper half, access is had to the windings and the acceleration chamber. The core is crossed with air ducts to remove the 13.6-kw iron losses (0.35-mm laminations with a loss of 1.1 w/kg are assumed). The maximum induction of the core is 14,500 gauss for a stacking factor of 77 percent. The yoke and iron returns are able to dissipate 28 kw by surface cooling. In these parts the stacking factor is taken as 90 percent and the maximum inductions chosen are 14,500 and 12,500 gauss, respectively. The total weight is 20 tons.

The air gap for an equilibrium orbit of radius =60 cm is 5 cm and about 20,000 effective ampere turns are required to produce in it a guide field of 5600 gauss. To accomodate the exciting winding (46.5 kg of copper, assuming a current density of 2 amperes/mm$^2$), a window of 800 cm$^2$ is provided. Thus a space factor 12.4 percent is obtained, allowing insulation of the winding to 30–50 kv. This voltage is so chosen that it will be the most economical one considering cost of capacitors. The copper losses of the transformer will be 5–6 kw and the required dead load 7500 kva. The purely constructional costs aside from development and research are estimated at 80,000 RM for the betatron, 120,000 RM for the capacitors, thus making a total cost of 200,000 RM. Using this 100-Mev design as a basis the weights, costs, dimensions, etc. of still larger machines may be estimated as has been done by Wideroe. Of interest here is the estimation for a 200-Mev machine which would have the following characteristics: core diameter 4.89 meters, core height 2.04 meters, weight 160 tons, core losses 400 kw, radiation load 400 kw, and cost about 1,120,000 RM. It is apparent that unless further refinement were introduced betatrons of still higher energy would be extremely costly.

### *Improvement of Yield by Means of Auxillary Lenses*

It was the hope of Wideroe and his group to increase the electron filling of the acceleration chamber by means of electro-static or electro-magnetic lenses. In the 100-Mev unit it was planned to fill the air gap as completely as possible with the acceleration chamber and to provide multiple injectors and guide fields on its periphery. Allowing four guide fields for each oscillation of the electron, 28 cathodes will be required for seven oscillations per revolution. With an average electron beam of 1 ma ($V_i$=300 kv) the frequency of the injection voltage will be 17,000 cycles for a 100-Mev betatron operating at 60 cycles. This gives a charging period of $2\times10^{-6}$ second per cycle. The average charging current for these times must therefore be one ampere and requires, assuming an efficiency of 10 percent, a total cathode emission surface of 500 mm$^2$. For 28 cathodes this amounts to 18 mm$^2$ per cathode. Cathode windows will also have to be of this order of size. To prevent any electronic charges from building up on the acceleration chamber the outside must be neutralized and grounded.

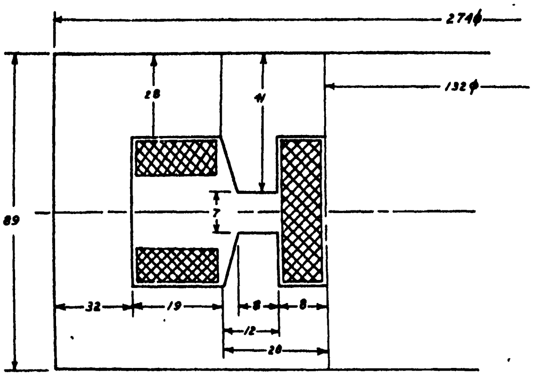

FIG. 5. Schematic construction of 200-Mev betatron (Wideroe).

### *Projected Design and General Description of 200-Mev Betatron**

As mentioned above it was evidently necessary to build a 200-Mev betatron with further refinement of design to keep the size and weight within reason. A first step in this direction was the elimination of the air gap of the 100-Mev design. Even with this feature the diameter of the machine would still be about three meters but a very considerable reduction in the weight was possible. Late in 1944 ideas had been crystallized and the Brown-Boveri firm which is skilled in the construction of large transformers was contracted in August. By mid-October a first rough design had been drawn by the firm which was discussed at length in Heidelberg. In this conference the Brown-Boveri firm was represented by its director Dr. Meyer-Delius, Chief Construction Engineer Otto Weiss, and Dr. Helmut Boecker, detail designer. The Megavolt Versuchsanstalt was represented by Dr. Wideroe and Dr. Kollath. The construction of models and a small experimental unit for the study of special problems was also considered at this time. Exact calculations were to be completed before the end of the year. In November, the MVA received some questions and designs to which reply was made by letter. In January, the first plans for construction were complete and the MVA was informed but it was too late for another conference and discussion of these plans. Since that time, the MVA had no contact with BBC and all work on this project came to an end with the occupation of Germany early in 1944.

The conference held at Heidelberg evolved a design that had the following general characteristics, which may be seen in Figs. 5 and 6. A radially laminated core of 1320 mm diameter was to be surrounded by ring-shaped radially laminated parts of about 200 mm width. These carry the guide poles which have an average separation of 7 cm and also the compensating windings. About these are placed the main exciter windings, divided above and below the median plane. To complete the magnetic induction circuit four mantels are provided 90 degrees apart on the circumference. A difficulty arising from this feature will be discussed below. The preliminary problems of the original design included the purely mechanical construction of the laminated parts of the machine, the fastening of the guide poles to the machine, the division of the transformer to facilitate installation of the acceleration chamber, pumping and electrical connections, and adjustments to the guide poles. It was planned to purchase about 40 tons of 0.35-mm transformer sheet (29 gauge) having a core loss of about 1.1 watts per kilogram.

The upper pole shoes were to be capable of being raised, and the four mantel yokes were to be displaced radially to allow access for leads, etc. A special difficulty was in the evacuation arrangements and in the cooling of the exciter windings. It was proposed to mount the inner winding directly adjacent to the core in a stationary oil case.

### *Final Form Decided Upon*

The general features of the final form evolved in the design work are shown in Fig. 6. In vertical section is shown the central core with its cooling system consisting of a number of parallel helically shaped cooling ducts winding through the body of the core and connecting at the upper and lower ends of the core to the compressed air inflow and return ducts *5*. The core has a stacking factor of about 70 percent. By means of ledges about its periphery, a ring of radially laminated pieces making up the pole shoes is held in proper position, and so that the upper pole shoe ring may be

---

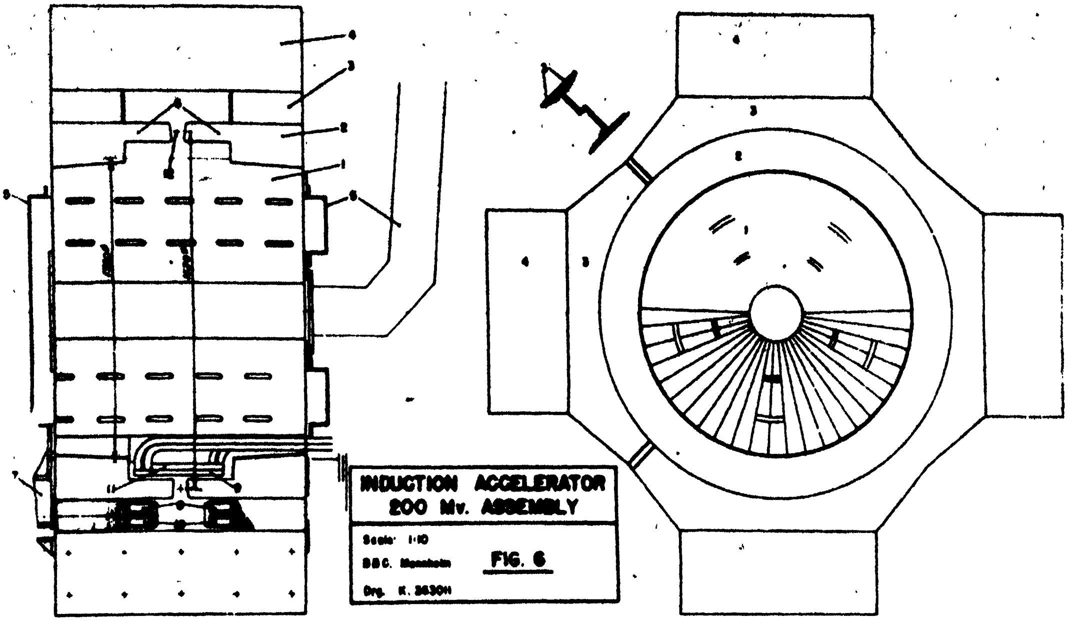

Fig. 6. Assembly of 200-Mev betatron.

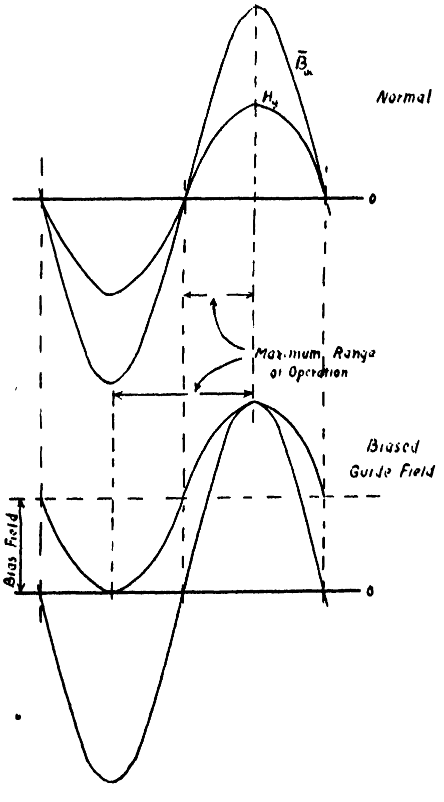

**Fig. 7. Principle of operation with biased guide field.**

raised together with the connecting ring *3*. This carries on its lower side the main a.c. exciter winding and the d.c. premagnetization winding. The original intention to complete the gapless magnetic circuit by means of the four mantels led to the difficulty that the uniformity of the magnetic flux in the guide poles will be disturbed by the locking of the mantels to the guide poles at only a few points. To avoid this difficulty, it was proposed to add an additional ring *3* (horizontally laminated) which serves the purpose of smoothing the flux from the core into the mantels *4*. This is electrically broken between adjacent mantels with a zig-zag joint to avoid an electrically continuous circuit about the flux passing to the guide poles. The figure shows the principal and compensating windings *8* and *9*, and the direct-current premagnetizing windings *10* and *11*.

By elimination of the air gap in this design a large central accelerating flux is produced by the main windings. These windings also serve to produce the guide field which at all times has to bear a fixed relation to the induction flux in order to maintain a stable electron orbit. In this design it is furthermore proposed to premagnetize the guide field so that it will be operative over nearly

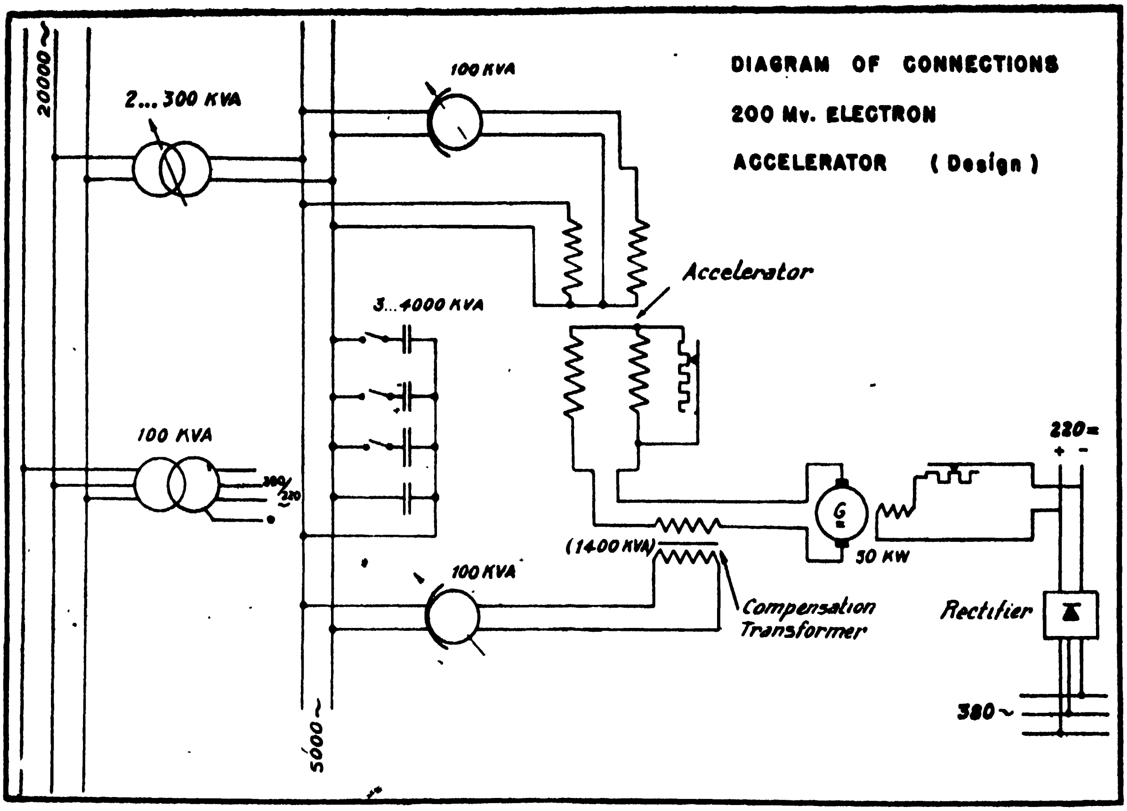

FIG. 8.

a half a cycle instead of a quarter of a cycle, thus permitting the induction field to accelerate the electrons for more than a quarter of a cycle. This principle is illustrated in Fig. 7, and has recently been discussed in the literature.[14,16]

The air gap of the earlier design provided the necessary relationship between the induction and guide fields by insuring their proportionality. Since the use of it leads to unnecessarily large power requirements, an attempt is made to provide the necessary relationship by a winding in the inner coil space (compensating winding) on which is impressed a fixed potential of the corresponding magnitude. For practical purposes the main magnetizing winding and its compensating windings may be connected to the same driving source and the flux *vs.* induction relationship may be regulated by proper proportioning of the windings of the two coils. For fine adjustment a regulation transformer may also be connected into the circuit. Figure 8 shows the manner in which these windings are to be energized from the power sources and the necessary compensating transformer connection to neutralize the a.c. voltage induced in the d.c. windings.

For this design the following windings were planned (see Fig. 6):

1. An alternating current winding placed outside of the guide pole.
2. A compensating winding correspondingly placed about the induction pole to depress the a.c. magnetization of the core to such an extent that the average induction of the core is only twice that of the induction at the center of the guide pole (fulfillment of the necessary 1:2 relation).
3. A premagnetization winding for the guide pole of which the induction is to vary from zero to a maximum.
4. A compensating winding corresponding to the above which, while in principle is not necessary, is used to prevent an undue loading of the machine by a d.c. magnetization with undesirably high induction and saturation characteristics.

Further general electrical characteristics on the design are:

Details on the exact form of the guide poles were not determined these being a feature to be worked out during the construction.

### *Stabilization of Orbit and Improvement of Orbit Control*

The magnetic stabilization forces, brought about by the suitable shaping of the guide poles, are known to diminish with an increase in size of the betatron while retaining the same sectional dimension of the acceleration chamber. Wideroe and Touschek have made a theoretical study of the additional stabilization that may be achieved by electron optical lenses. These may, in their simplest form, consist of a set of series connected coils spaced closely around the circumference of the acceleration chamber, the axis of each being tangent to the orbit. The principal advantage of such a lens system is that a greater electron filling of the acceleration chamber should be possible.

The maximum beam current is, in theory, determined by the effect of the mutual repulsion due to Coulomb forces of the electrons. These forces are compensated again by the magnetic forces mentioned above. Excess electrons thus injected are driven out of the beam and end on the walls of the acceleration chamber. The repulsive forces, although decreasing with time after injection of the electrons, are still relatively large. The effectiveness of the electron lens will be greatest in the early stages of the injection process. Wideroe has estimated that, in the 200-Mev design, it is possible to increase the stabilization forces for 10-kv injection about 1350-fold and that this would in turn increase the beam current from 0.1 to 135.0 microamperes. In the 15-Mev betatron the stabilization forces are greater and the relative improvement to be expected is much less. The improvement factor is here about 45 which would increase the current from 0.5 to 22.5 microamperes.

The magnetic lens system was tested out on the 15-Mev betatron at Wrist without any marked success. Further work on this scheme nevertheless is contemplated.

A further subject of concern in the design of the 200-Mev machine was the possibility of energy losses in the machine due to radiation damping set forth by Iwanenko and Pomerantschuk[15] and by others recently.[17,18] Views of Touschek and Lens are that as a result of the radiation damping a radiation of frequency $10^7$–$10^8$ cycles is generated. This radiation, behaving like visible radiation, might in part be reflected by the metallized walls of the acceleration chamber and be conserved. Certainty on this point however did not prevail and it was hoped to study such effects experimentally on a smaller machine before completion of the large 200-Mev betatron. It was also believed that a possible remedy lay in increasing the driving frequency considerably.

## III. BETATRON DEVELOPMENTS OF SIEMENS-REINIGER

Mention has been made previously in this paper of the activities of Dr. Steenbeck and his associates at Siemens-Reiniger. This firm at Erlangen has under development three units two of 5–7-Mev energy and one of 15 Mev. Only the former two are in advanced stages. Of these, the one operating on 550-cycle power is in operation; the other which is to operate on 50 cycles and embody some new ideas in the electron acceleration chamber is still in construction. The 550-cycle unit works quite well and has a radiation output equivalent to that produced by 12–20 grams of radium. The output depends very much on the vacuum conditions and hopeful extrapolation of yields based on the vacuum pressures in use lead to a belief in a possible 50-gram output. The Siemens firm was contemplating putting this machine into production. The betatron is shown in Fig. 9.

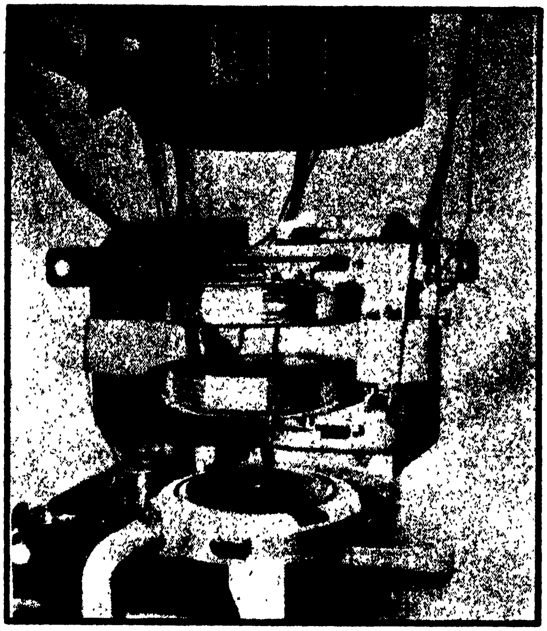

FIG. 10. View of 6-Mev betatron with acceleration chamber removed.

### *General description of 6-Mev, 550-cycle betatron*

This equipment, to be described in more detail below, follows closely the betatron of Kerst in general principles although the constructional details are somewhat different and ingenious. The electrons are injected into the acceleration chamber by a single electron gun which is similar to that of Kerst but modified by the use of auxillary electric deflection electrodes. Radically different methods of electron injection are contained in patent applications but these schemes were mostly in the design stage. A point of departure from the Kerst model lies in the fact that the electrons are injected near the center of the apparatus rather than on the periphery and also that the electrons are injected in that portion of the field between the guide poles where the magnetization forces of stabilization are either weak or absent. After injection into the chamber, the electrons proceed in spiral orbits into a final equilibrium orbit of nearly fixed radius. X-rays are produced after acceleration in the latter orbit by orbit expansion produced by momentary introduction of current into a central winding which increases the flux in the induction pole or may weaken the flux in the guide field.

### *Magnetic Yoke and Windings*

The general features of the yoke, exciter windings, and the acceleration chamber are shown in Figs. 10–13. As shown in Fig. 11 there is a yoke made of bolted stacks of laminations to make an approximately rectangular form with an open center to accommodate the coils and pole pieces. It may be noted that: (a) no gaps are provided for air cooling, (b) no radial construction is used in the large pole pieces which are made approximately circular by the expedient of making parallel lamination packets of different lengths, and (c) that the "staggering" method is employed to improve the general shape of the yoke. Cooling of the main guide poles is largely taken care of by the water cooled exciter windings which are hollow brass tubes on which special Litz wire is wound. Cooling of the injector mount is effected by air passing through ducts parallel to the induction pole and communicating with a suction (or pressure) duct at the base of the machine.

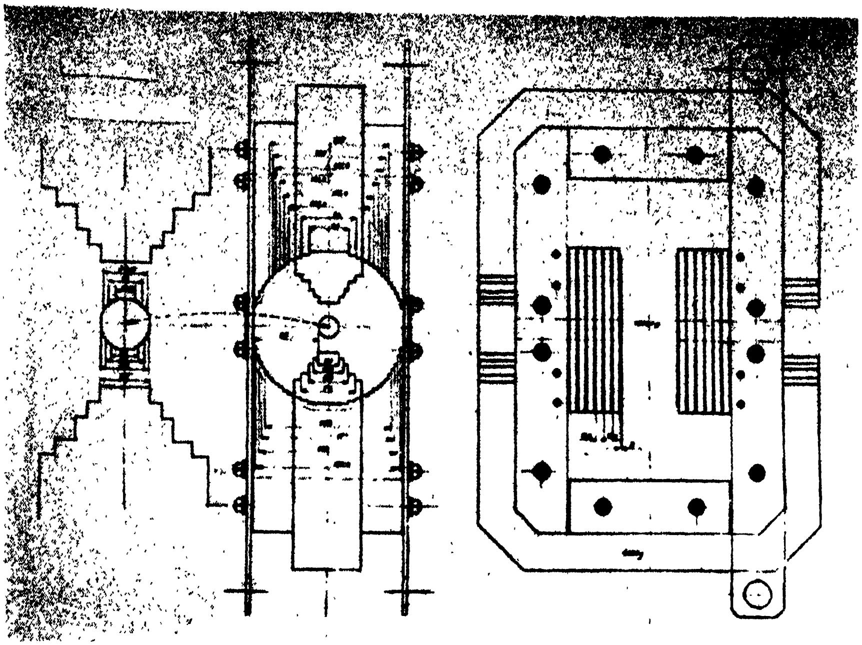

FIG. 11. Photograph of drawing showing yoke and construction of 6-Mev betatron. Since figures are not easily legible, the following scale may be helpful. As printed, reduction is $\frac{1}{16}$.

The guide pole pieces are finished by machining to precise flatness and against these rest the radially laminated packets which are built into the covers of the acceleration chamber and give the guide field its proper shape and intensity distribution. The major portion of the pole piece is thus built integral with the yoke and requires no special arrangement for supporting. At the center of the pole pieces may be seen a hole of approximately circular cross section extending continuously from the bottom to the top of the yoke. It connects at the lower side to the air supply duct, centers the middle section of the acceleration chamber and provides access from the upper side to screws for clamping or tightening the acceleration chamber assembly in place.

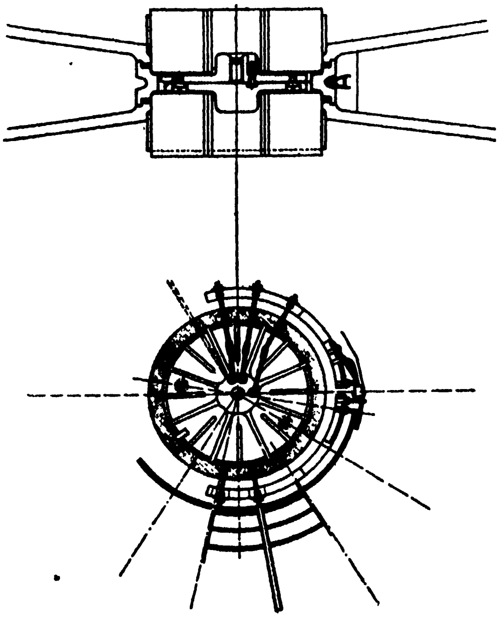

FIG. 12. Electron injection system for Siemens 6-Mev betatron.

The windings consist of 6-mm brass tubing which is wound transversely with five parallel strands of 5 sq. mm total section Litz wire, or of 9 parallel strands of somewhat smaller section Litz wire. These tubing turns were covered with tape, varnished, and formed into coils of 36 turns each (six high six deep) mounted on coil forms which are supported at the sides of the yoke by the binding plates of the yoke.

### *Acceleration Chamber*

The acceleration chamber, shown in Figs. 10 and 12, is the most ingenious and intricate part of the equipment. It is constructed from a porcelain-like material called "Kallait" and made so that it is completely demountable as may be noted in one of the figures. Essentially, it is a body ring with side exhaust port and with circular

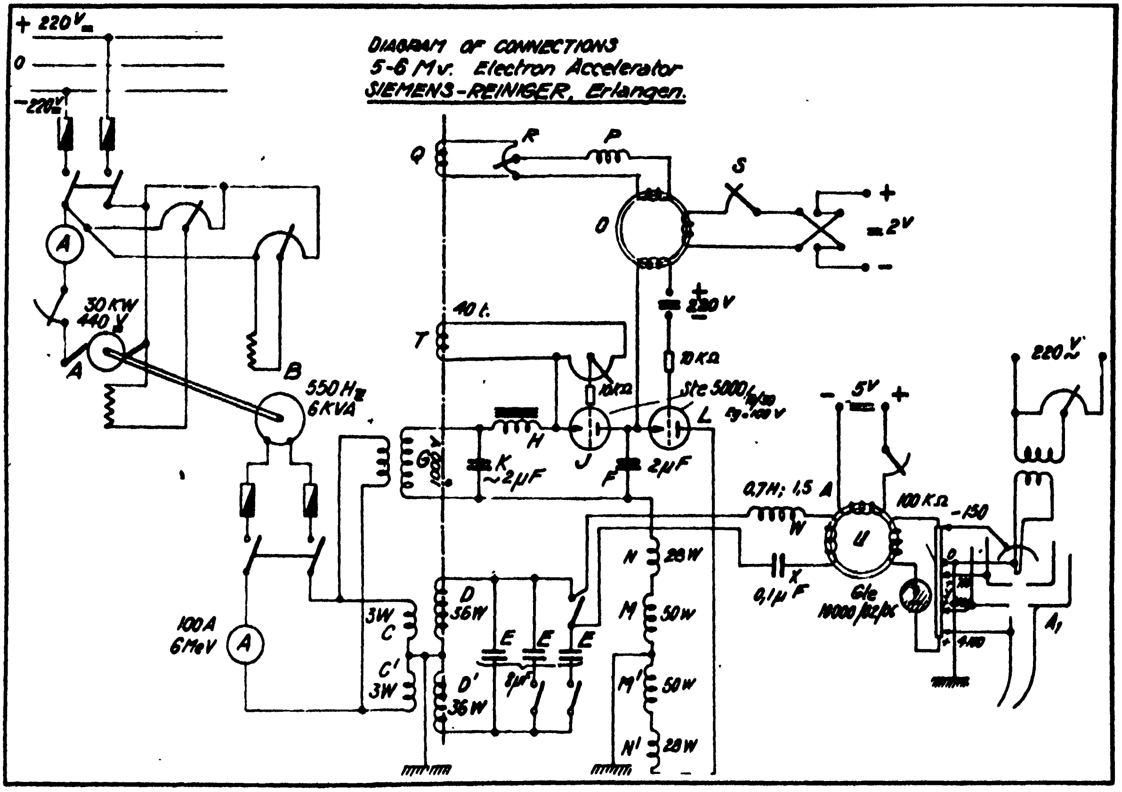

Fig. 13. Diagram of connections, 6-Mev betatron.

grooves for the gasket sealing lids which form the top and bottom of the acceleration chamber. These lids have built into their outward faces the radially laminated iron "faces" which on the outside are flat to match exactly the flat machined guide pole stump and on the inside are shaped to give the proper field shape and intensity distribution to the guide field. Near the center is located a cylindrical well into which is fitted the winding for producing orbit expansion by increasing the induction flux and weakening the guide field. The two lids mentioned have a central opening, the edges of which also make a gasket seat on the central "Kallait" core piece, which furthermore serves for carrying the electron injector structure and also all the necessary electrical lead-ins for its operation. It is cooled as noted above by an air stream passing through the center aperture of the yoke. Another feature of the acceleration chamber is its electrostatic shielding. This is accomplished by metallizing the inner walls of the top and bottom in grid fashion to break up complete electrical circuits about the pole or in its faces. Sections of this metallic coating are connected to radial leads distributed about the periphery of the wall ring. On the outside, these leads are connected together with high resistances and one point is grounded. The body ring also has a metallic spray coating which is contacted by the leads to the coating. On one side of the chamber is the target which is a small rectangular bar of tungsten held with its axis parallel to the field and which is mounted on one of the lead-in stems. On this side of the chamber a slot is provided in the wall of the body ring over which is cemented a thin metal foil window to minimize the absorption of x-rays and electrons passing out from the target. The direction of the radiation beam is approximately 45° to the long axis of the yoke, passing out of the betatron at a point just forward of the pump stem as shown in Fig. 9. This type of construction while apparently complicated is well suited to experimental work especially in view of necessary alterations to test out projected ideas on electron injection and field control.

### *Circuit Connections*

Figure 13 shows the circuit diagram for the 550-cycle betatron. Power is obtained from a 550-cycle motor generator unit consisting of a 440-volt, 30-kw, direct-current motor driving a 6-kva alternator. Frequency is regulated by a manual speed control of the motor and no equipment is used to stabilize the speed. The alternator is a special low voltage machine supplying 100 amperes for 6-Mev operation. This current is passed through six primary turns on the betatron which may be seen passing over the main driving coils in Fig. 10. These are divided into two sets and center grounded, likewise the main windings. Their 36-turn terminals are connected directly to a capacitor bank of 8-mf capacity. A part of the parallel capacitor connection is used to operate a peaking transformer used to provide the voltage pulse for the electron injection. A 5-volt, d.c. winding provides means for shifting the phase of the injection. The output pulse of about 10 kv is passed into a 100,000-ohm potential divider from which various voltages applied to the injector electrodes are obtained. The filament is heated by a separate transformer and is grounded together with one point of the potential divider.

The orbit expansion circuit derives power from a 1-kv utility transformer connected in parallel to the primary coil of the machine. The output passes over a smoothing filter, *K*, and *H*, and a grid-controlled rectifier which controls the charging of the 2-mf capacitor *F*. The grid-control feature of the rectification is not indispensable. Control is obtained from a forty-turn winding *T* divided on the two legs of the machine. A similar winding *Q* supplies power to another peaking transformer *O* having a phase-shifting bias winding. This actuates the thyratron *L* (*L* and *J* are Osram Ste 5000/10/30). The capacitor *T* is discharged at the desired operating point through the two fifty-turn, orbit expansion coils *M* and *M'*. In series with these are two 28-turn, compensating winding *N* and *N'* wound about the legs of the yoke whose purpose is to compensate the magnetization effect of the orbit expansion current pulse in the yoke. It may be noted that the injection and orbit expansion pulses are phased properly by having one peaker transformer actuated by the primary driving current and the other by the voltage derived from the primary flux which is in quadrature therewith.

### *Review of Betatron Patent Ideas of the Siemens-Reiniger and C. H. F. Müller Firms*

While the actual electron accelerator developments of Siemens-Reiniger seem to have covered only patent claims which are fairly well represented in one application[19] entered July 28, 1942, a number of ideas are contained in their present work and in other patent applications which will be reviewed briefly.

In an interesting experimental device use is made of a thermo element on the tungsten target of the betatron to measure the actual electronic current which is converted into radiation and heat. This is a more efficient indicator of output than the electron current passing from chamber to ground.

The use of the positive ion plasma for the purpose of increasing the electron density in the acceleration orbit by virtue of the electronic focusing and stabilization resulting from the positive ion space charge has been considered in a semi-theoretical way. This topic is on the program for further study.

Ideas contained in patent applications include the following:

a. Construction of the magnetic acceleration chamber in such a way that the magnetic guide field poles form the vacuum chamber itself and even contain the magnetizing windings to produce the guide field. This idea has met with experimental difficulties. It was intended for an accelerator for producing fairly strong circulating currents with several hundred kv energies.

b. Use of a built-in saturable magnetic core to keep the guide field constant for a short time during the injection period to increase the available injection time.

c. In relation to (b) use of a constant injection voltage during time in which guide field is constant.

d. Electron injection radially and normal to the field with asymptotic approach to an equilibrium orbit together with mechanism for transfer of orbit to a stable acceleration region or orbit.

e. A ring cathode with auxillary radial electric accelerating field. Applicable only on certain conditions.

f. Polygonal or elliptical ring cathodes to overcome limitations of (e).

g. A 1:2 magnetic field principle operative in asymptotic injection.

---

[19] Siemens Akt. 151,565, VIIIc/21lg.

h. Time dependant guide field further characterized by pre-magnetization of a special magnetic core with a.c. in quadrature with the guide field.

i. Electron source consisting of a pair of oxide emittor plates, above, below, and parallel to median plane of accelerator. An acceleration chamber with an open center.

j. Accelerator as in (i) in which a plurality of electron orbits pass through the axis and produce there a high electron concentration.

k. Acceleration in a stable orbit with either a time variant or time invariant guide fields, together with an electrostatic arrangement for release of an electron beam from the orbit.

l. Orbit expansion by means of local disturbance of guide fields by special windings located at advantageous points or areas in field.

m. Arrangements for d.c. premagnetized guide field, also time variant guide fields.

n. Production of injection potentials by special windings in induction field.

Patent applications[20,21] credited to Dr. Müller of the C. H. F. Müller firm also contain the idea of using a ring cathode and radial electric acceleration fields mentioned in Sections (d)–(f) above. These contain perhaps the novelty of using magnetic shielding material to protect the filament of the cathode from magnetic forces and also have a departure in the proposal: first, to accelerate the electrons by induction within an inner portion of the guide field, then to pass these on by means of an applied radial electric field to an outer region where they may be further accelerated in a stable orbit. In the course of the passage, these are to pass through a retarding radial electric field region, the purpose of which is to bring the radial speed of the accelerated electron back to values that will allow them to be introduced into the equilibrium orbit. Electrons that are slow radially naturally form a closed circular path tending to return them to the cathode. A difficulty presents itself in the delaying field in that it may draw electrons oscillating radially about the equilibrium orbit back into this space. To avoid this difficulty, it is proposed to inject the electron in a line parallel to but above or below the median or orbital plane. This, it is believed, will cause the electron captured by the equilibrium orbit to execute spiral tracks which will make difficult the reentry of electrons into the decelerating radial electric field.

In another Müller's application[22] the idea of spiral orbits about an equilibrium orbit is again set forth, this time as a possible means of avoiding collisions of injected electrons with the injector, the spiraling being so controlled that the electron will miss the injector. This is to be accomplished by applying a circular magnetic field whose lines of force are parallel to the electron orbit itself which field is to be applied only during the beginning of the injection.

In an application[23] it is proposed to release electrons after acceleration in a fixed equilibrium orbit in such a way that, on expansion of the orbit by saturation of the magnetic field, the electrons will move outward into a field varying so rapidly with distance that the spacing between successive turns of the spiral electron orbits becomes quite large. It then will be likely that an electron may strike a target or a window covering a certain angular range in its last revolution. No solution is given as to how the electron is so be properly phased to arrive at the desired instant in the required range.

Another application[24] contains an idea similar to that contained in Part (c) of the Siemen's applications. In this the magnetic guide field or the accelerating field is to be kept constant for a certain short time interval during the electron injection process by introducing into the electrical exciting circuit some controlling rectifier valves. These are usually a pair in parallel, one of which "saturates" in a certain time of operation after application of potential and thus produces the momentary constancy of field required. After a desired time the second grid controlled valve is fired and carries the current as a conductor of low resistance for the remainder of the half cycle. The scheme may be extended to produce a similar effect on the negative half-cycle. A C. H. F. Müller application[25] describes an electron injector in which the equilibrium orbit is allowed to pass through the injector structure without obstruction. The application includes the use of a manifold of such units about the accelerator orbit.

A very late application[26] describes an iron-less

betatron. The scheme, in which inductions considerably greater than 10,000 gauss are possible, is to consist of a coil of few turns and an acceleration tube of relatively small dimensions. The coil is of a hemispherical shape to give proper direction to the field lines and proper distribution of the flux through the orbit in the acceleration chamber. Because of the high power requirements due to lack of iron the betatron is to be operated by a sudden discharge of electricity stored in a capacitor bank. It is also proposed to obtain desired circuit time constants by proper design of self-inductance or by inclusion of external circuit impedance. The application further includes possible use of iron in such parts of the equipment where fields of 10,000 gauss are to be used. Iron, however, is not to be used in the regions of most intense fields, that is, 20,000 to 100,000 gauss.

## IV. SUMMARY AND CONCLUSION

The principal betatron developments which have been carried out during the war by several German firms or organizations have been discussed above in some detail. In the way of evaluation of these developments, especially in comparison with developments which have proceeded simultaneously in the U.S.A., the following notes may be added:

The developments seem to have the same basis in preceding scientific literatures; the main reference sources are the works of Wideroe and the patents of Steenbeck and of Kerst, upon which developments agreeing fairly closely in general principle have been made. The success of these developments has been of various degrees. The works of Wideroe and the associated groups MVA and BBC have resulted in an operating 15-Mev electron accelerator described above, and some projected designs. The x-ray output of this unit, reported to be as high as 1 kg of radium equivalent and as low as 30 grams at various times of experimental work, compares fairly well taking the upper figure with early American 20-Mev units allowance being made for difference in maximum energy. The technique of electron injection, although subjected to theoretical investigation, lacks considerably in refinement, perhaps partly due to the difficulties encountered in carrying on experimental work at all. The betatron of Wideroe presents a somewhat different design from that of Kerst in that saturating guide poles are used. This feature, however, has opened up some design possibilities which could not be foreseen in the Kerst design in which the guide fields are produced on the same pole unit carrying the accelerating flux. A comparison in regard to weight indicates perhaps a slightly more efficient use of iron which consideration however is influenced considerably by the dimensions of the air gaps.

The most interesting and remarkable development due to the Wideroe group has been the design of a 200-Mev unit in which a very considerable economy of iron may be found. An interesting comparison may be made in the way of weight, between this design which is to weigh about 40 tons for a 200-Mev rating and the 130 tons of the American General Electric Company 100-Mev machine. In this 200-Mev design certain improvements, such as the use of premagnetization, are considered. At present it may be premature and optimistic to believe that all of these improvements will be practically realized on a large betatron until such have been demonstrated on a smaller scale.

The most successful betatron development in Germany is perhaps that of the Siemens-Reiniger 6-Mev, 550-cycle betatron. This unit has a good output of radiation for its small size and weight and operates with almost unbelievable steady output. The actual details of electron injection follow American practice to some degree with the difference that inside injection is employed. Some interesting differences lies in the electron starting. X-ray production occurs in larger American machines by orbit expansion but somewhat different orbit expansion arrangements are used. The most interesting feature is the adaptability of the unit to various arbitrary injection and acceleration experiments. American betatron practice has advanced to the use of sealed off porcelain acceleration chambers. The use of porcelain, however, was anticipated by Steenbeck who used a tube of such material in 1935.

Although no visit could be made to Berlin, it is understood that the AEG were engaged in betatron development also and that their work is based largely on the preliminary achievements of Wideroe and Steenbeck.

In connection with the developments reviewed above there are to be noted many interesting and ingenious technical details. A review of the patent applications indicates a wealth of ideas which have been systematically studied only in part.

### APPENDIX I

Considering both the force of the electrostatic field of the beam of electrons in the equilibrium orbit, and the magnetic attraction force between this beam and the test electron moving parallel to it at a distance $\Delta r$ their difference will be seen to be

$$\Delta P_1=\frac{eQc^2}{\pi r_0\Delta r}(1-\beta^2),\quad Q\text{: charge in orbit.}$$

The difference in centrifugal and magnetic forces acting on the electron for a small deviation $\Delta r$ from the equilibrium orbit $r_0$ is

$$\Delta P_2=\frac{e^2B^2}{m}(1-n)\frac{\Delta r}{r_0},\quad n\text{: field law index}$$

to a first approximation. Equating these differences and solving for $Q$ the total charge in the equilibrium orbit is

$$Q=\frac{\pi(1-n)(\Delta r)^2(r_0B)^2}{r_0E_0(1-\beta^2)},\quad E_0=m_0c^2/e$$

$$=\frac{\pi(1-n)}{r_0c^2}(\Delta r)^2(E^2+2EE_0)\frac{(E+E_0)^2}{E_0^2}.$$

Eliminating $E$ by means of the damping relation: $-dr/r=\frac{1}{2}dE/E$ from which using $dE=rvdB$ and $dB\sim\omega B_m\cdot 2\pi r/v$

$$E=\frac{2\pi^2r^2\Delta rB_m\cdot f}{-dr}\quad\text{(injection voltage)}$$

$f$: operating frequency

we have finally that the average current supplied $i=f\cdot Q$ is

$$i=\frac{4\pi^3(\Delta r)^3(1-n)f^2rB_m}{-dr\cdot c^2}.$$

### Fiber Society—High-Polymer Joint Meeting

The third meeting of the Division of High-Polymer Physics, which was exclusively devoted to textile and fiber research, was held in Maury Hall of the University of Virginia on September 26–28, 1946. The meeting was sponsored jointly with the Fiber Society. Approximately 105 members of the Division and the Fiber Society and guests registered at the meeting.

The program was arranged by a joint committee under the co-chairmanship of Lewis Larrick and W. A. Sisson. Dr. Larrick also headed the local committee, in which undertaking he was ably and enthusiastically assisted by the staff of the Institute of Textile Technology.

In addition to addresses of welcome by Ivy F. Lewis, Dean, University of Virginia, and Ward Delaney, President, Institute of Textile Technology, three addresses of non-technical nature were given in the course of the three-day meeting. P. Larose of the National Research Council in Ottawa spoke on "Textile Research in Canada." Carl M. Conrad delivered a paper commemorating the life and work of the late Enoch Karrer, Fellow of the American Physical Society and a pioneer in high-polymer research. H. Wickliffe Rose presented, with numerous slides, impressions of Japan and the Japanese textile industry gained on a recent trip there.

Thirteen technical papers were presented. Titles and authors appear hereunder.

W. JAMES LYONS
*Division Secretary*

"Air and Water Vapor Permeability of Fabrics," L. W. Rainard, E. L. Wilson, and A. L. Nestmann, Institute of Textile Technology.

"Moisture Transfer to and from Tire Cords Encased in GR-S," W. James Lyons,* Hilda M. Ziifle, Mary L. Nelson, and Trinidad Mares, Southern Regional Research Laboratory.

"Curl in Woven Textile Fabrics," Ross Whitman, Kendall Mills.

"Tricot," C. W. Bendigo, *Textile World*.

"Tensile and Torsional Properties of Textile Fibers," L. G. Ray, Jr., E. I. du Pont de Nemours and Company.

"The Creep Behavior of Textile Fibers," M. T. O'Shaughnessy,† E. I. du Pont de Nemours and Company.

"Electron Microscopical Studies of Natural Cellulose Fibers," William G. Kinsinger and Charles W. Hock, Hercules Powder Company.

"The Measurement of Irregular Distances and its Use in Studying the Swelling of Cotton Fibers," Enoch Karrer and R. S. Orr, Southern Regional Research Laboratory.

"Performance of Tensile Testing Machines," Herbert F. Schiefer and Josephine M. Blandford, National Bureau of Standards.

"Apparatus for Determining the Coefficient of Friction of Running Yard," Francis B. Breazeale, The American Enka Corporation.

"Spun Nylon," L. L. Larson, E. I. du Pont de Nemours and Company.

"An Investigation of the Load-Deformation Characteristics of Celanese and Wool with Particular Reference to the Use of These Materials in Carpet Pile," R. W. Work, A. M. Thorne, and M. R. Livingston, Celanese Corporation of America.

"The Design of Parachute Shroud Lines as Influenced by Fundamental Energy Absorption Properties," E. R. Kaswell, Fabric Research Laboratories.

---

* Resigned April 1945.
† Now at Brooklyn Polytechnic Institute.

### New Appointments

Three new appointments to the staff of the National Bureau of Standards were recently announced. Dr. B. J. Miller is chief of the recently organized Guided Missile Electronics Section, Dr. H. K. Skramstad is chief of the Guided Missiles Section, and Dr. Ladislaus L. Marton is principal physicist in the Electronics Section.

### Awards

Professor P. W. Bridgman of the Physics Laboratories at Harvard University has been awarded the Nobel prize in physics for 1946.

Dr. Willis R. Whitney, organizer and first director of the General Electric Company's Research Laboratory, has received the Industrial Research Institute Medal for his pioneer work.

### Mathematical Tables Progress

The Mathematical Tables Project, 150 Nassau Street, New York, New York, in its progress report for October stated that work had been completed under the following headings:

Table of spherical Bessel functions, Volume II,
"Manila rope" distribution problem,
Spherical scattering functions for complex arguments,
Computations related to hydraulic analogy of shock wave intersections.

### Information on Preparation of Graphs

The editor of *American Journal of Physics* has announced that anyone wishing to have a reprint of the article "Preparation of Graphs for Physical Papers," which appeared in the March–April 1946 issue of that journal, may receive one without charge by addressing *American Journal of Physics*, Wabash College, Crawfordsville, Indiana. The article suggests "practices intended for the guidance of authors and draftsmen in preparing graphs for reproduction in technical publications." It further states that "most of the recommendations are in accord with those recently made by a committee of the American Standards Association."

### Postdoctoral Fellowship for Women

Announcement will be made early in March of the award of the third Sigma Delta Epsilon Fellowship of $1500. Women with the equivalent of a Ph.D. degree, carrying on research in the mathematical, physical, or biological sciences, who need financial assistance and give evidence of high ability and promise, are eligible. During the term of her appointment the appointee must devote the major part of her time to the approved research project, and not engage in other work for remuneration (unless such work shall have received the written approval of the Board before the award of the fellowship). Application blanks may be obtained from Dr. Louise S. McDowell, 28 Dover Road, Wellesley, Boston 81, Massachusetts. Applications should be submitted before February 1, 1947.

### High-Polymer Lecture Series

During the academic year 1946–1947 a series of lectures on the properties of high polymers is being given at the National Bureau of Standards in Washington. They have been arranged by Robert Simha. The lecturers include the nation's leading scientists in this field from industry and universities. The lectures are open to the public without charge and are held from 7 to 9 o'clock in the evening in Room 214 of the Chemistry Building, National Bureau of Standards. Remaining dates in the course are January 22 and 30, February 27, March 6 and 28, April 24, May 8 and 29, June 5 and 12.

### Necrology

Dr. Wilbur B. Rayton, director of the Scientific Bureau of Bausch and Lomb Optical Company, died October 31. He had been with the company since 1908 and was appointed head of the Bureau in 1926. Two months before his death he had received the Navy Ordnance Development Award.

## Determination of Magnification in Electron Micrographs

HENRY C. FROULA
*Assistant Physicist, Armour Research Foundation of Illinois Institute of Technology, Chicago, Illinois*
(Received November 1, 1946)

Electron microscopes are often calibrated through the use of a grating replica as a specimen. The assignment of magnifications to subsequent micrographs then depends,

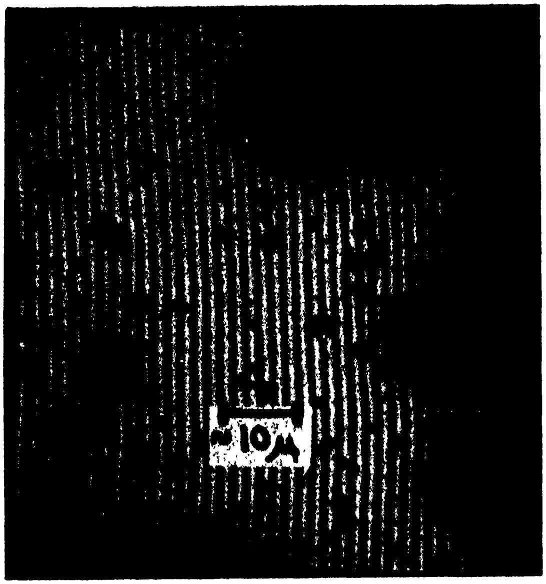

FIG. 1. An electron micrograph of coal dust supported by a 15,000-line per inch grating replica, prepared by the second method described herein. Magnification, approximately 1000×.

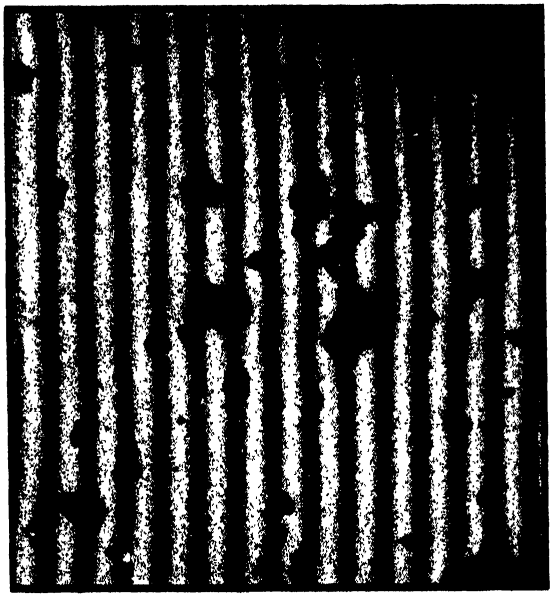

FIG. 2. A limited part of the field of Fig. 1 at a greater magnification, approximately 3000×.

essentially, either upon the constancy of the original calibration or upon a knowledge of how it varies.

Difficulties and skepticism in regard to the translation from the original calibration to subsequent micrographs led to the use of the two techniques described below in two recent studies of small particles.

In one procedure, used in a study of colloidal particles, a regular collodion grating replica was prepared and was mounted on a specimen screen. A small droplet of the sol was then placed on the replica surface. After evaporation of volatile components, the specimen was ready for observation.

In the second method, used in the study of a dry, powder-like material, the particles were mechanically dispersed in an amyl acetate solution of collodion. This mixture was then used in place of the plain collodion solution in making a replica of a grating.

In both of these methods, the replica was prepared in a manner similar to the cellulose-taper-stripping technique described by Schaefer.[1]

In both cases the final image shows the particles with a grating as a background. In this way each micrograph carries its own calibration as seen in Figs. 1 and 2. Furthermore, electron-optical distortions are partially compensated by similar distortions in the grid-like background. However, it will be noted that, while each of these two methods affords a relatively direct means of determining magnification, each still remains subject to inaccuracies caused by such factors as physical distortion of the replica and non-perpendicularity between the electron beam and the replica.

# New Books

## **Matter and Light.** The New Physics.

BY LOUIS DE BROGLIE. Pp. 300, 5×7⅜ in. W. W. Norton and Company, New York, 1946. Price $2.75.

This is an American printing of the translation by W. H. Johnston of Matiére et Lumiére which was originally published in French in 1937. It duplicates the English translation which appeared in 1939.

It consists of a series of twenty-one brilliant essays dealing with modern physics and with philosophical studies raised by these new developments. They are grouped under six headings, as follows: A General Survey of Present-Day Physics, Matter and Electricity, Light and Radiation, Wave Mechanics, Philosophical Studies on Quantum Physics, and Philosophical Studies on Various Subjects. Only two of the essays contain mathematical equations which are, however, familiar to students of modern physics. Since the essays are quite independent of one another, the major portion of the book may be read by anyone who is interested in the revolutionary ideas arising from the development of quantum theory, relativity, and wave mechanics. The line of thought leading to the foundation of wave mechanics by the author is retold in several of the essays with interesting variations.

In this book, the scientist in other fields than physics, the philosopher, and the cultured amateur may find a delightful popularization of the principal ideas of the new physics. The physics student will be pleased by the masterly resumé of modern physics and by the author's insight into related philosophical problems. However, not the least profit to be gained by reading this book is in regard to cultural values, to which the author is keenly sensitive. For example, the final essay, directed to science students, contains the following charge: "the younger generation must undoubtedly acquire learning so that they shall be able to benefit by past experience and by the stock of gathered knowledge; but beyond learning, they must acquire a love of beauty in all its forms, of the art of thinking, and of the expression of thought" and further—"without a zeal to pursue all that is loftiest in the intellectual, the esthetic, and the moral sphere—a civilization, however great the perfection of its material aspects, would soon be no better than a complicated form of barbarism." The intervention of a world war and the invention of the atomic bomb since the first printing of this book has only served to make it more worthy of careful study.

## Ion Beams in High Voltage Tubes Using Differential Pumping

E. S. LAMAR* AND W. W. BUECHNER
*Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received July 31, 1946)

Tests on a hydrogen ion gun assembly employing differential pumping are described. Focused beam currents as high as 215 microamperes were realized at the target end of a high voltage tube 6 feet long operating in the range from 300 to 400 kilovolts. Factors which limited the current to 215 microamperes are discussed and suggestions for realizing greater beam currents are presented.

### INTRODUCTION

A NUMBER of investigations of the production and focusing of hydrogen ion beams have been made at the Massachusetts Institute of Technology,[1-5] the ultimate end in view being the use of ion beams together with high voltage vacuum tubes for investigations of the atomic nucleus. In references 4 and 5, which were published together, studies of ion sources and focusing systems were presented which led to a proposed ion gun design using differential pumping. This ion gun, shown in Fig. 1, was built and tested in conjunction with a high voltage vacuum tube. This paper is an account of the tests of the ion gun and vacuum tube assembly which were completed before the recent war interrupted the research, and the conclusions which were reached as a result of these tests. In the sections of this paper which follow, the accounts of the tests of the various parts of the assembly are presented in much the same order in which they were made.

### THE ION SOURCE

The ion source was of the metal capillary type as described in reference 3. The capillary was 3.0 mm in diameter and 3.0 mm long. The outlet was 0.80 mm in diameter. In order to eliminate the need for water cooling, the arc chamber was made from a solid block of copper. The two cathode leads and the one for the anode were brought in through small spark plugs. Both cathode and anode ends of the arc chamber were closed by glass windows to facilitate visual examination of the arc.

The results of the total ion current measurements were in general agreement with those presented in reference 4. They are shown here in Fig. 2. The points shown are the averages obtained from a number of runs, the vertical lines giving the limits of the various measurements. On rare occasions, the output currents were outside the limits shown and approximated those characteristic of the glass ion sources described in reference 4. These rare runs have not been included in Fig. 2. The small fluctuations indicated in Fig. 2 and the larger ones just described are believed to result from changes in surface conditions as was discussed at some length in reference 4. A comparison of the ion currents obtained from the metal source with those to be expected from a glass one is sufficient in itself to show the desirability of completing the engineering development needed to produce a rugged glass ion source. This need is further sub-

stantiated by comparing the atomic ion yields of the two types as shown by the mass analysis reported in reference 4.

### THE INITIAL FOCUSING SYSTEM

The initial focusing system, shown in Fig. 1, had exactly the same electrode dimensions as the one described in reference 5. The outlet leading to the high voltage vacuum tube consisted of a canal ⅛ inch in diameter and 1 inch long. In most of the experiments the accelerating potential was applied in two steps: between the focusing cone and first cylinder, and between the first and second cylinders; i.e., a double rather than a single lens was used. With this arrangement, for any given current, greater ion currents through the canal and into the high voltage tube could be realized than with the single lens system. As was discussed in reference 5, for a given total focusing voltage, the aberrations at the source outlet are less for a double lens than for a single one.

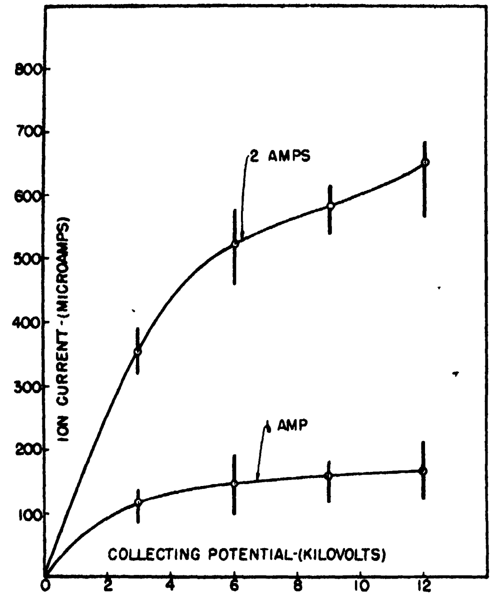

FIG. 2. Output ion current as a function of collecting potential for arc currents of 1 ampere and 2 amperes.

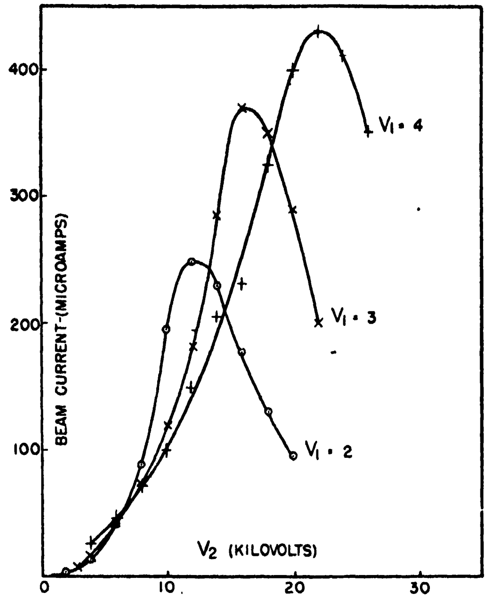

FIG. 3. Ion current focused through differential pumping canal into the high voltage tube as a function of the initial focusing potentials. Arc current = 2 amp.

Figure 3 shows a typical set of measurements of ion current entering the high voltage tube through the differential pumping canal. These measurements were made with all the tube electrodes connected together to form a deep Faraday collector. The potentials $V_1$ and $V_2$ of the first and second cylinders, respectively, were measured with respect to the focusing cone. It is to be noticed in Fig. 3 that for each value of $V_1$, the value of $V_2$ which gives the greatest beam current through the canal and into the high vacuum of the accelerating tube is quite critical. The ratio of voltages for best focus is a function of the first cylinder voltage $V_1$ and of the maximum output beam current. Since the maximum voltage of the power supply for the second cylinder was limited to about 26 kilovolts, it was not possible, in all runs, to read the point of best focus. For those runs in which the peak was reached, the ratio $V_2/V_1$ at the peak is given in Table I as a function of $V_1$ and the maximum beam current. As can be seen from the table, $V_2/V_1$ increases with increasing current and with decreasing voltage. In other words, the greater the space charge in the beam as it enters the second lens, the greater the second lens action required.

### THE PUMPING SYSTEM

The vacuum pump attached to the critical focusing region was of the tapered nozzle type and that for the high vacuum tube was a steel pump of conventional design. Both these pumps used mercury and were provided with dry ice traps. An idea of the net pumping speeds of each of these pumps can be obtained from ratios of pressures in various regions. For the first pump, computing the pumping speed from the ratio of pressures between arc and initial focusing chamber involves a slight complication. The arc

pressures at which the measurements were made were such that the mean free path of the gas molecules in the arc was of the order of the outlet diameter. Hence the speed of the outlet was not constant but was a function of the arc pressure. It was found that the pressure ratio between initial focusing region and the arc was

$$R = 5.03(10^{-3}) + 1.88(10^{-2})P_a, \qquad (1)$$

where $R$ is the pressure ratio and $P_a$ is the arc pressure. Using the low pressure part, i.e., $5.03(10^{-3})$, of this ratio, and the speed of the arc outlet, $5.0\times10^{-2}$ liter per second for air, for low pressures, gives 10.0 liters per second for air as the speed of the intermediate pumping system.

The ratio of pressures between intermediate and high vacuum regions was 162. Since, the speed of the ⅛-inch canal was about 0.13 liter per second for air, that of the high vacuum pumping system was about 21 liters per second for air.

### THE HIGH VOLTAGE TUBE AND GENERATOR

The high voltage tube was the one employed by Hill, Buechner, Clark, and Fisk.[6] For these tests the tube was mounted vertically with the source and pumps at the bottom at ground potential. The tube electrodes used by these authors were replaced by similar ones 5 inches in diameter except at the ion gun end. Here the first two electrodes were combined into one. The end of this electrode away from the ion gun was 5 inches in diameter. Several different electrode diameters were tried for the gap adjacent to the ion gun. The one finally adopted was 3″ as is shown in Fig. 1.

At the target end of the tube, several electrode arrangements were employed. The one finally adopted consisted of a deep "Faraday ice pail" having an insulated molybdenum plate at the far end and a two inch diameter opening facing the high voltage tube. A Pyrex window beyond the molybdenum plate made the plate visible from normal eye level. The molybdenum plate was connected to the end plate of the high voltage tube through a bank of B-batteries and a microammeter. The B-batteries provided a retarding potential of 135 volts to prevent secondary electrons from leaving the molybdenum plate.

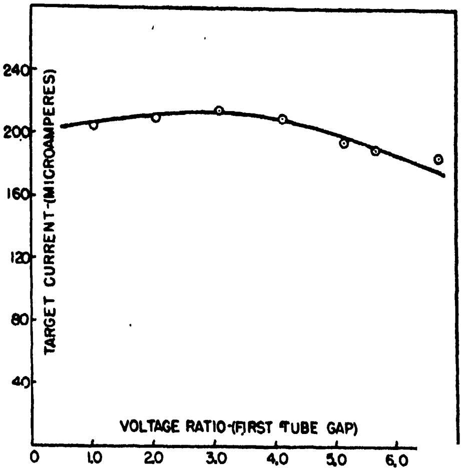

FIG. 4. Target current as a function of the ratio of the potentials across the first gap in the high voltage tube.

The large corona shield which covered the end plate and auxiliary apparatus was made partly of metal gauze to facilitate visual examination of the meter and of the molybdenum plate. The high voltage generator employed was of the belt type.[7] It was suspended from the ceiling and was connected to the corona shield by means of a length of stove pipe.

### TESTS OF HIGH VOLTAGE TUBE AND ION GUN ASSEMBLY

In order to determine the effect of the first high voltage tube gap on the focusing of the ion beam, several different pairs of electrodes were tried. The smallest of these was 1¾ inches outside diameter. Corona control permitted independent adjustment of the potential of the first high voltage tube electrode. Variations of this potential over quite wide limits showed little or no effect on the ion current collected at the target end of the tube. In other words, the first high voltage gap adds little or nothing to the focusing of the ion beam. This is shown in Fig. 4 where the ion current collected at the target end is presented as a function of the ratio of potentials on the two electrodes of the first gap in the high voltage tube.

---

[6] Hill, Buechner, Clark, and Fisk, Phys. Rev. 55, 463 (1939).

[7] We are indebted to Professor J. G. Trump of the Electrical Engineering Department for making this generator available to us for these tests.

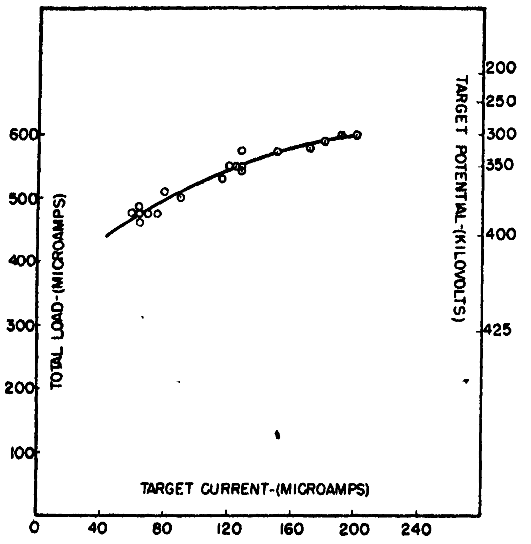

FIG. 5. Total tube current as a function of focused beam current.

The molybdenum plate was employed to give an indication of the state of focus of the ion beam when it reached the target end of the tube. With currents of the order of those presented in Fig. 4, a luminous spot, about $\frac{1}{4}$ inch in diameter, developed in the center of the plate. Because of radial heat conduction from the focal area, the luminous spot size serves only to set an upper limit to the diameter of the focal area. Since this was less than $\frac{1}{4}$ inch, the state of focus at the target end was considered satisfactory.

Attempts were made to realize currents at the target end of the tube greater than the 215-microampere maximum shown in Fig. 4. These attempts were not successful. Whenever the ion gun potentials or the arc current were increased beyond the values corresponding to this maximum, the generator potential dropped very rapidly, the high vacuum tube pressure increased, and electrical breakdown soon followed. These effects indicated the presence in the high voltage tube of a current in addition to that in the ion beam and the increase in pressure indicated that this parasitic current was, in some way, associated with the tube electrodes. The parasitic current may have its origin in the gas, at the electrodes, or both. In this connection, the results of Crenshaw[8] on the loss of energy of hydrogen ions in traversing various gases are of interest. If, under the present conditions, appreciable ionization takes place in the gas, certainly the positive products are not subsequently focused as is indicated by the fact that the target currents are about those to be expected from the primary beam. If the products of ionization strike the electrodes, they may be greatly multiplied by the emission of secondary electrons,[6] and large electron currents may thus originate from the electrodes. Such electron currents may be further augmented by photoelectrons resulting from excitation of the gas along the beam, since it has been observed, with ion beams in glass tubes, that the ion beam is quite luminous even at pressures as low as $10^{-5}$ mm of mercury. There is the further possibility that secondary electrons may be liberated from the electrodes by primary ions scattered from the walls of the canal. This possibility was ruled out in the following way: A new canal, consisting of a diaphragm facing the source and a slightly larger diameter canal facing the high voltage tube, was installed. Although this new canal possessed a much reduced scattering area, the results obtained using it were the same as those with the previous arrangement.

An attempt was made to measure the total current in the high voltage tube, as a means of evaluating the parasitic current. Since this measurement involved certain assumptions, it can be considered as indicative only. First of all, it was assumed that a one to one correspondence existed between generator voltage and generator load. A calibration of the generator was then run using a corona load which could be measured. With this calibration, a measurement of generator voltage provided a measurement of total current. In Fig. 5, this total current is presented as a function of beam current reaching the target. The generator voltage, corresponding to each total load current, is given on the right-hand edge of the diagram. It can be seen from Fig. 5 that, subject to the original assumption, the total load exceeds the beam load by some 400 microamperes.

It is clear that if beam currents of more than a few hundred microamperes are desired, the parasitic current must be reduced. Since the primary cause of this current is collision, either

---

[8] C. M. Crenshaw, Phys. Rev. 62, 54 (1942).

scattering, exciting, or ionizing, in the gas, it is essential that the gas pressure in the high voltage tube be kept as low as possible. If the two pumps of 10 and 20 liters per second, respectively, here employed had been replaced by a single pump used in the conventional manner, a net pumping speed at the source of approximately 1600 liters per second for air would have been required to maintain the same hydrogen pressure in the accelerating tube. Any multiplication of parasitic current by secondary electron emission from the electrodes can be reduced by introducing a diaphragm in the center of each electrode. Since the center is an equipotential plane, no distortion of field should result and the secondary electrons formed off the axis would be stopped after a maximum travel of one tube gap. The focusing results indicate that the hole in the center of the diaphragm could be as small as $\frac{1}{4}$ inch in diameter without cutting off the ion beam. If this were done, it would of course be necessary to arrange the rest of the tube geometry so as to maintain an adequate pumping speed, particularly if the pumping were done from the target end of the tube. Time did not permit investigation of this possibility in the present research. It is, however, strongly recommended for further work.

### ACKNOWLEDGMENTS

It is a pleasure to thank Professor R. J. Van de Graaff for his continued interest in the ion source work and for much helpful discussion. We wish also to express our appreciation to the other members of the high voltage group at the Institute for their suggestions and help in many ways. We are glad to have this opportunity to express our gratitude to the Research Corporation and to the Carnegie Corporation of New York for their generous grants supporting this work.

# X-Ray Diffraction Studies of Color Variation of Iron Oxide Pigments

H. Birnbaum, H. Cohen, and S. S. Sidhu
*Cooperative X-Ray Laboratory, University of Pittsburgh, Pittsburgh, Pennsylvania*

(Received August 16, 1946)

Samples of synthetic iron oxide (Goethite) taken at regular intervals from a twelve-day continuous process showed progressive change of color, ranging from pale yellow to dark brown. X-ray diffraction, electron microscope, and optical microscope studies lead to the conclusion that the color change in these samples is mostly caused by particle growth.

THE process of producing synthetic iron oxide pigments has been reviewed by Mattiello.[1] A characteristic feature of these pigments is the progressive change of color from

FIG. 1. X-ray diffraction patterns of samples 1 and 9. Fe$K$ unfiltered radiation, $\lambda = 1.933$A. Diameter of camera 143.2 mm.

---

[1] J. J. Mattiello, *Protective and Decorative Coatings* (John Wiley and Sons, Inc., New York, 1942), Vol. II, p. 300.

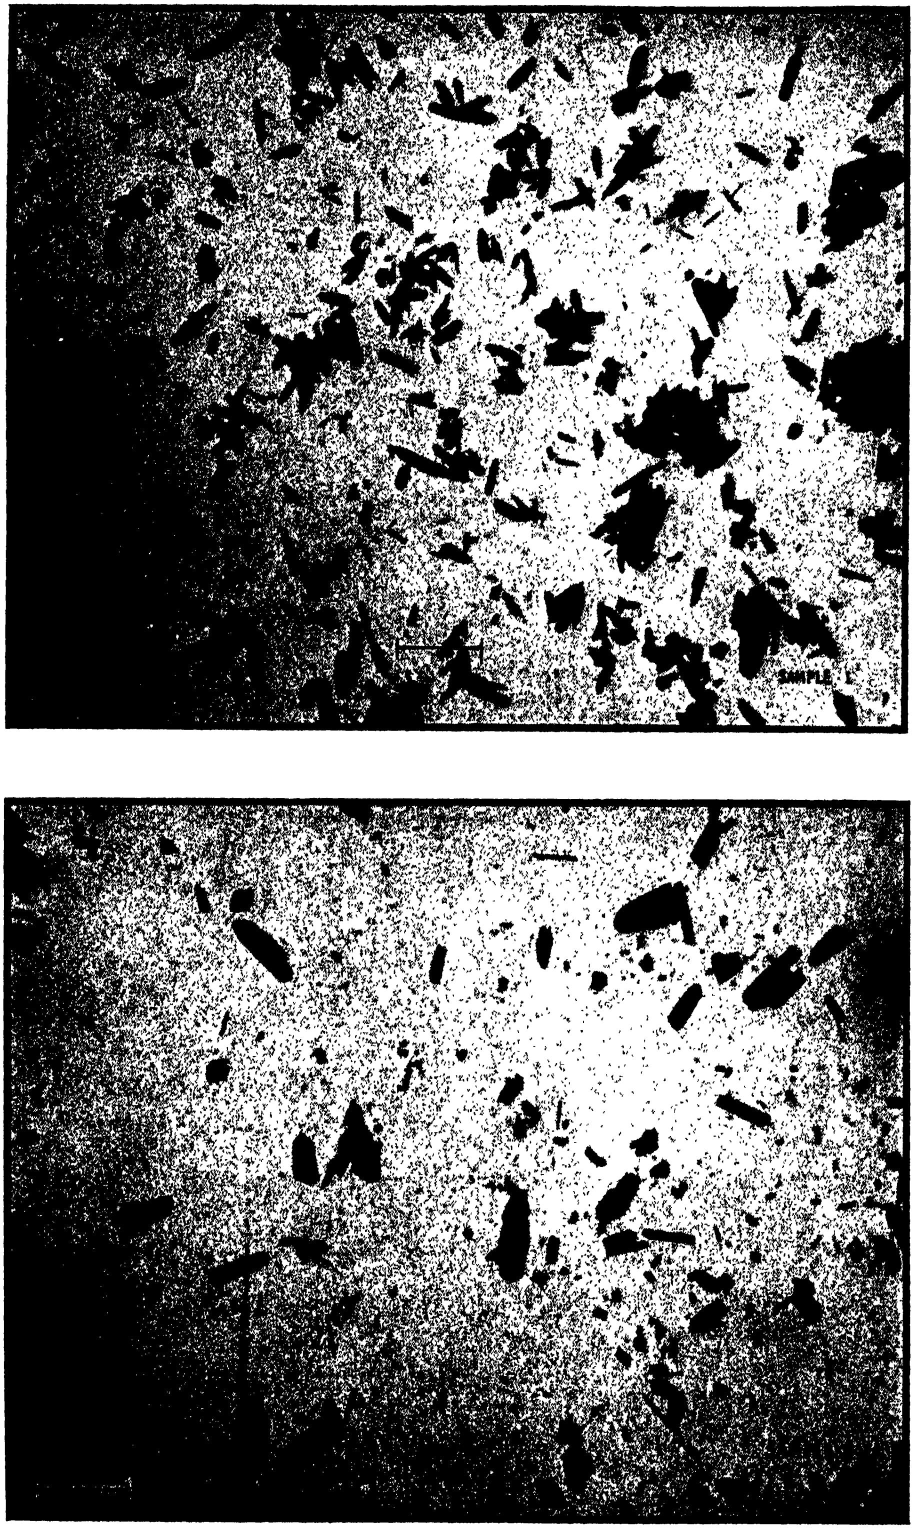

FIG. 2. Electron photomicrographs of samples 1 and 9. Magnification of sample 1: 11250×, and of sample 9, 12000×.

pale yellow to dark brown, as may be observed during processing. The commercially workable methods employ ferrous sulfate, scrap iron, air and steam. According to Fireman[2] a small amount of ferrous sulfate, about 1 percent to 2 percent, occasionally up to 3 percent, is converted into ferric sulfate.

"This suggests that the ferrous hydroxide from the partly hydrolyzed ferrous salt is first attacked by the oxygen of the air, causing the separation of the hydrated ferric oxide and releasing a corresponding amount of acid, which goes to form a certain amount of ferric salt. The latter is then reduced by the iron, which in dissolving restores the ferrous salt. Thus, the new incoming air finds the conditions of the solution exactly the same as the air which preceded it and repeats the same oxidizing action."

Since the chemical analysis of different colored pigments gave approximately the same average composition of 88.0 percent $Fe_2O_3$ and 12 percent $H_2O$, x-ray diffraction and electron microscope studies were undertaken to determine the nature of color variation. The pigments used in these studies were prepared as follows.

## EXPERIMENTAL

To 1100 cc of 9 percent $FeSO_4$ solution were added 200 g NaOH (89.4 percent purity) dissolved in 1000 cc water, under stirring at room temperature. The total volume was brought up to 10 liters and the gelatinous ferrous hydroxide oxidized by slow agitation. The crystallites of ferric oxide monohydrate thus obtained, including mother liquor, were transferred to a tank containing 70 liters of 5.7 percent ferrous sulfate solution and 22 kilograms of scrap iron. As the scrap iron was progressively converted into pigment, more metal was added to maintain a continous process.

The temperature in the reaction tank was kept between 60–65°C during the twelve days of continuous operation. The oxygen, necessary for the reaction, was supplied by forcing considerable air through the solution. Samples, given in Table I, were taken at stated intervals, then filtered, washed, and dried to constant weight at temperature of 125°C. X-ray diffraction patterns of the samples were made by the usual Debye-Scherrer-Hull method employing unfiltered Fe*K* radiation. In addition, all samples were examined with optical microscope for particle size, and electron photomicrographs were made of samples 1 and 9.

TABLE I. Color of pigments, depending on reaction time.

| No. of sample | Color | Reaction time |
|---|---|---|
| 1 | Light lemon yellow | 24 hours |
| 2 | Lemon yellow | 48 |
| 6 | Orange yellow | 168 |
| 8 | Light reddish brown | 216 |
| 9 | Reddish brown | 268 |

## DISCUSSION

X-ray diffraction patterns of samples in Table I were identified as those of the mineral Goethite.[3] Comparison of these patterns showed that the deepening of color in the pigment was accompanied by an increasing sharpness in the diffraction lines. This is illustrated by the photographs of samples one and nine in Fig. 1. Examination of the samples with the optical microscope disclosed a distinct difference in particle size. This was subsequently confirmed by the electron photomicrographs as shown in Fig. 2. While increase of sharpness and greater resolution in x-ray diffraction lines are, in general, an indication of grain growth, or strain free material or both, it appears from x-ray diffraction patterns, electron photomicrographs, and optical microscope studies that the progressive color change of the iron oxide pigments studied here is a visible expression mostly of the particle growth.

## ACKNOWLEDGMENT

The authors want to thank H. C. O'Brien, of the University of Pittsburgh, for the preparation of the electron photomicrographs. The contributions of M. J. Pooley of Hachmeister-Inc., Pittsburgh, Pennsylvania, who assisted in preparing the pigment samples, are also acknowledged.

# Mass Spectrometer for Leak Detection

A. O. Nier,[*] C. M. Stevens,[**] A. Hustrulid,[***] and T. A. Abbott[†]
*The Kellex Corporation, New York, New York*

(Received June 27, 1946)

A simple low resolution mass spectrometer is described which has been used successfully in detecting small leaks in high vacuum equipment. One part of He in 200,000 parts of air can be detected.

## 1. INTRODUCTION

THE problem of finding small leaks in a high vacuum system constructed of metal or glass and metal has always been a difficult and tedious task. Many methods for facilitating the location of leaks have been studied and described.[1,2] Most of the methods depend upon looking for a change of pressure in the system when the part suspected of leaking is waxed or closed with some other substance; or by looking for a change in the nature of the gas or vapor in the system when the part under test is painted with ether, $CCl_4$ and other liquids or when a stream of gas, such as $CO_2$, $H_2$, He, is directed on it. The device for indicating changes in pressure or in the nature of the vapor mixture must be very sensitive in order to find small leaks in systems having many leaks or in systems having surfaces which outgas and hence act as virtual leaks.

Of the various methods for hunting leaks, the scheme of directing a stream of relatively inert test gas at the suspected part of the apparatus and then looking for changes in the concentration or the presence of this particular gas in the system under test has many advantages. Some of these are: (1) gas will not contaminate the system or the pumps; (2) it will enter the system readily through small leaks; (3) there is no danger of closing a leak and having it open some time later; and (4) once a leak is found, there is no time lost in continuing the hunt because the test gas entering the system is quickly pumped out. The ideal "leak detector" is then an instrument which continually samples the gas in the system and instantly notes the presence or change in concentration of the test gas regardless of the presence of other gases or vapors.

A method which has been used with success in the construction of large vacuum equipment employs improved vacuum techniques and a new leak-detecting instrument. The outstanding contributions have been the development of a special mass spectrometer and a method of using it with a tracer gas in the location of minute leaks.[3]

A typical leak-testing arrangement employing the tracer gas method and using a mass spectrometer as a detector is shown in Fig. 1. The system which is being tested is evacuated by the continuous action of the vacuum pumps. An atmosphere of tracer gas may completely surround the system or a small jet of it may be used to probe the suspected zones. Any tracer gas which leaks into the system is rapidly detected by the mass spectrometer which continuously samples the gas being pumped from the system under test. Helium is one of the best tracer gases because it has a low molecular weight, does not occur to any extent in air or in other gases, is not adsorbed on the surfaces, can be readily pumped out of the test equipment, and is easily procured.

## 2. THE MASS SPECTROMETER AS A DETECTOR

The first portable mass spectrometer designed for detecting leaks was built at the University of Minnesota in the spring of 1943. A more recent model was developed in The Kellex Corporation

laboratories and differs from the first model by including an all-metal spectrometer tube and diffusion pump and a special electrode at the collector end of the tube for decreasing the background ion current.

The several components of the mass spectrometer are shown in Fig. 1. The details of the all-metal spectrometer tube are shown in Fig. 2. The gas enters the tube at the top and is ionized by a stream of electrons which are emitted from the heated filament and accelerated toward the trap. The number of ions produced depends on the electron emission and energy and on the gas pressure in the ionizing electron beam.

The ions are pulled out of the electron beam and accelerated by an electric field between the shield and plate containing the source slit. The emission regulator contains the necessary electronic rectifying and regulating circuits for maintaining the desired potentials on the accelerating and focusing plates, as well as holding the electron emission constant at any desired value.

A magnetic field is produced between the iron pole pieces by a permanent magnet. Since the magnetic field is wedge-shaped, it has a refocusing property for divergent ion beams as well as a resolving property.[4-6] The magnetic strength is such that an ion accelerating voltage of about 300 volts is required for collecting helium ions.

After leaving the magnetic field the selected ion beam passes through two baffle plates and a suppressor plate before striking the collector plate. The intensity of the selected ion beam is measured by a conventional battery-powered, negative feedback amplifier with a milliameter as an output meter. As shown in Fig. 2, the first stage of the amplifier which consists of a 954 tube and a $10^{11}$-ohm input resistor is mounted inside the spectrometer tube.

The pressure in the spectrometer tube is measured by an ion gauge whose electron emission is held constant by electronic regulating circuits. The ion gauge is provided with a special filament cut-off circuit consisting of an amplifier tube and a relay. This circuit protects the ion gauge and spectrometer tube filaments from burning out by automatically cutting off their currents when the pressure exceeds a predetermined value.

The tube is evacuated by a high speed oil diffusion pump. A liquid nitrogen trap between the pump and spectrometer tube is used to achieve a residual pressure of $2\times10^{-6}$ mm Hg in the tube. The pumping speed measured at the ionization gauge is approximately 30 liters/sec. This insures a rapid response of the instrument to changes in tracer gas concentration at the throttling valve. In probing, an indication is obtained on the output meter within a few seconds after the probe passes a leak.

### 3. PERFORMANCE OF THE LEAK DETECTING MASS SPECTROMETER

Although the instrument can be used to detect any one of several different gases by the adjustment of the ion accelerating voltage, it is normally tuned to indicate only He$^+$ ions. The selectivity of the instrument is shown by the mass spectrum of air containing a small amount of helium which is plotted in Fig. 3. The amplifier output current is plotted for the different values of the accelerating voltage. The heights of the current

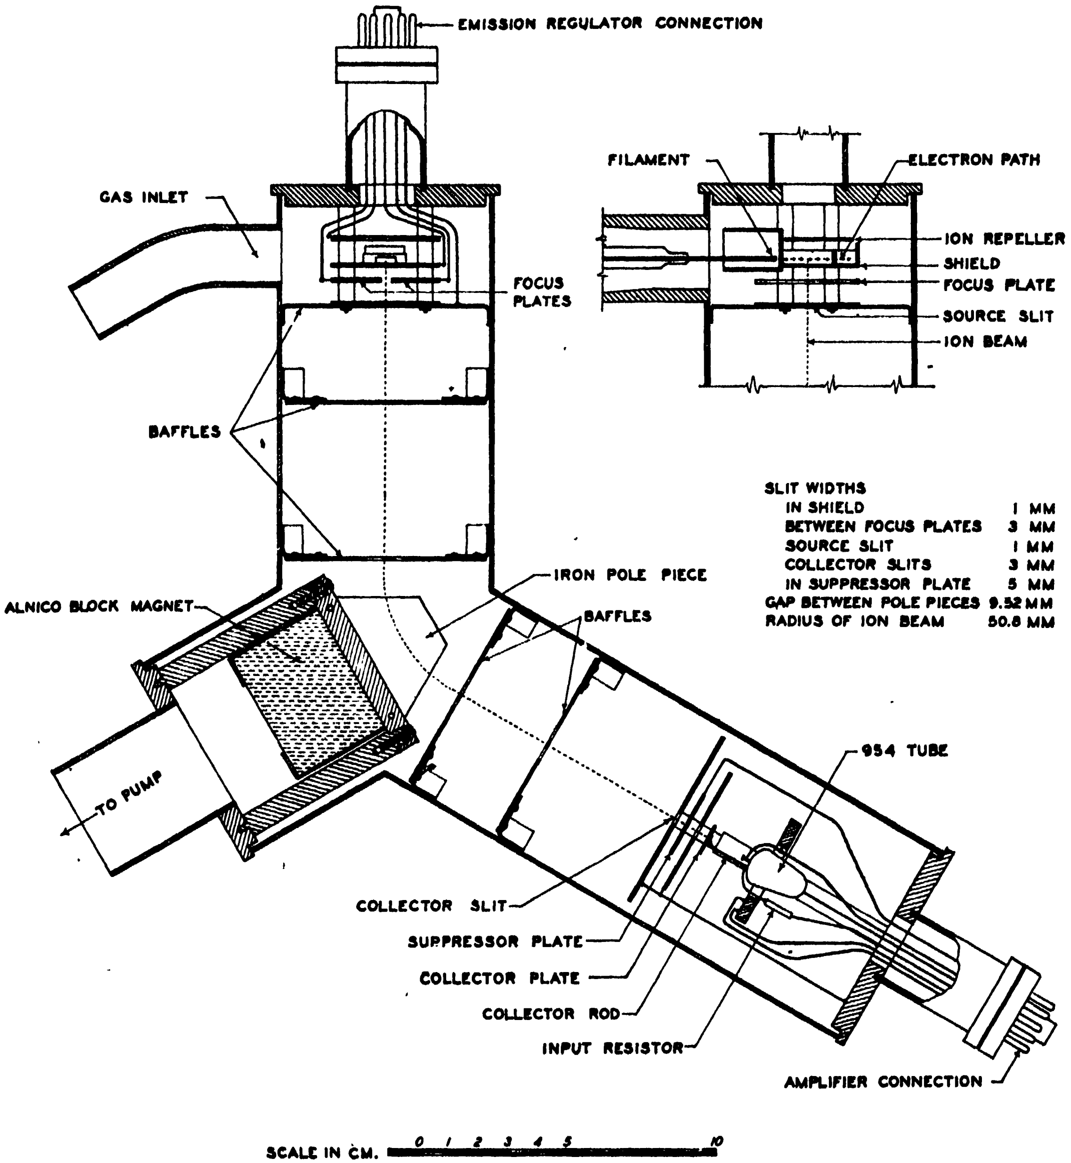

FIG. 2. All-metal spectrometer tube for leak detecting mass spectrometer.

peaks are proportional to the relative concentrations of the ionized gases in the sample. High sensitivity is made possible by two special features of the tube which will be explained below.

If the pressure in the tube is increased, the peaks increase in height since more ions are produced. Unfortunately, increased pressure also greatly increases the width of the peaks at the base especially on the high voltage side of the peak. This produces an increase in background which more than offsets the advantage gained because of the increased height of the peaks. The background is increased because at the higher pressure more nitrogen and oxygen ions lose energy by collision in passing through the region between the source and the magnet and are collected at the same time as are ions of lower mass.

The insertion of a baffle between the ionization chamber and the rest of the tube insures a high pressure in the ion source without a correspondingly high pressure in the rest of the tube. Thus, this baffle materially increases the effective sensitivity of the tube.

A further increase in sensitivity has been obtained by the use of a suppressor plate which is placed just ahead of the collector plate. This plate is operated at a potential near that of the ionizing region so that those ions which have lost energy by collision cannot pass through the slit in the suppressor plate and are not collected on the collector plate. Thus, oxygen and nitrogen ions which have lost energy and would otherwise be collected along with $He^+$ are repelled, and the background is again decreased to materially increase the sensitivity to helium as shown in Fig. 4. Moreover, the $He^+$ ions in passing through the suppressor plate lose almost all their energy so that they produce only a negligible number of undesirable secondary electrons.

Under normal conditions the throttling valve connecting the spectrometer was opened until the ion gauge indicated a pressure of $10^{-5}$ mm in the spectrometer pump lead. This corresponded to an ion source pressure of $2\times10^{-4}$ mm. With an electron emission of 5 ma and a He to air mixture of 1 to 10,000 a $He^+$ ion current of $6\times10^{-12}$ amp. was obtained. This corresponded to a full scale deflection of the output meter. Since it was possible to detect conveniently $He^+$ peaks as small as 5 percent of full scale reading of the output meter, the sensitivity of the instrument was said to be 1 in 200,000.

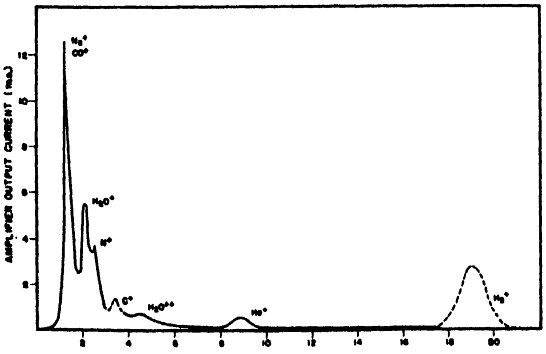

FIG. 3. A typical mass spectrum of air and helium mixture taken on a leak detecting mass spectrometer.

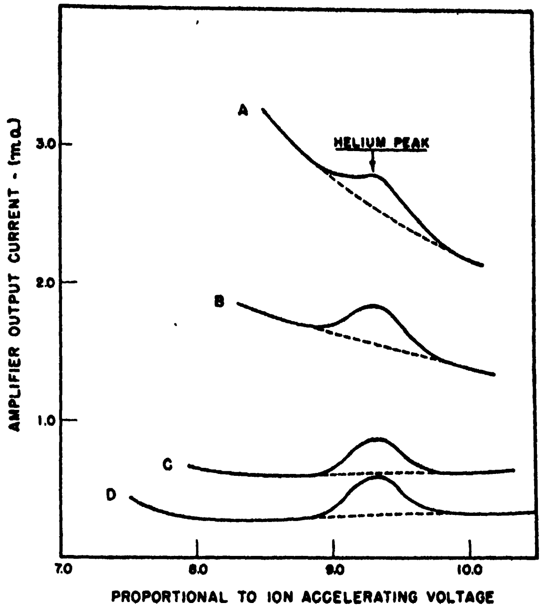

FIG. 4. Effect of suppressor field on mass spectrometer background current in the region of the $He^+$ peak for a sample having one part He to 50,000 parts of air. Pressure in spectrometer tube body $= 1.1\times10^{-6}$ mm Hg; pressure at ion source $= 20\times10^{-6}$ mm Hg.

| Curve | Volts |
|---|---|
| *A* | 0 |
| *B* | +175 |
| *C* | +250 |
| *D* | +400 |

Energy of helium ions approximately 330 volts. Helium ions are collected in case of curve *D* in spite of high suppression voltage due to fact that slit in suppression plate is wide and hence potential of space in slit opening is lower than 400 volts because of proximity of grounded plates on either side.

In order to reduce the sensitivity of the apparatus it was possible to reduce the electron emission or add resistance to the output meter circuit. A sensitivity reduction of a factor of 1000 could be obtained.

## 4. ACKNOWLEDGMENTS

The authors wish to acknowledge the many contributions made by R. B. Thorness to the design and development of the leak detecting spectrometer. This paper is based on work done for the Manhattan Project under Contract No. W-7405 Eng. 23 at the Kellex Corporation and on earlier work at the University of Minnesota under OSRD Contract OEMsr-149.

# New Developments in Vacuum Engineering†

Robert B. Jacobs* and Herbert F. Zuhr**
*The Kellex Corporation, New York, New York*

(Received June 12, 1946)

Methods developed for obtaining vacuum tightness in the K-25 Gaseous Diffusion Plant for the separation of $U^{235}$ are described. A general account of the vacuum engineering of the K-25 Plant also is given. The dynamics of vacuum systems are described, including the use of the mass spectrometer leak detector on rapidly responding systems. New techniques described include, among others, the helium hood method for measuring vacuum tightness and the use of calibrated leaks.

## 1. INTRODUCTION

### 1.1 Degree of Tightness Required

The development of leak detection techniques for the Gaseous Diffusion Plant for the separation of $U^{235}$ was one of the major engineering problems connected with the project. A greater degree of tightness was required than had been achieved, hitherto, in any commercial plant, and the construction schedule did not permit the use of the time-consuming methods generally employed. It was recognized, accordingly, that vastly improved techniques were necessary to greatly increase the sensitivity and speed of testing, otherwise a prolonged period of testing would intervene between the completion of construction and the initiation of operations. After all known methods and several new ones were considered, the mass spectrometer was selected as the basic testing instrument. This paper describes the techniques for leak detection developed with the mass spectrometer, and indicates the general utilization of those techniques.

#### (*a*). *Process Specifications*

Process design required that the inleakage of ambient air into the process stream be no greater than one one-hundredth of a standard cubic foot per hour per thousand cubic feet of plant volume. This is equivalent to a pressure build-up at high vacuum of eight microns (0.00015 lb./sq. in.) per hour. Ambient air must be kept from the process stream, principally because of its water vapor content. Water causes destruction of the uranium hexafluoride, the products of the reaction plugging the minute pores of the barrier. To assure continued, efficient operation of the plant by reducing the effects of inleakage to a minimum, a large portion of the plant equipment was surrounded by air with a dewpoint of −40°F. Elaborate precautions still were necessary to assure that the tightness of the plant was maintained.

Equivalent tightness was required also in the heat exchange equipment, which might otherwise leak coolant into the process system.

#### (*b*). *Precedents*

Industrial precedent for vacuum tightness of the required degree had been limited to compact equipment of relatively small volumes, such as radio tubes, and some of the smaller mercury rectifiers. Indeed, the general trend in industry had been toward accepting leakage in vacuum systems and evacuating continuously with large, high speed diffusion pumps, in order to maintain sufficiently low pressures. The continuously pumped mercury arc rectifier, with a volume of about seventy cubic feet, composed of some fifteen separate parts, had constituted the largest piece of high vacuum equipment generally used on a commercial scale. A few mercury turbine installations had been made with inleakage approximately ten times that permitted the Gaseous Diffusion Plant. Perhaps the modern vacuum still for petroleum oil most closely approximated the complexity and size of the proposed plant, and these units had been considered tight, when the inleakage was approximately 500 times those

** Present Address: Hydrocarbon Research, Inc., New York, New York.

permitted by process specifications for the Gaseous Diffusion Plant.

### 1.2. Schedule *vs.* Effort Required

Early experience in the laboratories and pilot plants, working in the diffusion process, both here and in England, indicated that the existent testing methods, if applied to a full scale plant would require a testing effort (measured in man-hours) at least equivalent to the effort required to manufacture and assemble such a plant. Indeed, in many laboratories it was common practice, after several men of graduate caliber had devoted a month or two in an unsuccessful attempt to make an experimental set-up tight, to coat vessels with organic "vacuum" waxes. The requirement that the process stream be free from organic contaminants precluded the use of such subterfuge in the Gaseous Diffusion Plant. Further, the exigencies of the project would not permit such an uncertain method of excluding air from the process stream.

Through application of the leak detection techniques developed, using the mass spectrometer as the basic testing instrument, it was possible to improve the process specifications fourfold. A pressure build-up at two microns (0.00004 lb./sq. in.) per hour in the assembled plant was achieved at an effort measuring approximately one percent of the total effort required to manufacture and assemble the process plant.

### 1.3. Pressure Units

Pressure units employed in high vacuum work differ from those most commonly encountered in engineering practices. The unit most frequently used is the micron which is 0.001 mm of mercury absolute or 1/760,000 of standard atmospheric pressure (14.7 lb./sq. in. absolute). Hence, a micron corresponds to a pressure of $1.94\times10^{-5}$ lb./sq. in. absolute. The so-called high vacuum range usually refers to that where the pressure is less than one micron.

### 1.4. Leakage Units

Leakage units are usually microns per hour, when referred to a particular vessel, or more generally, micron cubic feet per hour (mcfh). The first unit only has meaning when referred to a particular vessel. Multiplying the rate of rise of pressure in microns per hour due to inleakage by the volume of the vessel in cubic feet gives the value of the inleakage in micron cubic feet per hour. The latter unit completely defines the leak, since it is independent of the volume of the vessel, and from it the mass rate of inleakage may be computed directly. Hence, a leak of one micron cubic foot per hour means that the leak is of such value as to cause a rate of rise of pressure of one micron per hour in volume of one cubic foot.

## 2. KNOWN TESTING TECHNOLOGY AT THE BEGINNING OF THE PROGRAM

### 2.1. Pressure Methods

It was general practice to test process equipment operating under vacuum, using an internal test medium under pressure, in conjunction with an external indicator for location of the leaks. After all possible leaks were discovered and repaired using this procedure, the system was evacuated and the rate of pressure rise observed as a measure of the inleakage. If the pressure rise exceeded specifications, the system was repressured and the entire cycle repeated. These pressure testing techniques are discussed in more detail in Appendix 7.2. Where applicable to process service lines, these techniques were used in the construction of the Gaseous Diffusion Plant. Design of the process equipment would not permit the application of more than five lb./sq. in. gauge to most of the plant, further decreasing the applicability of pressure testing techniques. However, an improvement of several hundredfold would be necessary for use of this method in the testing program for the plant proper.

### 2.2. Vacuum Methods

Small pieces of vacuum equipment were usually tested using vacuum techniques. Such methods consisted of observing the change in apparent pressure in the system, as measured with either a hot wire or an ionization gauge when the nature of the residual gas in the system was changed by the substitution of a probe gas (or vapor) for the air normally entering through the leak. Most commonly used was the technique of observing a hot wire gauge, while the exterior of the vessel was sprayed with acetone. A more detailed ac-

TABLE I. Analysis of basic leak detection instruments.

| | Mass spectrometer | Differential pirani gauge | Single pirani gauge | Pressure testing |
|---|---|---|---|---|
| Inherent instrument sensitivity (ratio of probe gas to air detectable) | $\frac{1}{100{,}000}$ | $\frac{1}{3000}$ | $\frac{1}{300}$ | Bubble growth at 10 $mm^3$/hr |
| Operating pressure | <0.1 microns | <25 microns | <50 microns | 45 psig |
| Speed of probing | 5 ft./min. | As fast as area can be wet with spray gun | As fast as area can be wet with spray gun | Observation of smooth soap film for at least 5 min. |
| Smallest leak detectable on vessels having a pressure build-up at 200 microns per hour and a volume of: | | | | |
| <1 cubic foot | <0.01 mcfh | 0.10 mcfh | 1.0 mcfh | 5 mcfh |
| 1–10 cubic feet | 0.01–0.02 | 0.10– 1.0 | 1.0– 10.0 | 5 |
| 10–100 cubic feet | 0.02–0.2 | 1.0 –10.0 | 10.0– 50 | 5 |
| 100–1000 cubic feet | 0.2 –2.0 | 10.0 –50 | 50 –500 | 5 |

count of these methods is given in Appendix 7.3. Results obtained using these methods indicated that some improvement over pressure testing techniques could be reasonably expected. However, a corresponding increase in the caliber of the necessary personnel using these methods was also indicated, and the increase in the speed of testing was uncertain.

### 3. DEVELOPMENT OF DYNAMIC VACUUM TESTING TECHNIQUES

Study of the evidence on hand indicated that further advances in pressure testing methods would, at best, advance their useful sensitivity to equivalence with the then existent vacuum techniques, at the expense of an increase in testing time. It was evident that improvement of the existing vacuum techniques could have been effected, but again only at the expense of additional testing time. The increased time factor made both proposals most unattractive. However, new vacuum techniques were visualized which would permit a tenfold improvement in sensitivity and a simultaneous improvement in the speed of testing. These new techniques included:

1. Use of selective instruments; that is, instruments which give a nearly null reading for air and residual gases, responding only to a probe gas.
2. Use of these instruments dynamically; that is, as adjuncts to a high speed evacuating system permitting their use under optimum conditions.
3. Use of the selectivity of the indicating instruments to permit estimation of the amount of leakage even in the presence of outgassing and unrepaired leaks.

It was therefore decided to investigate and develop, if practical, a selective, continuously sampling leak detector, and to determine the optimum conditions for its use.

### 3.1. Leak Detectors Developed and Investigated

The Kellex Vacuum Engineering Group developed the Differential Pirani Gauge as a new continuous sampling unit, and investigated the use of the optical spectrometer as a continuous sampling unit. The University of Minnesota group had developed a compact, specialized mass spectrometer.[1] The use of the instrument, as a continuous sampling (or dynamic) instrument, was developed by the Kellex group. All three of these instruments were selective. Comparison of the Differential Pirani Gauge and mass spectrometer to older methods are made in Table I.

#### (a). *Optical Spectrometer*

The optical spectrometer, off-hand, would appear to be a suitable instrument for leak detection work. It is simple, its response is instantaneous, and its sensitivity for certain probe gases is very high. However, under actual working conditions, it is found to be unreliable due to the uncertain "clean-up" of the discharge tube used as a source after exposure to different gases.

#### (b). *Differential Pirani Gauge*

This instrument consists of two hot wire vacuum gauges known as Pirani Gauges. These

---

[1] A. O. Nier, C. M. Stevens, A. Hustralid, and T. A. Abbott, "Mass spectrometer for leak detection," Contribution from the Kellex Corporation, Research Paper C3.

are connected electrically in opposite arms of a Wheatstone bridge. The two gauges are connected to the vacuum line of the system under test by a short "tee" connection. A cold trap is placed on one of the arms of the tee leading to the gauges, but not on the other.

When air is the only gas present, the pressures in the two gauges are equal and the galvanometer reads zero. However, when a leak is probed with a liquid such as methanol, the latter reaches one gauge only, due to the presence of the trap in front of the other, and the Wheatstone bridge is thrown off balance. The instrument thus acts as a detector for condensible probe gases, being little affected by the presence of other gases.

### (*c*). *Mass Spectrometer*

The mass spectrometer has been used by physicists for many years, principally to determine the isotopic constitution of different substances. In its usual form it is a large and rather complex instrument requiring a highly skilled operator.

A simplified instrument specifically designed for vacuum testing was developed at the University of Minnesota. A considerable reduction in size and weight was made, making a portable instrument possible. Several electronic controls were incorporated reducing the number of manual adjustments required. However, carefully trained operating and maintenance crews are required to use these instruments successfully for leak detection on a large scale.

In popular literature, the mass spectrometer is referred to as an "Atom-Sifter" due to the ability of the instrument to "sift out" and measure the concentration of atoms of any kind.

This characteristic of the mass spectrometer was the basis in choosing a probe medium. This medium should have the following properties:

(1) It should be unique in the mass spectrum of residual gas in the system under test and practically non-existent in the normal atmosphere surrounding the equipment under test.
(2) It should be readily removed from the system by pumping and should not contaminate the system.
(3) It should be of low molecular weight and low viscosity, and should be readily available.

Helium fulfills all of the requirements and was chosen as the probe gas for use in the testing program.

The instrument works in the following manner: Referring to Fig. 1, the gaseous mixture to be analyzed is pumped into that part of the spectrometer which includes the source. When used as a leak detector, the spectrometer is fed through a throttle valve connected to the main vacuum lines. The pressure in the spectrometer is kept less than $10^{-4}$ mm by continuous pumping. In the source of the spectrometer, molecules of the different elements present are ionized by an electron beam. The number of ions of any particular element so produced in a function of the concentration of that element in the gaseous mixture fed into the spectrometer.

The ions thus formed are collimated and given a certain momentum toward the analyzer by suitable electrical potentials. On passing through the wedge-shaped magnetic field, the ions are deflected through certain angles which depend upon their respective masses.

In Fig. 1, the electrical fields are adjusted so that $He^+$ ions enter the collector where they are measured. Ions of greater or of smaller mass fall on either side of the collector slit and are not measured. Ions of any given mass may be brought

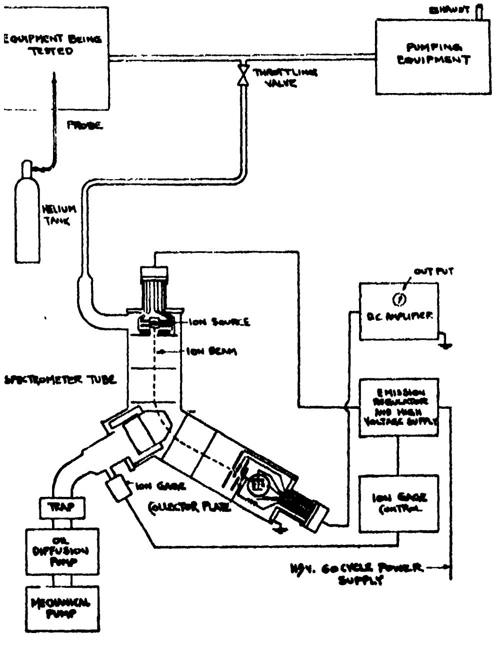

FIG. 1. Schematic line diagram showing use of mass spectrometer leak detector.

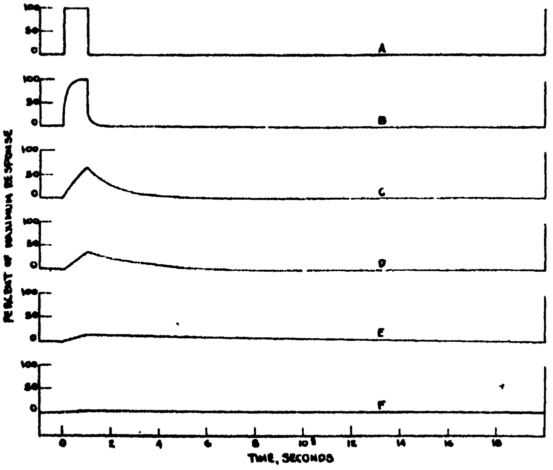

FIG. 2. Appearance and disappearance of probe signal for systems of varying response characteristics. (Probing is for a period of one second beginning at $T=0$.) Curve A is the probe pulse at the leak. Curves B through F have $S/V$ values of 300, 60, 30, 6, and 3 minutes$^{-1}$, respectively, when $S$ is expressed in cfm and $V$ as ft.$^3$.

into the collector by properly adjusting the electrical fields. For leak detecting purposes, the instrument is adjusted for He$^+$ ions, since helium is a most satisfactory probe gas. Theoretically, the instrument, when thus adjusted, will show a zero reading, unless helium is present in the gas stream under analysis. Actually, however, due to necessary physical imperfections in the apparatus, there is a continuous "background" reading. The presence of helium then is indicated by an increase over the normal background reading.

A separate report[1] gives detailed information on the construction and operation of the instrument developed at the University of Minnesota. Accordingly, we are concerned here, principally, with the performance of the instrument as a leak detector.

The first mass spectrometers used for leak testing purposes were all glass instruments using mercury diffusion pumps. The fragility of these machines for plant use was recognized, but the magnitude of the trouble caused, thereby, was discovered only after attempting to institute the production testing program. The entire spectrometer was redesigned by the Kellex Special Instrument Group. In addition to greater durability due to the practically all-metal construction (only the filament stem and the ion gauges remained glass), the new tube possessed a higher inherent sensitivity from design, and a greater sampling capacity through the substitution of an oil diffusion pump for the mercury model.

### 3.2. Dynamic Requirements for Rapid, High Sensitivity Vacuum Testing

Use of a high sensitivity, dynamic, leak detector such as the mass spectrometer is of little avail if the system under test does not possess the required characteristics. It is shown mathematically, in Appendix 7.4, that the ratio of $S/V$ (pumping speed of the system with respect to the volume pumped) is of greatest importance, both with respect to dynamic sensitivity and speed of leak hunting. In Fig. 2, the response (at the leak detector) after exposing the leak to probe gas for one second is plotted for different pumping speeds.

The sharpness of the response to probing will, in a large measure, determine the ability of *any leak detector* to function efficiently. Figure 2 illustrates the impossibility of attaining a sharp response without a sufficiently high $S/V$ ratio: i.e., about 6 or more reciprocal minutes.

When a large leak is probed, the system becomes temporarily "flooded" with a probe gas, and it is impossible to continue leak hunting until this gas is removed. In Fig. 2 probing is discontinued at the end of 1 second. Those parts of the curves for time greater than 1 second represent the "clean-up" period. The length of time required for "clean-up" is a function of the ratio $S/V$. Thus, for example, if a large leak is probed until a probe response of 25 percent of maximum is obtained, and pumping is then continued until all but 0.5 percent of the probe gas is removed, the "clean-up" times indicated in Table II are obtained. These calculations have been confirmed experimentally.

Loss of time by slow clean-up can prolong the leak hunting period considerably, perhaps much more than is indicated in Table II. The reason for this is the following: When one is hunting for leaks with too small a pump (low $S/V$), the dynamic sensitivity is low, and as a result, leaks

TABLE II. Evaluation of clean-up time as function of $S/V$.

| $S/V$, minutes$^{-1}$ | 300 | 60 | 30 | 6 | 3 |
|---|---|---|---|---|---|
| Clean-up time, seconds | 1.7 | 5.8 | 11.1 | 139 | 546 |

must be carefully and repeatedly probed to establish their exact location. Consequently, by the time this is done, a considerable quantity of probe material will be introduced into the system. Since this must be removed before probing can continue, the leak detecting crew finds it necessary to remove a large quantity of probe gas at a slow rate, which is doubly time consuming.

A simple experiment was made which confirmed the above predicted results. The calculations have since been confirmed many times in practice, both under mass production and field conditions.

It must be recognized, that the *S*/*V* ratio refers to the speed of the entire vacuum system, including the process equipment under test. Thus the largest high speed vacuum pump will be of little use if the rest of the system throttles the flow to the pump. Rather, the use of a pump oversize for the system speed will further penalize the sensitivity, by making it impossible to obtain an adequate sample in the gas evacuation line through the leak detector. It is necessary that the lines of the system under test be sized to permit adequate speed of pumping. This can be done by sizing them for molecular flow according to the formula: Speed $= 14D^3/L$, where the speed is expressed in cubic feet per minute, $D$ is the internal pipe diameter in inches, and $L$ the length in feet. One of the more important functions of the Vacuum Engineering Division was to check all design to assure that the sufficient speed was always attained at the test connections.

The need for high speed pumps is apparent from the preceding discussion. These pumps had other special requirements:

1. The pumps and all associated vacuum equipment, i.e., valves, gauges, and piping, had to be tight, and engineered to maintain this tightness.
2. Provision to reduce the back diffusion of diffusion pump oil, without seriously impeding the speed characteristics of the pump, was necessary to prevent the contamination of the process equipment under test.
3. The complete pump unit, including mechanical and diffusion pumps, and all necessary controls, had to be self-contained and portable, and should require only connections to the system under test, water, power, and drain lines, to permit operation.

A typical vacuum pump unit is shown in Fig. 3. For initial evacuation, provision is made to by-pass the diffusion pumps through a roughing line. Pump units of suitable design were developed by Westinghouse Electric Corporation, National Research Corporation, and Distillation Products, Incorporated, in conjunction with the Kellex Vacuum Engineering Division.

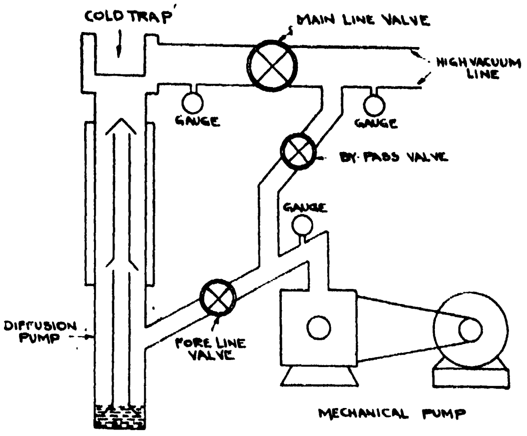

FIG. 3. Typical pumping unit.

## 4. MEASUREMENT OF TIGHTNESS

The general plan of attack, to secure over-all plant tightness, was to apportion the total allowable leakage among the different plant components, and to check individually for tightness each such component, one or more times prior to its installation.

This measurement of tightness, involving about 1,000,000 individual tests in all, threatened to be a serious bottleneck in the fabrication schedule. The only known method for measuring tightness consisted of evacuating the equipment sufficiently long to outgas it thoroughly and then to measure the pressure rise. This method usually required an average of 12 hours of continuous evacuation for each piece of equipment tested. Since the estimated number of vacuum tests on the individual components of the plant totaled over 600,000, it is evident that approximately 1000 leak rate stations each working more than 8000 hours would be required to prove the tightness of equipment before installation. This estimate does not include the time spent leak hunting, setting up the equipment for test, and retesting of rejects.

Evaluation of the mass spectrometer as the basic leak detection instrument indicated that its

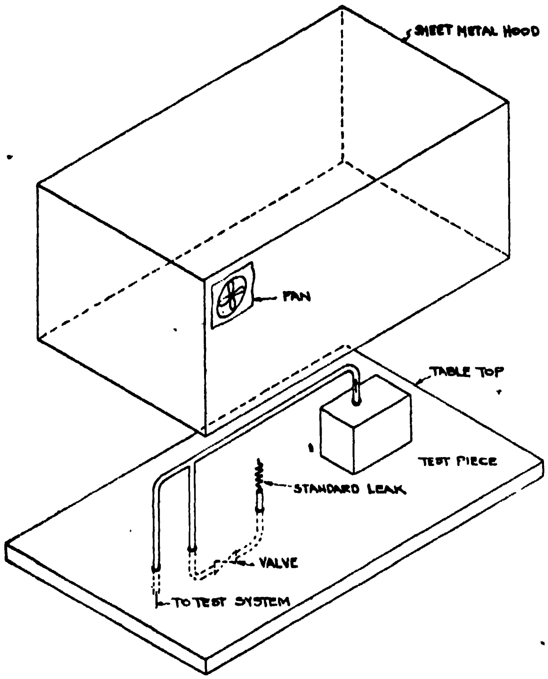

FIG. 4. Typical hood test set-up.

quantitative aspects could be adapted to measurement of the inleakage into the vacuum system. Accordingly, the so-called "Hood Method" for tightness testing was devised. Using this method in conjunction with the rapidly responding dynamic system for leak detection, the testing load for production testing was reduced to approximately 100 stations each working 2450 hours.

The Hood Method consisted of surrounding the equipment under test with a gas-tight hood in which a fixed concentration of probe gas was maintained, and comparing the amount of the probe gas entering the system through the leaks in the equipment to the amount of probe gas entering through a standard calibrated leak. This comparison was made by direct reading of the output of the mass spectrometer. The results thus obtained have been quantitatively checked against results obtained by measuring the inleakage of thoroughly outgassed vessels by the usual pressure build-up method.

A typical hood set-up is shown in Fig. 4. For small objects several manifolds are attached to one pump-leak detector combination, allowing the objects to be set up or taken down on one manifold, while the units on the other are under test. For larger equipment, individual pump-leak detector combinations are required. The test is made in the following manner:

With the valve leading to the calibrated leak in an open position helium is forced into the hood until its concentration there is sufficient to give a predetermined reading on the leak detector. This reading (reading 1) is proportional to the total inleakage consisting of: (a) unknown vessel leakage, (b) known leakage from the calibrated leak.

The valve leading to the calibrated leak is then closed, and a second reading taken (reading 2). This reading is, of course, proportional to the unknown leakage alone. From these two readings the following equation may be derived:

Unknown leakage =

$$\frac{\text{Rdg }(2)}{\text{Rdg }(1)-\text{Rdg }(2)}\times\text{calibrated leak.}$$

This equation gives the unknown leakage in terms of the two readings referred to above and the value of the calibrated leak. Knowledge of the helium concentration in the hood is not necessary. The only requirement is that this concentration remains substantially constant during the time the readings are taken. Normally, this requires from five to ten minutes. Well constructed hoods show practically no decrease in helium concentration for considerably longer periods.

A modification of the hood technique, that has proved extremely useful for testing "hidden" leaks, involves the use of undiluted helium on both the standard leak and the unit under test. This method is best achieved by evacuation of the re-entrant interior volume suspected of

TABLE III. Contribution of various process components to inleakage (based on manufacturer's specifications).

| Component | Volume contribution per $100\ \text{ft.}^3$ | Inleakage specification pressure build-up, microns/hr. | Inleakage contribution, mcfh |
|---|---|---|---|
| Diffusers | 68.6 | 0.25 | 17.1 |
| Centrifugal pumps | 2.2 | 0.50 | 1.1 |
| Process drums | 3.8 | 0.1–1.0 | 0.4 |
| Process piping and valves | 25.4 | 1.00 | 25.4 |
| Instruments | <0.1 | <1.00 | <0.1 |

leaking into the vacuum space proper, and breaking the vacuum with pure helium. Then the reading of the mass spectrometer output is compared to that obtained when a standard leak is surrounded by pure helium.

### 5. PRODUCTION TESTING

Experimental evidence indicated that the process specifications could probably be reduced from eight microns per hour to two microns an hour through the use of the methods just described. It was evident that most careful preassembly testing would be necessary to hold the number of leaks in the assembled plant to an absolute minimum. That is, it was most essential to be able to certify that various complex pieces of process equipment would not have to be disassembled for repair in the field, and that the vacuum testing crews in the field could have confidence in the tightness of the component pieces of equipment. The decision to pre-test every piece of process equipment and piping subassembly required the preparation of many varied procedures and specifications, and the education of manpower to use these new techniques in the different places of manufacture. Specifications for each unit were made on the basis of mechanical complexity and the number of such units occurring in each assembled cell of the plant. Table III lists the major components of each cell, the contribution of their volume per one hundred cubic feet of cell volume, and the inleakage contribution and the specified inleakage rate. It should be noted that, if no damage occurred during transport and erection, and if all field welds were tight, the assembled plant would have an inleakage rate considerably below 2 microns pressure rise per hour. Thus a margin was available for depreciation and safety.

Each manufacturer was asked to send several engineers to Kellex for training in the techniques of leak hunting, using the high sensitivity dynamic method and the hood test for the tightness testing. At the conclusion of the training program these engineers were asked to prepare detailed procedures applicable to their particular process unit. These procedures were reviewed by the Kellex Vacuum Engineering Division before they were put into practice. In all cases high $S/V$ ratios were maintained for production testing in keeping with the heavy production schedules. Many jigs and fixtures were designed and built for this purpose; since the undependability of rubber hose and similar makeshift connections was recognized, large sized equipment had flanged connections for testing, while for small equipment the Dresser type coupling proved successful. Best vacuum practice was followed in the construction of testing rigs; packless valves were used and all possible joints were welded, brazed, or hard soldered. In several instances, rigs were equipped with packed valves and sliding jigs; however, these units always proved to have lower sensitivity than those of all metal construction. Figures 5 and 6 show schematically some of the manifolds used for production testing.

### 6. TESTING THE ASSEMBLED PLANT

Delivering sound, vacuum-tight equipment to the plant site was one job. Perhaps a bigger one was to see that this equipment was assembled without injury, and that the assemblies were made tight. This program required the following groups: (1) Vacuum Engineering; (2) Construction Coordination; (3) Vacuum Testing; (4) Acceptance Control and Records.

Vacuum Engineering for the assembled plant was concerned with four major problems:

(1) Definition of the subsections of the plant to be tested as units.
(2) Location of test connections in process system, to assure sufficiently high $S/V$ ratios for efficient testing.
(3) The magnified effect of sorption of the probe gas, when a large number of diffusers were tested simultaneously.
(4) Excessive extraneous leakage through the shaft seals of the centrifugal pumps.

Provision of sufficient test connections on the test cells allowed a careful study of all these problems to be made.

The process design of the plant largely determined the basic sections for testing, since the addition of valves to facilitate testing might interfere with orderly process operation. Thus a cell, building and cell by-pass lines, and the cold traps, were tested as subsections. The limits and state of completion of each subsection were accurately defined.

Each proposed layout of test connections was analyzed using an electrical analogy. The resistance of the piping to gas flow may be considered equivalent to electrical resistance. Consequently, an analysis of resistance network was used to demonstrate the optimum location for the test connections. These analyses were made mathematically or were measured on resistance networks. The results were quantitatively confirmed by later field measurements.

The Construction Coordination Group reviewed the progress of construction and established standards for completion of defined subsections. Briefly, these subsections were defined so that (1) no interference between construction and testing could exist (i.e., all subsections were ended past a limiting valve, so that opening of the valve to permit welding was unnecessary); (2) operations could follow vacuum testing so as to bring the process on stream in a practical orderly manner. Before transfer of buildings or sections to the Vacuum Testing Groups the Construction Coordination Group reviewed the unfinished construction items which might interfere with vacuum testing, and checked the results of preliminary pressure testing. Once a section of the plant was turned over to the Vacuum Testing Group, further construction made necessary by redesign or other reason was subject to the approval of the Construction Coordination Group.

Actual vacuum testing was performed by three-man crews assigned to each leak detector-pump unit combination. These crews were headed by a person of at least high school education and were all given a two-week special training course in the mechanics of the leak testing operation. Because of the complicated nature of the leak detectors and pump units, the test crews were not permitted to make any adjustments or repairs to the equipment. Highly trained personnel was used for the maintenance of all leak detection equipment.

Vacuum Testing Acceptance Control and Record Groups kept a record of all leaks found, the status of testing, and repairs. The results of studies by this group suggested several changes in design, erection procedures, and testing sequence, which considerably reduced both the probability of leaks and the time required for testing. The major function of this group was to review the test data for conformance to specification.

The efforts of the Vacuum Testing Program involving well over 1100 men were climaxed when the plant was brought below a leak rate of 2 microns per hour. This was accomplished in the face of a constantly accelerated construction schedule and achieved within a very narrow margin of time allotted for vacuum testing after the completion of construction.

## 7. APPENDICES

### 7.1. Fundamentals of Vacuum Engineering*

Industrial uses of high vacuum have increased very rapidly in the past few years. Among such applications may be listed the manufacture of radio and x-ray tubes, lamp bulbs, rectifiers, etc., and the reduction of various metal bearing ores.

To satisfy the growing needs of industry in the field, much time and energy have been spent in the design and development of rugged, high capacity pumping equipment, by means of which the pressure in vessels of several hundred cubic feet of volume may be reduced to exceedingly low values with great rapidity.

#### (*a*). *Tightness and Cleanliness*

Tightness and cleanliness are absolutely essential in all vessels used in high vacuum systems. This becomes obvious when one considers that one cubic inch of standard air will occupy a volume of approximately 760,000 cubic inches at one micron pressure, and that one cubic inch of water when vaporized will occupy 945,000,000 cubic inches, at one micron pressure. Unless systems are clean and free from leaks, it is, therefore, extremely difficult to reduce the pressure in them to the high vacuum range.

#### (*b*). *Vacuum Pumping System*

A vacuum pumping system consists of three essential units known as the fore pump, the diffusion pump, and the vapor trap. (See Fig. 3.)

*Diffusion Pump.* The diffusion pump provides a means of obtaining large volumetric pumping capacities in the high vacuum range of pressures. The pumping action originates in the streaming of either oil or mercury vapor from a suitably designed jet. The gases to be pumped diffuse into this vapor stream and are carried along with it away from the system being evacuated. Pumps of this type usually attain their full volumetric capacity at about one micron pressure, and maintain this same value to very low pressures. The capacity of a well-designed pump will be approximately 50 cubic feet per minute per square inch of opening at the jet, and is, therefore, nearly $\frac{1}{3}$ the molecular flow through a hole equal in diameter to the pump housing when absolute vacuum is maintained on one side.

The diffusion pump will not exhaust directly against atmospheric pressure. There is a critical fore-pressure or threshold pressure above which it will not pump at all. This required fore-pressure (about fifty microns) is maintained by a mechanical pump, an ejector, or a combination of the two.

*Fore Pump.* The fore pump is a mechanical pump or ejector. It must have sufficient capacity to handle the gases compressed by the diffusion pump and maintain the fore pressure against which the diffusion pump operates at a value lower than the critical threshold pressure. Mechanical pumps will not in themselves produce pressures lower than about one micron. For lower pressures, the diffusion pump must be added.

*Vapor Trap.* The vapor trap is necessary to prevent the migration of oil vapor from the diffusion pump to the system being evacuated. In most cases, a suitably designed water-cooled baffle will suffice. However, a refrigerated cold trap is required to obtain pressures lower than 0.01 micron, or when it is desirable to prevent small traces of oil from entering the system which is being exhausted. Pressures lower than 0.01 micron may be obtained without the use of cold traps, but only with great difficulty and an excessively long "conditioning" time.

#### (*c*). *Flow of Gases*

The flow of gases in the high vacuum range obeys laws quite different from those familiar to the hydraulic engineer. This fact cannot be stressed too highly since it is overlooked all too frequently by the uninitiated.

Extremely large and short pipes must be used to handle the large capacities of a diffusion pump,

---

* By J. R. Downing, Kellex Corporation. (Present address: Cook Electric Company, Chicago, Illinois.)

TABLE IV. Capacity loss through pipe connections to a diffusion pump (capacity 2600 cfm below 0.1 microns).

| Length of pipe in feet | Percent capacity reduction 4″ I.D. | 8″ I.D. | 12″ I.D. |
|---|---|---|---|
| 2 | 88 | 52 | 27 |
| 6 | 95 | 73 | 45 |
| 20 | 98 | 89 | 71 |

although the resultant mass transfer is very small. For piping systems longer than a few feet, the pipe size used must be of larger diameter than the pump opening. It is customary to calculate pumping system capacities in terms of the capacity of the pump and the flow capacity of the pipe. The expression for over-all pumping capacity is:

$$\frac{1}{S_{\text{system}}}=\frac{1}{S_{\text{pump}}}+\frac{1}{S_{\text{pipe}}}$$

where the various pumping capacities are expressed in cubic feet per minute. If the length of the pipe is more than ten times the diameter, the capacity of the pipe for air is given by:

$$S_{\text{pipe}}=\frac{0.51D^4P}{L}+\frac{14D^3}{L}\,\frac{1+0.62DP}{1+0.76DP},$$

where $D$ is the pipe diameter in inches, $L$ is the length in feet, and $P$ is the average line pressure in microns. A second semi-empirical expression for the capacity of short lengths of pipe at pressures less than 0.1 microns is given by:

$$S_{\text{pipe}}=\frac{14D^3}{L+(D/9)},$$

where $L$, $D$, and $S$ have the same units as in the above formula. It is evident from these expressions that the pipe size may be the limiting factor in the capacity of a pumping system regardless of the capacity of the pump. Table IV gives the reduction in capacity caused by various lengths of pipe connecting a 2600 cfm diffusion pump to the vessel being evacuated.

### (*d*). *Precautions and Techniques*

Precautions and techniques necessary to the attainment and maintenance of high vacuum are so many and varied that the subject will be dealt with here only in the most general way. This is summed up by saying that vacuum systems must be capable of attaining high vacuums without the use of waxes, greases, lacquers, soft solders, and the like.

Sound engineering, cleanliness, ruggedness, and good materials are all of prime importance.

The equivalent in weight and strength of standard 150-pound flanges and fittings is recommended. These may seem excessively heavy but, in view of their reliability and trouble-free operations, they are well worth the additional cost.

### (*e*). *Evacuation Time*

The time required for evacuation may be calculated fairly well for the range of pressures from atmospheric down to a few hundred microns. The expression is:

$$T=\frac{V}{S}\ln\frac{P_1-P_0}{P_2-P_0},$$

where $T$ is time in minutes, $V$ is volume of vessel in cubic feet, $S$ is the pump capacity in cubic feet per minute, $P_1$ is the initial pressure, $P_0$ is the pressure attained by the pump above at blank off, and $P_2$ the final pressure. Since $P_0$ is small compared to $P_1$ and $P_2$, the expression may be simplified to:

$$T=\frac{V}{S}\ln(P_1/P_2).$$

With $P_1$ atmospheric pressure and $P_2$ a few hundred microns, the term involving the logarithm becomes about eight so that the time required for "roughing" a vessel becomes:

$$T=8(V/S).$$

The latter expression holds quite well, provided the system is free from inleakage and the volumetric capacity ($S$) of the pump stays reasonably constant. For most mechanical vacuum pumps the latter condition is true down to pressures of a few hundred microns,

In the range of pressures lower than 100 microns, the above expression is quite useless for three reasons:

1. The capacity of the diffusion pump is by no means independent of pressure.

2. Degassing and vaporization of substances on the inner walls of a vessel contribute so greatly to the volume of gases which must be handled by the pump, that the residual volume of air becomes negligible by comparison.

3. Impedance of connecting pipes becomes an important factor.

If the amount of degassing per unit surface area is known as a function of time and pressure, then the pump-down time may be estimated by a graphical integration method. However, such data are usually not known very accurately so that choice of pump size is dictated largely by experience. The modern trend is to use diffusion pumps of very large capacity so that a high vacuum may be produced quickly and in spite of degassing, small leaks, etc.

### (*f*). *Special Gauges*

Special gauges have been developed for the measurement of pressures lower than one millimeter of mercury. The forces involved are so small that a direct measure of the pressure by observing the deflection of a diaphragm or the equivalent does not prove practical. Some other property of the gas which varies with pressure and which is capable of easy application must be chosen.

The McLeod gauge has long been the standard for the accurate measurement of pressures less than one millimeter of mercury. A sample of the gas in the system is entrapped and compressed by a known ratio. A measure of the resulting pressure then permits calculation of the initial pressure. Compression ratios as high as a million may be used enabling the measurement of pressures as low as 0.001 microns. Because of the high compression ratio, the gauge may only be used for the measurement of pressures due to permanent gases.

The thermocouple and Pirani gauges depend upon the variation of heat conductivity with pressure of the gas. These gauges are, therefore, not absolute and must be calibrated by comparison with the McLeod gauge described above. They are sensitive in the range of pressures between one millimeter of mercury and one micron.

The ionization gauge is capable of measuring pressures from one micron to the lowest attainable which, at present, is about one millionth of a micron. The gauge is essentially a three-element vacuum tube operating with its grid at a positive potential and plate negative with respect to the filament. Electrons from the filament gain energy in their passage to the grid and so will cause ionization of those gas molecules with which they may collide. The resulting positive ions are collected at the plate and constitute the plate current. Since the probability for ionization is proportional to the molecular concentration of the gas, the plate current represents a measure of the pressure.

Ionization gauges, like the thermocouple or Pirani gauges are not absolute, but must be calibrated by comparison with a McLeod gauge.

A number of other gauges have been developed for measuring low pressure, but few if any of them have ever proved practical in industrial applications. There is considerable room for improvement in apparatus for measuring low pressures, since none of the gauges now in use are wholly satisfactory.

## 7.2. Pressure Testing Techniques

Pressure testing for tightness has been applied to vessels in both vacuum and pressure service for many years. Therefore, this section of the report will merely indicate the various methods briefly and discuss their applicability to testing process equipment for high vacuum service. Table V indicates the various methods in general use and indicates the smallest leak that may be detected practically. Extremely careful application of the method will perhaps decrease the quoted figure two- to fivefold.

TABLE V. Pressure testing techniques.

| Test medium | Probe | Response | Leak size at 45 psig, mcfh | Special requirements |
|---|---|---|---|---|
| Air-nitrogen | Flame | Wavering | 5000 | Draft free room. |
| | Sound | Hissing | 5000 | Low noise level. |
| | Soap film | Bubbles | 5 | Each area to be observed under good light for at least five minutes and soap film maintained. |
| | Immersion | Bubbles | 20 | Five to fifteen minutes observation—occluded air on surface must be avoided. |
| Organic halide | Halide torch | Flame color change | 5 | |
| Acidic gas—($CO_2$ or $SO_2$) | Ammonia | Fumes | 5 | |
| Ammonia | $CO_2$; HCl | Fumes | 5 | |
| Liquid under high pressure | | Wet exterior surface | 500 | |

These techniques are used only to locate leaks and do not permit any measure of the amount of leakage to be made. Application of pressure drop measurements are not, in general, suitable to checking the tightness of systems for vacuum service, the permissible drop being beyond the limits of accuracy of the best commercial gauges generally available. This drop for diffusion plant standards would be less than 0.001 lb./sq. in./hr. and corresponds to a temperature change of about 0.005°F. The uncertainty of the temperature correction further invalidates this method for measurement of the vacuum tightness of process vacuum equipment.

After all leaks are thought to have been found, the equipment under test must be evacuated and the rate of pressure rise observed. Consideration of the gas laws reveals that the temperature correction in the absolute pressure range of 1–100 micron is negligible. Vacuum gauges can readily measure the pressure changes required for tightness. However, a serious drawback is the effect of outgassing on the observed leak rate. The subject is more completely discussed in Appendix 7.3.

Other practical drawbacks to the use of pressure testing techniques are (1) the requirement that the system be depressured before repairs are attempted; (2) inability to check hidden leaks (leaks that are not visible on the exterior to the system) such as valve seats and heat exchanger tubes.

### 7.3. Vacuum Testing Techniques Prior to 1943

Many devices used in vacuum practice will not stand internal over-pressures high enough to make pressure testing practical; therefore the use of vacuum testing techniques became necessary in the laboratories and specialty shops dealing with high vacuum equipment. These methods were considered usable only by specialists, and were not considered applicable to commercial process equipment before the inception of the testing program described in this report. The earliest form of vacuum testing was on all glass systems. After evacuation of the system was begun, the discharge of a Tesla coil was played over the glass surface. A leak would show up as a bright spot or "pip." Experienced operators could detect leaks on metal parts of the system by observing the color change of the discharge when the leaks were sprayed with water or acetone. However, considerable uncertainty was attached to this technique, and one often resorted to "painting" the metal system with a vacuum wax, or lacquer, on a wiped layer of solder or lead.

Perhaps the first large scale vacuum testing of metal systems was done by research groups working with cyclotrons and similar equipment used in nuclear research. In general, those methods depend upon the effect on a hot wire gauge of the change of composition of the gas in the system when the probe fluid displaced the air flowing through the leak. Precautions were taken to insure electrical stability and sensitivity of the measuring circuits and mechanical stability of the gauges used. Probe fluids were carefully chosen to insure maximum effect on the gauge. Thus the ideal probe fluid had low viscosity and either high or low thermal conductance compared to air.

When tightness requirements became more severe, the hot wire gauge was replaced with an ion gauge, since the tightness was sufficient to permit the evacuating pumps to reduce the pressure below the operating maximum of this gauge (<0.5 micron). Hydrogen gas or a gaseous hydrocarbon was most generally used for the probe fluid, although good results were reported for other fluids. Ease of ionization of the probe molecules is a determining factor in the choice of the probe fluid, since the ionization produced by electron bombardment is proportional both to the concentration of the gas in the gauge and to the character of the gas.

To obtain the ultimate sensitivity of these methods the dynamic method was discarded and one of the following methods adopted: (1) the "backing space" technique, or (2) the apparent change in rate of pressure build-up when probe gas displaces air flowing through the leak. Both methods achieve the improved sensitivity at the expense of an increase in testing time.

Backing space is the name given to the process of multiplying the effect of the probe gas by permitting the diffusion pump to compress the gas into a dead volume. This is achieved by shutting the valve in the foreline leading to the mechanical pump. The method further requires judgment in the analysis of the signal indicated on the gauge controls. The caliber of the personnel required to assure foolproof operation is quite

TABLE VI. Resumé of vacuum testing methods in use prior to 1943.

| Leak detector | Operating range, microns | Size of leak discernible, mcfh | Commonly used probes | Remarks |
|---|---|---|---|---|
| Tesla coil | 50–1000 | | Tesla coil | Can be used only on glass systems. |
| Discharge tube | 100–1000 | | Acetone; Methanol; $CO_2$; $H_2$ | Residual gases confusing. |
| Hot wire gauge | Less than 100 | 10–1000 | Acetone; Methanol; $H_2$ | Affected by pressure changes and residual vapors. |
| Ionization gauge | Less than 0.5 | 1–100 | Gaseous hydrocarbons; $H_2$; $O_2$ | Affected by pressure changes and residual vapors. |
| Hot wire with backing space | Less than 100 | 50–100 | Gaseous hydrocarbons; $CO_2$; $H_2$ | Time-consuming since method is discontinuous. |
| Ionization gauge with backing space | Less than 0.5 | 1–100 | Gaseous hydrocarbons; $CO_2$; $H_2$ | Time-consuming since method is discontinuous. |
| Hot wire with pressure build-up | Less than 50 | 1–100 | Gaseous hydrocarbons; $H_2$; $CO_2$; masking with vacuum putty | Extensive outgassing required. |
| Ionization gauge with pressure build-up | Less than 0.5 | 1–100 | Gaseous hydrocarbons; $H_2$; $CO_2$; masking with vacuum putty | Extensive outgassing required. |

high—this method having been reported by groups using only post-collegiate personnel.

Analysis of the apparent change in pressure build-up caused by the introduction of probe gas is very time consuming, requiring that a careful schedule for probing be adhered to, and a subsequent analysis of the time-pressure graph in conjunction with this schedule be made. A further drawback of the technique is the entirely nonproductive testing time spent reducing the outgassing of the system under test. This period varies between 8 to 48 hours per unit depending on the volume and area of outgassing surface involved.

Having found all possible leaks, a measure of tightness is taken in the following manner. The equipment under test is valved off from the evacuating pump and the pressure rise of the system observed. Evacuation of the equipment during the leak hunting period in general has reduced the outgassing sufficiently so that the pressure rise is an approximately true measure of the inleakage. Outgassing may be detected on the pressure-time graph of the leak rate by a pronounced change of slope. The true leak is generally taken after this change of slope has been noted. The rate thus measured does not differ appreciably from the rate of the same system after it has been completely outgassed.

Outgassing is a complex and unpredictable effect, as the gas contributing to the effect may be adsorbed, absorbed in solid or liquid solution, evaporated from a liquid, or the product of chemical decomposition.

A resumé of vacuum testing methods prior to 1943 is presented in Table VI.

### 7.4. Relation between the Volume Pumped, Pumping Speed, and the Response to the Probe

Assumed that $L$ standard cubic feet per minute are leaking into a volume of $V$ cubic feet which is being pumped at a rate of $S$ cubic feet per minute at the total pressure existing in $V$.

Then, if at time $t=0$ probing of the leak is initiated, the volume $V$ will:

(1) Gain: $Ldt$ (standard cubic feet of probe gas per differential of time $dt$).

(2) Lose: $pSdt$ (standard cubic feet of probe gas per differential of time $dt$) where $p$ is the partial pressure of probe gas, expressed in atmospheres, in $V$.

The net gain of probe gas in volume $V$ is:

$$d(pV)=(L-pS)dt,$$

or

$$V\frac{dp}{dt}=(L-pS).$$

Integration of this differential equation gives the partial pressure of the probe gas in the volume and accordingly the partial pressure, $p_t$, of the probe gas in the stream passing the leak detector at any time $t$ after probing of the leak has begun:

$$p_t=\frac{L}{S}[1-\exp(-St/V)].$$

If, at time $T$, the probing is discontinued, a similar analysis will show that the partial pressure of the probe gas remaining in the system will be given by the equation:

$$p_T=\frac{L}{S}[1-\exp(-ST/V)]\exp[-S(t-T)/V].$$

In Fig. 2 the response and clean-up to a probe applied to a leak into a volume of forty cubic feet for a period of one second is shown. The response is expressed in terms of percent of the equilibrium response which is given by the equation:

$$p_\infty=L/S.$$

# The Magnetic Electron Microscope Objective: Contour Phenomena and the Attainment of High Resolving Power

JAMES HILLIER AND E. G. RAMBERG
*RCA Laboratories, Princeton, New Jersey*

(Received September 3, 1946)

A theoretical and experimental investigation of contour phenomena observed in electron microscope images near focus has been carried out. An explanation for the apparent reversal of the Fresnel fringes at exact focus is given and a method is described for the determination of the degree of asymmetry from the fringe patterns. A procedure for empirically correcting the asymmetries usually present in magnetic electron microscope objectives is outlined and some of the results obtained with a compensated lens are shown. A number of instrumental defects which may prevent the attainment of the ultimate resolving power of an instrument, together with methods for their elimination, are listed.

## I. INTRODUCTION

IN a recent paper[1] it was pointed out that investigations made on the pole-piece system of the objective lens in a magnetic electron microscope operating under optimum instrumental conditions indicated that the practical limit of resolving power of this instrument had been imposed in the past by asymmetries in the lens field. The work also indicated that it may be possible to attain, in practice, the theoretical limit of the existing lenses if those asymmetries could be completely removed.

The present paper is intended as a more complete report on those studies and on others, made subsequently, which have led to a better understanding of the magnetic electron microscope objective, to quantitative methods of testing the quality of a given pole-piece system, and to a method of empirically compensating for the asymmetries in the imaging system of a magnetic electron microscope.

The work has indicated that the larger magnetic electron microscopes in use in this country are inherently capable of resolving powers of the order of 10A when provided with objective lenses of sufficiently high quality. Furthermore, the attainment of such a high level of performance appears to present a parallel to the attainment of the limiting resolving power in the light microscope in that it depends on the skill and experience of the individual microscopist as much as on the availability of particularly good lenses and other equipment. In fact, as will be seen from the following, the methods by which this performance has been achieved in this laboratory

---

[1] J. Hillier, "Further improvement in the resolving power of the electron microscope," J. App. Phys. 17, 307–309 (1946).

are, for the present at least, not dependent on any commercial development and can be repeated in any electron microscope laboratory possessing normal facilities. Because of this, it is the further intention of the authors to present, in as detailed form as possible, procedures and precautions which must be observed in order to achieve the maximum attainable resolving power.

After the instrument used in this laboratory[2] had been "tuned up" to the point where no instrumental defects other than those inherent in the lenses were limiting the performance, at least at the 20A level, it was realized that asymmetries in the field of the objective were the most important cause of the remaining defects in the image and that the appearance of the image contours in the best-focused images was the most sensitive test of these asymmetries. Owing to the refractive effects in a transparent membrane, as discussed below, there is an apparent reversal of the Fresnel fringes as the power of the objective is varied through the focal value. In the best-focused images produced by a lens which is not symmetrical, that is, a lens for which the focal length is not independent of the azimuth of the meridional plane in which any particular paraxial ray is traveling, the reversal in the Fresnel fringes produces a characteristic type of asymmetry which is shown in Fig. 1. This is a high magnification image of an opening in a thin collodion membrane. Here, in one direction (vertical) the contours are those obtained when the power of the objective is less than the focal value, while the contours in the other direction (horizontal) are those obtained when the power of the objective is greater than the focal value. In Figs. 2 and 3, which are images of the same field as in Fig. 1, taken with the same lens, but with objective powers, respectively, much less and much greater than the focal value, the image asymmetries are no longer visible. In practice, the range of the objective current over which the image asymmetries are detectable provides a quantitative measure of the degree of asymmetry existing in the lens. As a further check it is

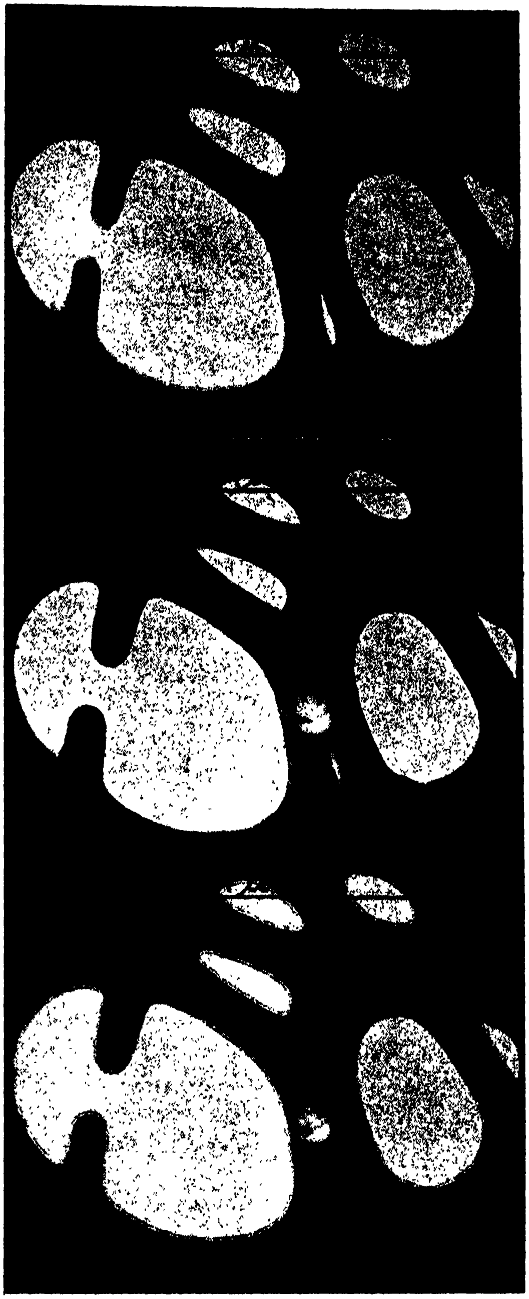

FIG. 1 (upper). Focused image of holes in collodion membrane obtained with asymmetrical objective. Vertical edges show fringes characteristic of under-focused image. See Fig. 2. Horizontal edges show fringes characteristic of overfocused image. See Fig. 3.

FIG. 2 (middle). Underfocused image (focal length too long) obtained with the same objective.

FIG. 3 (lower). Overfocused image (focal length too short) obtained with same objective.

---

[2] An RCA EMU electron microscope using the saturated emission type electron gun and fitted with a telescopic image viewing device (reference 1). With the exception of these differences and those introduced later as a result of the present work, the instrument is a standard commercial model.

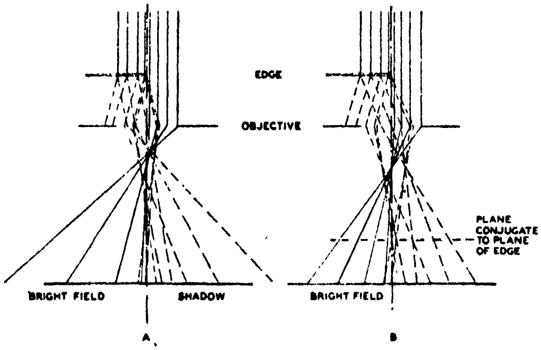

FIG. 4. The imaging of an edge by a parallel beam of electrons: A. Effect of spherical (or chromatic) aberration; B. Effect of defocusing.

possible to estimate the variation of focal length with the azimuth of the meridional plane from a photometric study of the asymmetries in the contours as described below. While important in the academic study of contour phenomena, this latter technique is cumbersome in practice and was not used in the actual compensation of the lenses.

## II. THEORY OF CONTOUR PHENOMENA FOR SMALL ANGLE OF ILLUMINATION

At the edge of an object projecting into space or of a hole in a film the electron intensity distribution in the image ceases to bear a simple relation to the scattering power of the object. Fringe systems are observed whose intensity distribution depends both on the focusing of the objective lens and the condition of illumination. It will here be assumed that a straight edge intersecting the optic axis of the electron microscope at right angles is being observed and that the object is illuminated by a parallel beam of electrons.

Disregarding, to begin with, diffraction phenomena, it is seen that all the electrons passing through the unobstructed part of the object plane fall on the corresponding half-plane of the image, forming there a near-uniform intensity distribution, regardless of the condition of focus and the optical quality of the objective (Fig. 4). The electrons passing through the material portion of the object will be scattered to some extent, so that, except for the position of perfect focus of a perfect lens, a fraction of the electrons leaving the material portion of the object near the edge will fall on the bright half-plane of the image. Thus, for parallel illumination and with diffraction phenomena disregarded, spherical aberration, chromatic aberration, and defocusing all give rise to the same type of contour phenomenon—a bright fringe on the bright side of the edge and a dark fringe, antisymmetric to the bright fringe, on the dark side of the edge (Fig. 5).

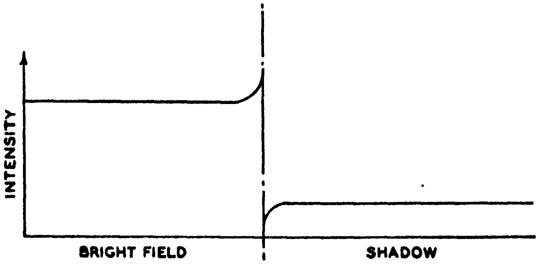

FIG. 5. Intensity distribution at the image of an edge illuminated by a parallel beam, neglecting diffraction effects.

The contour fringes normally observed with small angle of illumination are much more complex than this. This complexity must be ascribed primarily to Fresnel diffraction at the edge. The intensity distribution on a screen placed a distance $l$ behind an opaque object illuminated by a parallel beam of light is shown in Fig. 6. It may be regarded as the result of interference between the unobstructed plane wave, cut off sharply at the geometrical shadow of the edge,

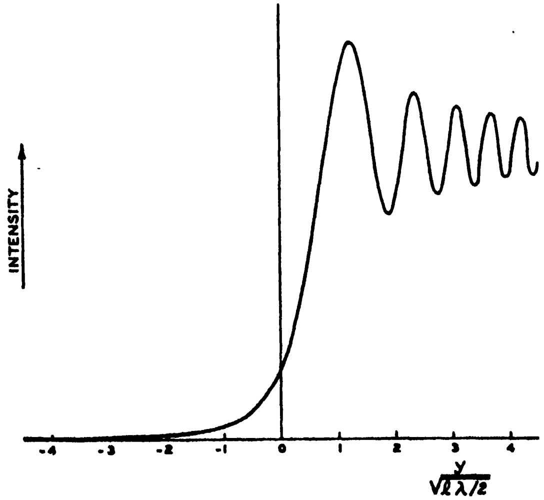

FIG. 6. Intensity distribution behind the edge of an opaque screen illuminated by a plane wave.

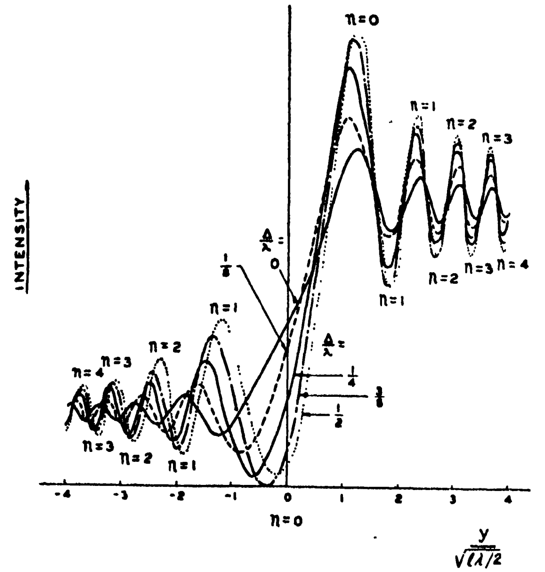

FIG. 7. Intensity distribution behind the edge of a screen transmitting a quarter of the incident radiation with a phase delay $2\pi\Delta/\lambda$ (real pattern).

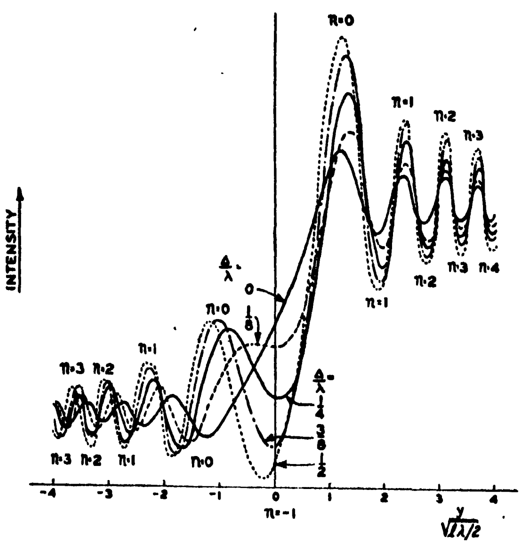

FIG. 8. Virtual intensity distribution ahead of the edge of a screen transmitting a quarter of the incident radiation with a phase delay $2\pi\Delta/\lambda$.

and a cylindrical wave diverging from the edge.[3] The intensity of the edge wave is a maximum in a forward direction and drops off laterally. Its phase is retarded by $\frac{1}{8}$ cycle with respect to the plane wave in the shadow of the edge, advanced by $\frac{3}{8}$ cycle in the bright region; at the shadow of the edge (where this representation ceases to be valid) a phase reversal takes place. In view of these relationships the maxima and minima of the diffraction pattern in the bright part of the field are located at a distance from the shadow of the edge given by

$$y_{\max} = (2l\lambda[n+\tfrac{3}{8}])^{\frac{1}{2}}, \quad y_{\min} = (2l\lambda[n-\tfrac{1}{8}])^{\frac{1}{2}}, \qquad n = 0, 1, 2, 3, \cdots. \tag{1}$$

Here $\lambda$ represents the wave-length of the radiation employed. In the shadow the intensity falls off uniformly.

If a plane ahead of the edge is imaged on a screen by a perfect lens, an identical pattern is observed, though now the fringes result from the interference of the shadow portion of the edge wave with the direct wave. Since the wave advances in phase by a quarter cycle in passing through a line focus[4] the phase of the virtual wave continued backwards from the shadow portion of the edge wave is retarded by $\frac{3}{8}$ cycle with respect to the plane wave. Furthermore, the sign of the path differences for the two interfering waves is reversed in the virtual pattern, so that its maxima and minima have the same location relative to the shadow of the edge (continued backwards) as the maxima and minima of the real pattern. Mathematically, if the amplitude of the wave is given in complex notation, the amplitude in the virtual field ahead of the edge becomes simply the complex conjugate of the amplitude in the real field, an equal distance behind the edge.

If the screen transmits a given fraction $p^2$ of the incident radiation without destroying its coherence or modifying its phase, the expected pattern may be obtained from a superposition of the amplitudes for two plane waves of equal phase differing in initial amplitude by the factor $p$ and incident on complementary opaque screens. Again the expected intensity distribution in a real plane behind the edge and the virtual distribution in a plane at the same distance ahead

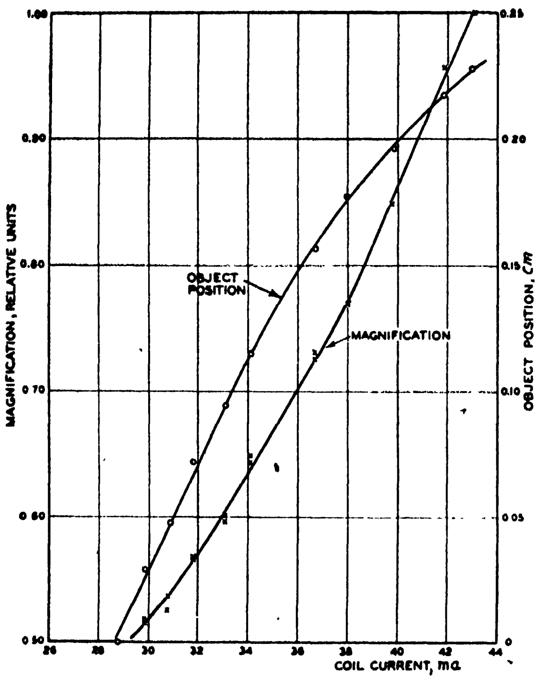

FIG. 9. Measured variation of object position and magnification as function of objective coil current.

of the edge are identical (Figs. 7 and 8, curves for $\Delta/\lambda=0$). It should be noted that in the real pattern the fringe system in the shadow region results from the interference of the wave transmitted through the object with the shadow portion of the edge wave, while in the virtual pattern this fringe system results from interference of the transmitted wave with the part of the edge wave scattered into the bright field.

If the screen with the transmission factor $p^2$ introduces a phase delay in the transmitted wave, the real and virtual diffraction patterns cease to be identical. Let, e.g., the difference in the index of refraction of the screen material and that of surrounding space be $\delta n$ and the thickness of the screen be $t$; then the optical path difference between the wave passing through the screen and that passing through the clear space outside of the screen is $\Delta=t\delta n$. Thus, the phase delay introduced by the screen becomes $2\pi\Delta/\lambda=2\pi t\delta n/\lambda$. The intensity distribution in the diffraction pattern may now be obtained from a superposition of the amplitudes for two plane waves differing in initial amplitude not by $p$, but by the complex quantity $pe^{2\pi i\Delta/\lambda}$, incident on complementary opaque screens. This intensity distribution was calculated, both for the real and for the virtual pattern, for $p=0.5$ and $\Delta/\lambda=\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{8}$, and $\frac{1}{2}$. The results of the calculations are shown in Figs. 7 and 8. For $\frac{1}{2}<\Delta/\lambda<1$ the real and virtual patterns are identical with the virtual and real patterns, respectively, for $1-\Delta/\lambda$, so that, in effect, the curves in these two figures represent all possible intensity distributions for phase delays which are integer multiples of $\lambda/8$.

The results of the calculations may be summarized as follows:

1. A phase delay enhances the prominence of the diffraction fringes; it becomes greatest for $\Delta/\lambda\rightarrow\frac{1}{2}$.
2. In the range $0<\Delta/\lambda<\frac{1}{2}$ the real pattern contracts to an increasing extent. If the fringes are counted off in the same manner as for the opaque screen (Eq. (1)), the fringes of high order number on the shadow side are displaced, for $\Delta/\lambda=\frac{1}{2}$, by half a fringe toward the edge; on the bright side they are not displaced.
3. For $\frac{1}{8}\leqslant\Delta/\lambda<\frac{1}{2}$ the virtual patterns possess an added minimum and maximum, which may properly be designated as the minimum of order $-1$ and the maximum of order 0 on the shadow side. The high order fringes on the shadow side are displaced a fraction of a fringe away from the edge.

## III. OBSERVED CONTOURS

Contour fringes in out-of-focus electron microscope pictures have been observed and interpreted as Fresnel diffraction fringes by a number

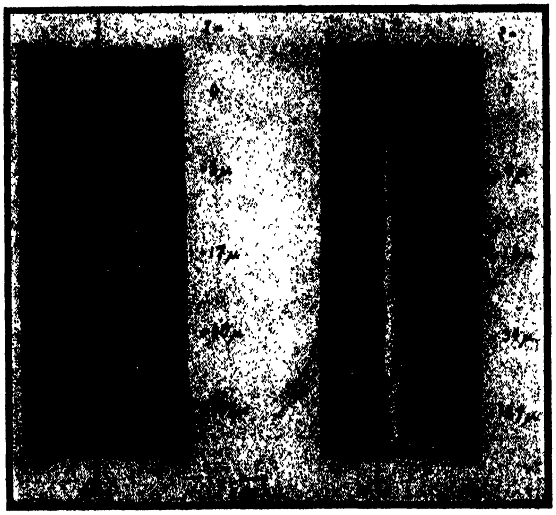

FIG. 10. Electron micrographs of the edge of a collodion film for various degrees of defocusing. The amount of defocusing is given to the right of edge section. Positive and negative values are for over and underfocused images, respectively. The true position of the edge is marked. Compare with Figs. 2 and 3.

of authors.[5-7] Boersch,[7] who made a particularly careful study of the phenomenon, noted that the fringes in the bright field were much more marked in the virtual pattern (objective lens too weak) than in the real pattern (objective lens too strong). He interpreted this as signifying that the shadow portion of the edge wave is much stronger than the edge wave scattered into the bright field. He had reached the same conclusion before from dark field observations.[8] These showed that object edges facing the direction of illumination appeared less bright than the edges remote from the source.

The observations to be presented here were made largely in the hope of shedding more light on the behavior of the fringes near focus. A collodion film with a number of holes of the order of 1 micron in diameter served as object. The illuminating cone was slightly elliptical and had maximum and minimum half-angles of 6 and $4\cdot 10^{-5}$ radian, respectively. These were calculated from the observed image of the effective source, the condenser current, and the geometrical dimensions of the electron microscope which was employed. The variation in position of the object plane of sharp focus with the objective lens current was determined by displacing the object by measured amounts and reading the currents required to bring the image into sharp focus (Fig. 9). It should be mentioned that hysteresis effects in the lens pole pieces cause a variation in the relation between the object displacement and the lens current, so that possibly more accurate estimates of the former may be obtained from the observed diffraction pattern as indicated below. The object displacements as determined by the two methods differed randomly by 10 to 20 percent. The geometrical position of the edge relative to the pattern could be determined roughly, at large deviations from focus, by measuring the magnification of the plate and comparing the known diameter of the hole obtained at focus with the diameters of specific fringes about the hole edges. Results so obtained agreed within experimental error with the edge positions inferred from a comparison of the observed diffraction pattern with that predicted theoretically.

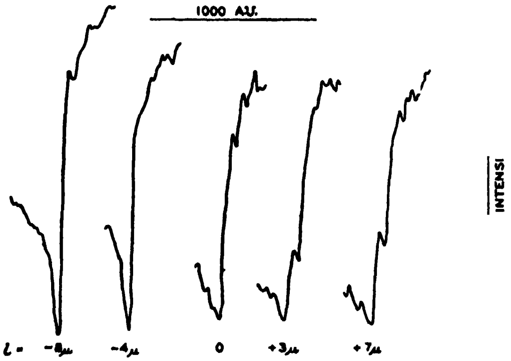

FIG. 11. Microphotometer traces of micrographs of edge taken near focus.

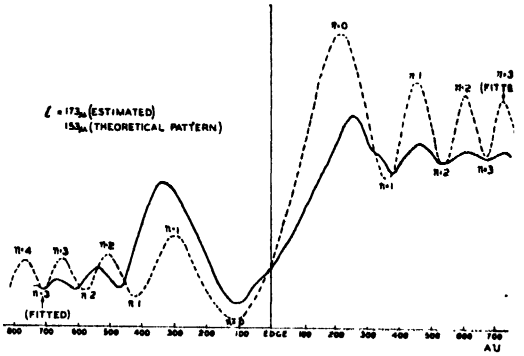

FIG. 12. Comparison of microphotometer trace and Fresnel pattern for edge of screen transmitting a quarter of incident radiation with a quarter cycle phase delay (real pattern).

Figure 10 shows a series of fringe patterns observed for positive (real pattern) and negative (virtual pattern) values of the deviation from focus, as indicated next to the individual micrographs. A vertical line marks the position of the edge. Figure 11 reproduces some microphotometer traces across the pattern for the region close to focus. An inspection of the contour patterns reveals the following:

1. Patterns corresponding to numerically equal deviations from focus in the direction of too great lens currents (real pattern) and too small lens currents (virtual pattern) differ markedly.
2. Proceeding from what, rather arbitrarily, will be

referred to as the condition of sharp focus ($l=0$ in Figs. 10 and 11) toward smaller lens currents, an increasingly sharp bright fringe appears on the bright side of the edge, followed by a dark fringe on the dark side. As the lens current is decreased still further, these fringes gradually move apart and added maxima and minima are resolved outside of either.

3. Proceeding from the point of sharp focus to higher lens currents, there appear at the edge a dark fringe and a bright fringe, the bright fringe lying on the shadow side of the dark fringe. These increase rapidly in prominence. Eventually fringe systems become visible outside of these primary fringes, as in the case of too low lens currents. It should be noted that the fringes in the shadow of the edge are much more prominent than in the case of too low lens currents. This is in accord with Boersch's observation that the amplitude of the part of the edge wave scattered into the shadow is greater than that of the part scattered into the bright field. For too high currents (real pattern) the shadow fringes are produced by interference between the transmitted wave and the shadow portion of the edge wave, for too weak lens current (virtual pattern), by interference between the transmitted wave and the portion of the edge wave scattered into the bright field.

## IV. COMPARISON OF OBSERVATIONS AND THEORY

The presence of diffraction fringes in the shadow of the collodion film indicates that the latter has not introduced large *random* phase variations in the electron wave transmitted by it. On the other hand, a comparison of the microphotometer traces of the fringe systems for large deviations from focus with the curves in Figs. 7 and 8 indicates that a satisfactory agreement between the positions of the maxima and minima in the observed and theoretical patterns can only be obtained if the wave passing through the film is assumed to experience a phase delay. The curves for $\Delta/\lambda=\frac{1}{4}$ resemble the observed patterns most closely. Since $\Delta=t\delta n$ and $\delta n=\delta V/(2V)$, where $t$ is the thickness of the film, $\delta V$ the difference in the mean potential within the film and that outside of it, and $V$ is the accelerating voltage of the electron beam, this leads, for $\delta V=10$ volts and $V=50{,}000$ volts, to the perfectly reasonable value for the film thickness, $t=134$A.

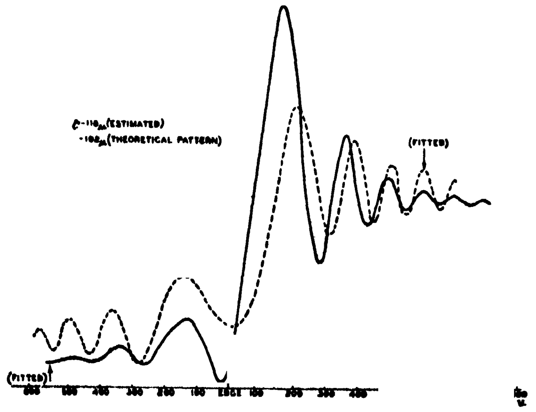

FIG. 13. Comparison of microphotometer trace and Fresnel pattern for edge of screen transmitting a quarter of incident radiation with a quarter cycle phase delay (virtual pattern).

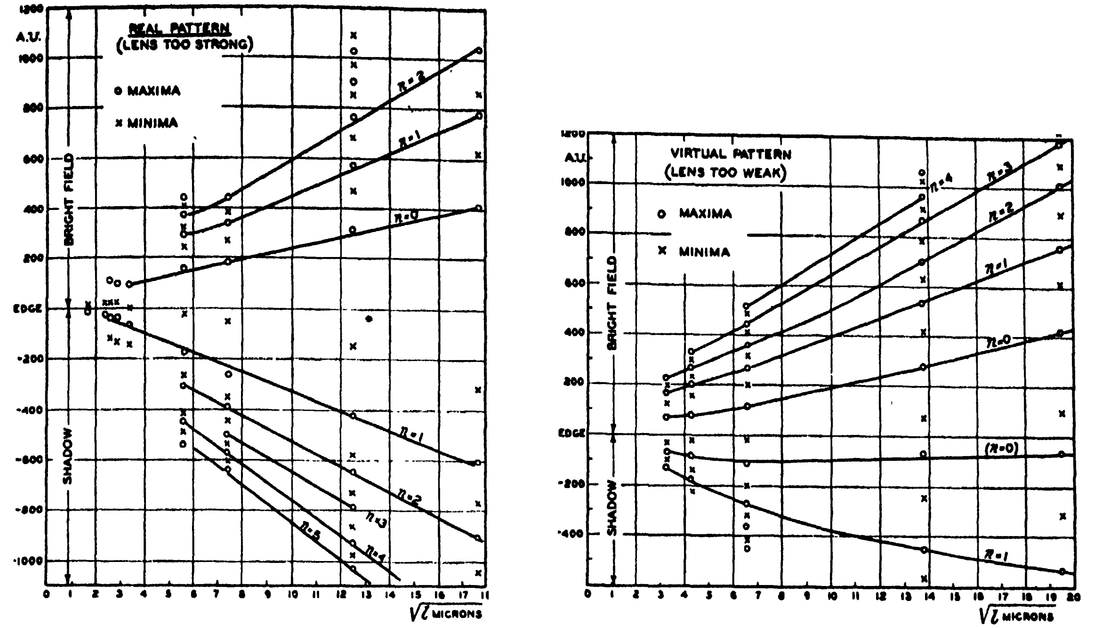
Figure 12 shows a smoothed microphotometer trace of the contour pattern for a deviation, estimated from the lens currents used, equal to 173 microns (lens too strong). In addition, the theoretical curve for $p=0.5$ and $\Delta/\lambda=\frac{1}{4}$ has been plotted as a broken line, adjusting the value of $l$ ($=153$ microns) and the position of the edge so that the maxima $n=3$ on the bright side and the minima $n=3$ on the shadow side of the observed and theoretical curves, respectively, are brought to coincidence. It should be stressed that these curves are comparable only with regard to the positions of the maxima and minima, not to their relative intensities. This is so for the following reasons:

1. The theory here presented does not account for the greater intensity of the shadow portion of the edge wave as compared with the bright-field portion; this appears as a peculiarity of the Fresnel diffraction of electrons by material screens.
2. The finite illuminating aperture employed must lead to a more rapid flattening out of the maxima and minima with increasing order number in the observed curves.
3. The photometer traces shown are simple density plots, no attempt having been made to correct for the nonlinear relation between exposure and density of the photographic material employed.

Figure 13 compares the photometer trace obtained for a virtual pattern (lens too weak; estimated deviation from focus, $-118$ microns) with the theoretical curve for $p=0.5$, $\Delta/\lambda=\frac{1}{4}$. The fitting points were in this case the maximum $n=3$ on the bright side and the minimum $n=2$ in the shadow, the theoretical value of $l$ required to obtain the fit being $-102$ micron.

For both the real and the virtual patterns the correspondence in the positions of the maxima and minima of the observed and theoretical curves, as well as the agreement between the



A. B.

FIG. 14. Variation of distance of maxima and minima from edge with square root of estimated distance between edge and focal plane. A. Real pattern. B. Virtual pattern.

estimated and the theoretical values of the deviations from focus, are close enough to render the interpretation of the observed contour fringes as Fresnel diffraction fringes quite definite.

## V. BEHAVIOR OF THE CONTOURS NEAR FOCUS

If the positions of the maxima and minima relative to the shadow of the edge are plotted against the square root of the separation between the plane of the edge and the plane in which the pattern is observed, these plotted points should fall along straight lines. In practice, deviations are observed, which must in part be ascribed to inaccurate estimates of the distance between the plane of the edge and the plane of focus, as well as to the uncertainty in establishing the position of the geometrical shadow of the edge in the image (Fig. 14). For too large currents the first maximum ($n=1$) and the first minimum ($n=0$) in the shadow can be followed down to the smallest deviations from focus (Fig. 15). Their separation can conveniently be employed as a measure of deviation from focus. Figure 15 shows that these separations are generally slightly larger than the theoretical value for a normal Fresnel pattern, even with a phase delay $\Delta/\lambda = \frac{1}{4}$. For too small currents the maximum $n=0$ in the bright field and the "extra" minimum ($n=-1$) in the shadow are seen farthest. The separation of these two points (Fig. 16) also increases systematically with the deviation from focus, though only relatively slowly.

## VI. IMAGE ASYMMETRIES AND THEIR ORIGIN

### 1. Asymmetries in Electron Micrographs

Contours of the type described above are observed quite generally in electron micrographs; in particular, the character of the fringes nearest the edge is only slightly influenced by the aperture of illumination within the range commonly employed in electron microscopy: The outlying fringes melt into the background as the aperture is increased. Micrographs obtained with an objective lens having some degree of asymmetry will show differences in the fringe patterns surrounding differently oriented edges. These differences are accentuated when the object is focused very carefully (Fig. 1). It will then occur that one edge of a particular object will exhibit the

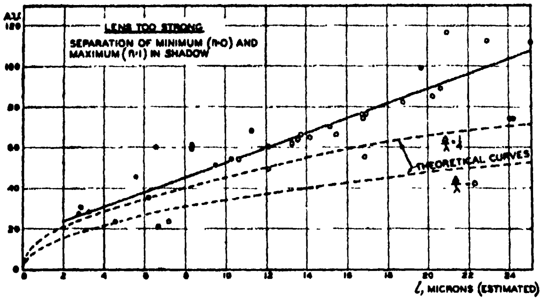


FIG. 15. Separation of first maximum and first minimum in the shadow as function of focal deviation (real pattern—lens too strong).

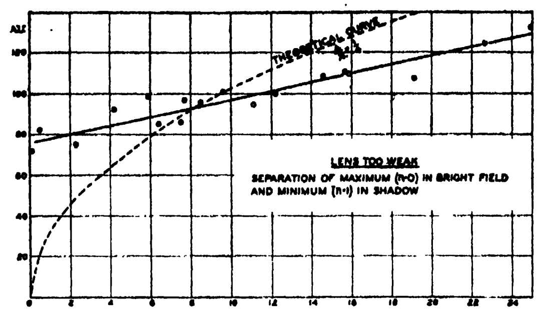

FIG. 16. Separation of first maximum on bright side and first minimum in shadow as function of focal deviation (virtual pattern—lens too weak).

characteristic virtual pattern, corresponding to too low focusing current, while an edge at right angles thereto will appear definitely overfocused. This indicates that the imaging pencils are astigmatic. The degree of astigmatism, i.e., the maximum deviation in focus for two mutually perpendicular directions, can be determined with the aid of the curves in Figs. 15 and 16. The deviation in focus for Fig. 1 may thus be estimated to be 4 microns. Two factors may give rise to asymmetries of the type described: A deviation from axial symmetry of the lens field and a misalignment of the objective.

## 2. Effect of Pole-Piece Ellipticity

Deviations from axial symmetry in the field of a magnetic pole-piece lens may be caused either by imperfections in machining or defects of the magnetic material in the form of inhomogeneity of susceptibility and the presence of blow holes or occlusions. Of these several factors an ellipticity of the pole-piece openings, introduced by imperfect machining, most readily admits of analytical treatment. On the basis of such a treatment it is possible to establish manufacturing tolerances in harmony with a prescribed maximum amount of astigmatism in the image.

The effect on the ray paths of deforming a permanent-magnet ring producing the lens field into an ellipse is derived in Appendix I. The permanent-magnet ring, for which the axial field distribution is shown in Fig. 17, was chosen in preference to the pole-piece lenses usually employed for reasons of ease of calculation. There can be little doubt that the qualitative conclusions—and the quantitative conclusions as far as order of magnitude is concerned—are directly applicable to the types of lenses normally used as electron microscope objectives.

The results of this study, for three objectives of the same focal length, but of varying width of the field distribution (different values of the

$H$ = magnetic field
$\Phi$ = accelerating voltage of electrons
$f$ = focal length of lens
$a$ = radius of permanent-magnet ring
$s_F$ = distance of focal point from center of lens
$\Delta z_F$ = longitudinal separation of point of closest approach to axis for deformed lens from focal point of undeformed lens

$d.c.a.$ = distance of closest approach to axis for aperture angle $\alpha = 5\cdot 10^{-3}$ radian
$\chi_a$ = total image rotation
$\Delta\varphi$ = difference in azimuth of parallel ray in image space leading to maximum value of $\Delta z_F$ (weakest lens action) and of the major axis of the ellipse
$\epsilon$ = eccentricity of the ellipse: $\epsilon^2 \cong 2(a-b)/a$, where $a$ is the major and $b$ is the minor axis of the ellipse

radius of the magnetic ring), are summarized in Fig. 18 and Table I. A ray which is parallel to the axis in image space will intersect the axis in object space for only four specific values of the azimuthal angle $\varphi$, measured relative to the meridional plane containing the long axis of the ellipse. For all other values there will exist a distance of closest approach ($d.c.a.$) to the axis, at a point a distance $\Delta z_F$ from the focal point of the undeformed lens (Fig. 19). The ratio of $\Delta z_F$ to the focal length $f$ and the distance of closest approach are plotted as functions of the azimuthal angle in image space, $\varphi$, in Fig. 18. The results shown lead to the following conclusions:

1. An ellipticity of the pole-piece bore results in an astigmatism of the imaging pencils. The distance between the two points of sharpest focus (the focal lines) is proportional to the percentage difference between the two axes of the ellipse. For a focal length of 3 mm a difference in the two axes equal to 0.01 percent ($\epsilon^2 = 2\cdot 10^{-4}$) leads to a separation of the two focal lines of the order of one micron.
2. The ratio of the distance between focal lines and the focal length decreases as the ratio of lens thickness to focal length is increased. This may be ascribed to the fact that, as an imaging ray rotates in the field, the ray is acted upon both by portions of the field which are strengthened and such as are weakened by the deformation. The amount of the rotation is greater for a thick lens than for a thin lens.
3. For weak or short lenses edges in the image which, for proper adjustment of focus, may be made sharp, are parallel to the two axes of the ellipse (edges which appear sharp at the higher lens current are parallel to the minor axis). For strong or thick lenses the two orientations corresponding to the sharpest possible focus are shifted by a small angle with respect to the axes of the ellipse.
4. For weak or short lenses the astigmatic pencil has two focal lines, so that the apparent sharpness of object edges oriented parallel to these, duly refocused, is not reduced by the deformation. For stronger lenses the focal lines become flat ellipses. Under these circumstances—i.e., the presence of "anisotropic astigmatism"—the deformation results in some loss of sharpness throughout the image. The focal ellipses are sufficiently flat, however, that the diffusion of the edges parallel to their axes becomes negligible if the asymmetry in the image is not apparent.

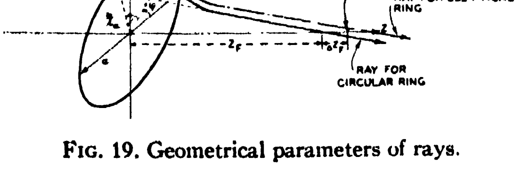

FIG. 19. Geometrical parameters of rays.

### 3. Effect of Misalignment of the Objective

Asymmetries in the image may also be introduced by a horizontal displacement of the objective relative to the projector or a tilt of the objective lens relative to the instrument axis. If $S_4$ is the aberration coefficient of astigmatism[9] for the objective, $M$ its magnification, and $f$ its focal length, the displacement of the two focal lines referred to the object becomes

$$\Delta z_{F\,\max} - \Delta z_{F\,\min} = 2(S_4/M)\cdot f\cdot (d/M)^2 \qquad (2)$$

for a displacement $d$ of the objective relative to the projector and

$$\Delta z_{F\,\max} - \Delta z_{F\,\min} = 2(S_4'/M)\cdot f^3\cdot \delta^2 \qquad (3)$$

for a tilt angle $\delta$ of the objective. The coefficient $S_4$ differs from the coefficient $S_4'$, since the first applies to a position of the effective limiting

---

[9] $S_4 r_0^2 r_a$ is the radius of the circle of confusion owing to astigmatism which forms the image of an object point a distance $r_0$ from the axis, imaged by a pencil whose cross-section radius in the aperture plane is $r_a$. See V. K. Zworykin, G. A. Morton, E. G. Ramberg, J. Hillier, and A. W. Vance, *Electron Optics and the Electron Microscope* (John Wiley and Sons, Inc., New York, 1945), pp. 551, 562, and 636.

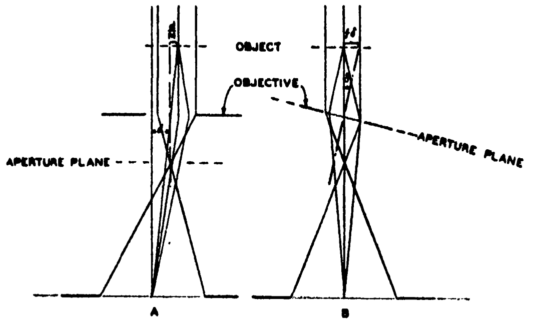

FIG. 20. Passage of imaging pencil through displaced objective (A) and through tilted objective (B).

aperture at the rear focal plane of the objective, the second to one at its nodal point (Fig. 20). To take only one example, the values of $S_4/M$ and $S_4'/M$ for a magnetic objective formed by two unsaturated equidiameter cylindrical pole pieces with a small separating gap are for $\Phi=50$ kv, $f=0.3$ cm, $H_{\max}=6270$ gauss, radius $a=0.575$ cm, which corresponds to a very thick, strong lens,

$$S_4/M=16\ \text{cm}^{-2};\quad S_4'/M=1.5\ \text{cm}^{-2}.$$

For a permissible difference in focus of 1 micron ($10^{-4}$ cm), the tolerance in the displacement $d$ and the tilt $\delta$ become

$$d=\pm 0.3\ \text{cm};\quad \delta=\pm 0.035\ \text{radian}=\pm 2.0°.$$

Both tolerances are seen to be quite large; the normal alignment procedure should render the effects of objective displacement negligible.

## VII. METHOD OF ELIMINATING ASYMMETRIES

When it was realized that the asymmetries in the magnetic field of the electron microscope objective were mainly responsible for the limitations on the resolving power it was assumed at first that these asymmetries were the result of mechanical inaccuracies—elliptical openings and misalignment of the openings of the pole pieces. To overcome these, a lapping technique was devised which insured the required precision of mechanical symmetry and alignment. As will be shown later, mechanical inaccuracies were actually only partially responsible for the asymmetries observed. However, a remarkable improvement[1] was obtained in most cases by the use of the lapping technique and for that reason a brief description is included.

The pole pieces used in these tests are standard objective lens pole pieces for the RCA EMU electron microscope—actually rejects from the commercial production—used *without* an objective aperture. They consist of two soft-iron sections bearing the active pole faces and openings and part of the magnetic circuit of the objective coil unit. The iron sections are threaded into a brass spacer which maintains the proper spacing and alignment through the provision of appropriate pilot surfaces. The cross section of these pole pieces is shown schematically in Fig. 21.

A conical brass lap with a 1°–2° taper was used for lapping the openings. The pole faces were lapped on a plate-glass surface, a large brass jig being used to hold the axis of the lower section accurately perpendicular to the plate. The two openings were lapped simultaneously with the pole pieces assembled in order to obtain accurate axial alignment as well as symmetry. It was necessary, of course, to disassemble the pole pieces in order to gain access to the pole faces for lapping or for cleaning. In order to avoid as much as possible differences in alignment of the two sections occurring as a result of the disassembling, fine scratches were made on the outside of the pole-piece assembly across the boundaries between the pole-piece sections and the brass spacer. Each time the pole pieces were assembled, great care was taken to clean the threads and pilot surfaces and to align the scratches accurately.

The procedure followed was to lap, alternately, lens openings with the lens assembled and faces, individually, with the same grade of grinding compound. A wet paste of 400-mesh carborundum was used for the initial lapping which was continued until all machining marks and other defects disappeared. Lapping was then continued with wet pastes of 600-mesh carborundum and 900-mesh alundum, lapping with the last two grades of grinding compound being continued until the effects of the preceding grade were removed and until there appeared to be a perfect fit between the brass lap and the pole-piece openings for all angular positions of the lap. Considerable care was taken to avoid exerting too much pressure with the lap as this was found to damage the critical edge between the pole-piece openings and the faces. When the grade of grinding compound was changed the pole pieces were very carefully washed to remove all traces of the coarser grade. After the lapping was completed with the 900-mesh alundum and if no imperfections were visible with the 10× eye lens, particularly in the regions near the critical edges, those regions of the pole-piece openings and faces were polished using a wet paste of jeweler's rouge on a round toothpick.

Pole pieces which were treated in this way invariably showed considerable improvement in performance and rather consistently gave limiting resolving powers in the range of 20–30A (Fig. 22). It was soon realized, however, that the asymmetries were seldom completely removed by this technique. Moreover, if considerable asymmetry existed after the first lapping, it was usually found that it persisted upon further lapping. In cases where the asymmetry was found to increase with further lapping, it could generally be shown to arise from defects in the magnetic material of the pole piece, in particular, blow holes or occlusions which occurred in the neighborhood of the critical edge and which would eventually be uncovered. These observations indicated rather conclusively that the asymmetries remaining after lapping were caused by various forms of imperfections in the magnetic properties of the pole-piece material.

Considerable effort was expended in an attempt to obtain ideal magnetic materials. Up to the present none has been found. In fact, the outcome of this work pointed to the empirical correction of the lens asymmetries as being more likely of success and less tedious in execution.

Asymmetries of the magnitude encountered in the uncorrected objective may be considered as a superposition of a cylindrical magnetic lens on an accurately axially symmetrical magnetic lens. The practical method of correction involves, therefore, the production of an additional superimposed cylindrical field which is of the proper strength and at right angles to the existing cylindrical component. There are many possible ways of accomplishing this. The device selected is illustrated in Fig. 23. It consists simply of eight soft-iron rods 0.070 inch in diameter threaded into the wall of the brass spacer (72 threads to the inch), perpendicular to the axis of the lens in the plane of the pole-piece gap and 45° apart. Figure 24 is a photograph of a pole piece with the compensating screws in place.

The procedure of compensation is as follows:

1. A focal sequence (Series 1) is obtained under the conditions to be described below with the rods adjusted so that they are approximately equidistant from the axis of the lens. The orientation and magnitude of the asymmetry is noted on the appropriate exposure (Fig. 25).
2. Any opposite two of the rods are moved as far as possible toward the axis and another focal sequence (Series 2) is obtained under conditions identical to those of Series 1. This operation puts in an extreme degree of asymmetry and permits a correlation to be made between the direction of the asymmetry in the image and the direction of adjustment of the rods in the lens (Fig. 26).
3. The pair of rods which must be moved toward the axis in order to correct for the asymmetry existing in Series 1 is then determined by a comparison of Series 1

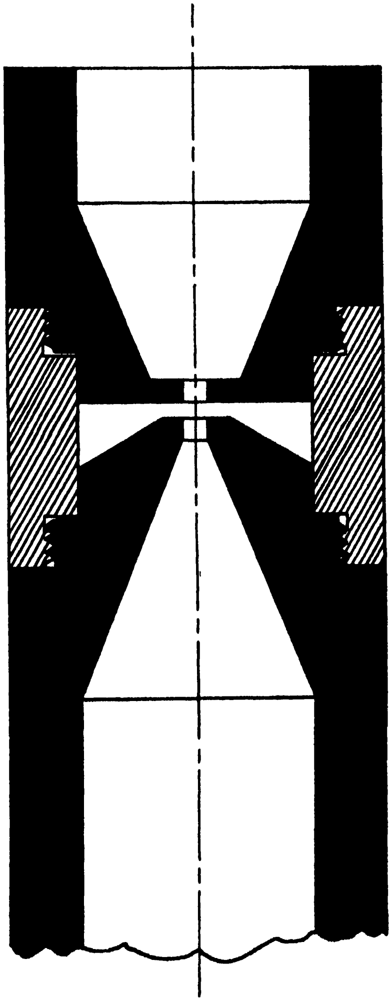

FIG. 21. Cross section of objective pole pieces.

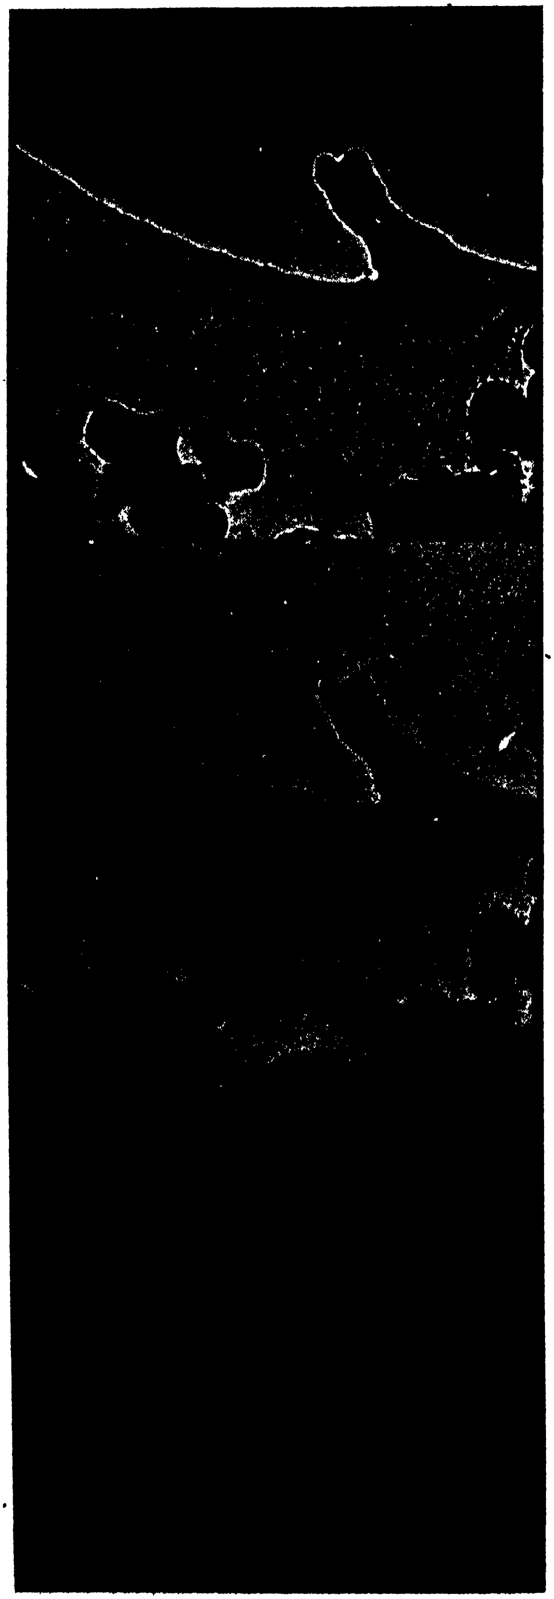

FIG. 22. A focal series obtained with a lapped lens, showing fairly complete elimination of asymmetries. The specimen is a very light evaporated film of gold on a carbon black in collodion mount. This series shows the rapid increase in the diameter of the images of small particles which occurs as the instrument is put out of focus.

and 2. The compensation is of course perpendicular to the pair of rods which would increase the asymmetry observed in Series 1.

4. Starting with the rods equidistant from the axis the two selected for the first correction are moved toward the axis and a third focal sequence (Series 3) is obtained. The direction and degree of asymmetry remaining is determined from the proper image (Fig. 27).

5. If the asymmetry is found to be decreased but has not changed direction the same two rods are moved closer to the axis and another focal sequence (Series 4) is obtained. As shown in Appendix II, the maximum correction attainable by moving any one pair of rods toward the axis is reached when the direction of the asymmetry in the image is rotated through an angle of 45° (Fig. 28).

6. With the rods used in the initial correction set at the point where the direction of the asymmetry has been rotated by an angle in the range of 30° to 45° from its original direction a new direction of correction is determined by comparison of the last series and Series 2. With the rods in the newly selected direction advanced slightly toward the axis another focal series is obtained (Series 5 -- Fig. 29).

7. Correction is continued in the newly selected direction until the direction of asymmetry again changes.

8. This systematic compensation of the asymmetries is continued until no detectable asymmetry exists in the images (Fig. 30).

In actual practice it is found that the asymmetry decreases very rapidly and a third direction of compensation is seldom necessary.

## VIII. INSTRUMENT ADJUSTMENT

In discussing the correction of a lens by the above method no mention has been made of the adjustment of the other components of the electron microscope employed. It is obvious that all the images used in the course of the correcting procedure must be obtained under identical electron-optical conditions. It has been found, furthermore, that the compensation obtained by the above technique is accurate for only *one* adjustment of the instrument. As would be expected, the method described corrects not only the asymmetries inherent in the lens, but also those introduced by stray fields from the other components of the instrument. The various phenomena encountered and the adjustments which must be carried out if the procedure is to give consistent results are listed below:

*1. Specimen.*—A suitable specimen must be used. Small holes in the collodion membrane or spherical carbon-black particles mounted without a supporting membrane have been satisfactory in this laboratory. *Crystalline materials are to be avoided* because of the artificial asymmetries sometimes introduced by different interactions of the electron beam with different faces of the crystals.

*2. Illumination.*—The angular aperture of the illumination should be kept as small as possible in order to obtain the sharpest possible definition in the contour fringes. In the present work the angular aperture of illumination was, in general, below $10^{-4}$ radian, though it might have been as much as an order of magnitude larger without seriously limiting the method. The illumination must arise from a single source.

*3. Lens Position.*—The objective pole-piece assembly must be replaced in exactly the same position in the objective lens coil structure each time it is put back after making an adjustment. This concerns only the angular orientation since the axial position is usually fixed by the structure of the lens.

*4. Specimen Position.*—It is obvious that an empirical method of compensating for lens field asymmetries arising as a result of imperfections in the magnetic properties of the material will be precise for only one condition of magnetization. This means that the specimen position and the accelerating potential of the electrons must be accurately reproduced both during the compensation of the lens and during subsequent high resolution work.

*5. Magnification.*—The preceding condition insures that the objective magnification be constant during its compensation and use. Because of the stray fields produced by the projection lens, and the dependence of the alignment on the power of the projection lens, it was found necessary to keep its magnification constant, preferably at its maximum value. The total instrumental magnification used in the present tests was 16,000× for the objective shown in Fig. 23 and 25,500× for the standard pole pieces used in subsequent tests.

*6. Excitation of the Objective Lens.*—External compensation in a magnetic lens field of asymmetries which are the result of irregularities in the susceptibility of the magnetic material requires, as already mentioned, that the same condition of magnetization be maintained during the compensation and use of the lens. The purpose of this particular section is to point out that the same condition of magnetization cannot be achieved unless the lens current is turned on in such a way as to insure that every region of the material of the pole pieces is at the same point on its hysteresis loop every time the lens is operated, either during the compensation procedure or in use. The procedure which was arbitrarily selected for the present work and which was found to be satisfactory is as follows: The image is focused visually and the objective current turned off. It is left off for about ten seconds to allow the circuits

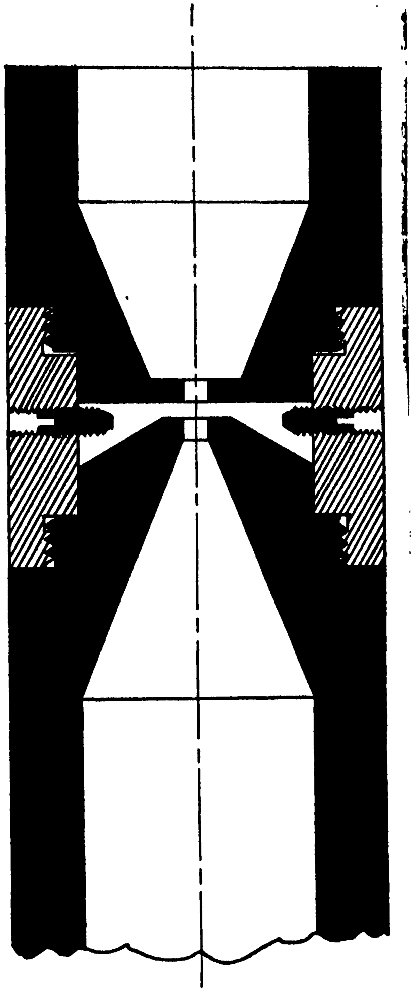

FIG. 23. Cross section of objective pole pieces provided with compensating screws.

FIG. 25. Focused image obtained with an uncompensated objective.

FIG. 26. Focused image obtained with one pair of correcting screws turned in as far as possible (11 turns). This puts in a large asymmetry which can be correlated with the compensating direction.

FIG. 27. First stage of compensation. The appropriate pair of screws has been selected and has been moved in five turns. The asymmetry is in the same direction as in the initial test (Fig. 25) but of smaller magnitude.

FIG. 28. Illustrates the maximum obtainable compensation with the one pair of screws (7 turns). The magnitude of the asymmetry is greatly decreased and its direction has changed.

FIG. 29. Shows compensation in the selected second direction (4 turns).

FIG. 30. Image obtained with fully compensated objective. The particles in the lower right hand corner are at exact focus. Other particles are either considerably above or below focal plane. Differences in level are emphasized in the compensated objective.

to become stabilized and then turned on again. The image is then observed and refocused. This procedure is repeated until the image comes into exact focus without further adjustment every time the lens current is turned on. The above technique was found to obliterate the previous magnetization history of the pole pieces and to produce consistent results as judged by the observed asymmetries.*

---

* *Note added in proof:* It has been found that the standard objective lens controls were not sufficiently fine for the most critical work. To overcome this a vernier has been

*7. Instrument Alignment.*—As a result of the present investigations the ideas on instrument alignment previously accepted in this laboratory underwent considerable revision. It was found that the quality of the images obtained with a reasonably symmetrical and clean objective lens was insensitive to alignment if considered from the point of view of astigmatism, but was quite sensitive considered from the point of view of chromatic change in magnification and rotation. This is in agreement with theory. The variations in the accelerating potential were measured and found to consist, primarily, of a 3-volt (peak to peak) 60-cycle ripple, which amounts to 0.006 percent of the total voltage and is well within the permitted variations for the attainment of a resolving power of 10A. This tolerance is valid, however, only if the "voltage center" (that is, the point of the image which remains stationary with change in accelerating potential) coincides with the center of the image field. In the present work it was found that, as a result of asymmetries associated with the projection lens, the magnetic and voltage centers were widely separated when the instrument was aligned on the basis of image rotation with objective current change and that the chromatic variation in magnification appeared as a 40A image shift.**

It is obvious from these observations that the alignment should be carried out on the basis of voltage rotation. The alignment procedure actually employed is as follows:

a. Center objective over projector mechanically.
b. Turn the accelerating voltage off and on very rapidly at the lowest projector setting and with the condenser adjusted to maximum power at which an image can still be seen, observing the effect on the image.
c. Translate condenser until center of voltage rotation or expansion is in center of field.
d. Reduce condenser current and translate gun until maximum illumination of field is obtained.
e. Alternately repeat steps c and d until voltage center remains in field for all condenser currents.
f. Raise magnification to maximum value and bring voltage center into field by translating objective.
g. Check e.

When the compensation of the objective was carried out according to the routine outlined above and the instrument adjustments, also listed above, were checked every time the objective lens was inserted for measurement it was found that the compensation was accomplished in accord with theory and that any setting of the lens-correcting screws gave reproducible results. It was found further that under the same condition a fully compensated lens was stable over reasonably long periods. One standard compensated lens maintained its symmetry over a two-week period of constant operation by one operator. In the succeeding two-week period, during which time the instrument was operated by several operators, the same lens became very slightly asymmetrical. However, since accurate records of the results of compensating adjustments in the original correction of the lens had been kept, it was a relatively simple matter to re-attain complete symmetry in the lens.†

## IX. ACCIDENTAL INSTRUMENTAL DEFECTS

Throughout the preceding discussion it has been assumed that the electron microscope being used in these tests performed perfectly within the limitations inherent in its design. Electron microscopists are aware, however, that such is seldom the case in practice and that the attainment of consistently high resolving power is only possible if the operator is continuously on the alert for indications of the presence of any of a large number of possible accidental defects. This situation is accentuated when resolving powers better than 20A are desired. In the following, a number of the more common accidental defects which are particularly important in the high resolving power range will be described and some methods for their detection and elimination given.

### 1. External Magnetic Fields

Commercial electron microscopes are normally carefully shielded for stray alternating magnetic fields, so that the image defects due to such fields are reduced below the 20A level. However, in the attainment of high resolving powers, particularly in the case of unusually bad locations, such stray fields still are an important limiting factor. In this laboratory an image shift of 20A (using an objective lens with a 2.5-mm focal length) was traced to this source.

The conventional electron microscope is most

---

added for which the total variation is 1/10 of that of what was previously the finest control.

** *Note added in proof:* The separation between the magnetic and voltage centers has now been eliminated by the introduction of a soft iron tube immediately above the projection lens pole-piece opening and extending to the top of the coil form. This tube was mounted coaxially with the projection lens system and magnetically isolated from it.

† *Note added in proof:* Since the second correction described above was made, this lens has remained accurately symmetrical over a period of six months during which time the pole pieces have been removed from the instrument and replaced well over 100 times.

sensitive to the effects of alternating magnetic fields in the region of the instrument immediately below the objective lens. Thus, the direction and absolute magnitude (that is, *not* referred to the scale of the specimen plane) of the image shifts resulting from alternating magnetic fields must be constant for all images taken with constant projection lens power and must be independent of the objective lens strength and alignment. These properties are sufficient for the identification of image defects due to alternating magnetic fields.

A single additional shield of small diameter (½ in.) mu-metal tubing placed along the axis of the instrument between the objective and the projection lenses was sufficient to eliminate these defects.

### 2. Specimen Vibration

In the present work some image shifts which were fairly consistent in the 10–20A range and erratic in the 20–40A range were finally traced to vibrations of the specimen holder. Since the resolving power of the instrument for visual observation through the final image telescope[1] at 250,000× is approximately 30A only the larger transitory vibrations could be seen. These were correlated with the boiling of the oil in the diffusion pump and the operation of the shutter.

This vibration, which was extremely troublesome in critical work, was finally eliminated by the simple expedient of lengthening the specimen holder until it just touched the upper face of the objective pole pieces. Unfortunately, under these conditions the stage movement controls had considerable backlash and were extremely difficult to manipulate. Thus, while the technique served for the present work, it is not considered a satisfactory solution of the problem.

### 3. Specimen Stage Drift

In the course of the present work it was found that the specimen stage did not remain motionless after being adjusted but tended to drift by as much as 30A during a 30-second exposure. The effect could be partially eliminated by carefully relieving mechanical strains in the stage mechanism by appropriately adjusting the controls and observing the results at high magnification. The above-mentioned technique of steadying the specimen, with its attendant difficulties, was most successful in eliminating specimen stage drift.

### 4. Specimen Drift (Thermal)

When the angular aperture of the illumination is varied from its maximum value for visual observation to a considerably lower predetermined value for photographic recording the total electron current reaching the specimen remains constant, but its distribution over the specimen changes considerably. This is particularly true in the instrument used for the present work. Since, at maximum angular aperture, the area of irradiation is only 10 microns in diameter, the wire supporting screen is seldom bombarded. On the other hand, at an angular aperture of $5 \cdot 10^{-5}$ radian, at which the micrographs are recorded, the area of irradiation is 330 microns in diameter and, hence, includes several meshes of the wire screen. It is obvious that when the change is made a new condition of thermal equilibrium in the specimen screen must be established and that this may involve a change in position of parts of the specimen screen owing to thermal expansion. It has been found that image shifts due to such thermal movements are very common unless special precautions are taken to avoid them. Woven screens are particularly bad in this respect because individual wires can move independently of the rest. Electrolytically produced copper screens give the best results at the present time, though even these are not always completely satisfactory. The screens must be fairly heavy, which means, of course, that the open area is small (20 percent). Special care must be taken with the clamping of a screen in the specimen holder to insure that it is held tightly around its entire circumference.

### 5. Charging of the Specimen

In accord with observations made with the probe diffraction camera it was found that the area of the specimen irradiated became highly charged *if it did not include a grounded conductor.* While the charging of the specimen does not affect the image quality as far as can be determined by visual observations it does give rise to erratic image shifts, making it impossible to attain high resolution micrographs. These image shifts can be completely eliminated by spreading the beam until one of the screen wires is included in the area of irradiation. Under these conditions the entire area of irradiation is held at the same potential as the screen. The mechanism of this discharging, which appears to be the same as encountered in the use of electron "sprays" in electron diffraction, is not yet understood.

It was also found necessary to take special precautions to clean the specimen screens before use. Large particles of lint or other insulating materials outside the area of irradiation often collect sufficient charge to deflect the beam and produce image shifts.

### 6. Contamination of Specimen Holder

Insulating particles and remnants of previous specimens clinging to the edges of the specimen cap are also a common source of image shifts. The existence of such particles can usually be detected by the occurrence of changes in image position with changes in intensity. In this laboratory the specimen cap and the surface of the hole through the specimen holder are kept polished by frequent cleaning with a very fine grade of steel wool wrapped around a round toothpick. The specimen cap is examined with a 10× eye lens for such contamination before inserting the specimen every time high resolution images are desired. Obviously, care must be taken to avoid leaving any loose threads of the steel wool on the holder.

### 7. Contamination of Objective Lens

Insulating particles clinging to the surfaces of the pole-piece openings introduce both image shifts and image asymmetries and are a continual source of trouble. As in the preceding case the existence of such particles makes itself apparent through a change in image position with change in intensity. The particles can be removed satisfactorily with lint-free lens tissue[10] on a toothpick, a 10× eye lens being used to observe the operation.

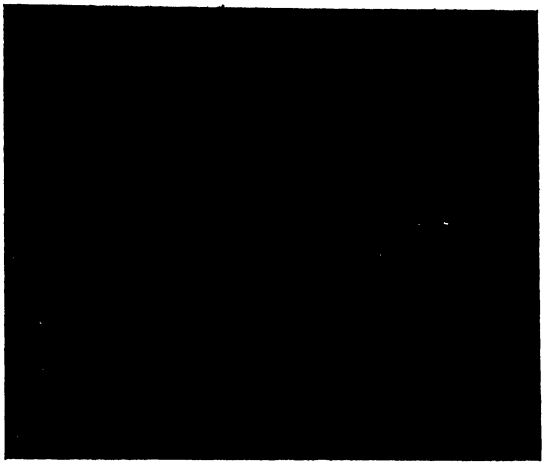

FIG. 31. High magnification image of colloidal gold taken with compensated objective ($f = 3.8$ mm).

### 8. Change of Focus with Change of Illumination

In the early critical work the change of focus which occurs when the intensity and angular aperture of illumination is changed gave considerable difficulty for the narrow range focal series used. The use of the high intensity gun and telescopic viewing device making it possible to focus the instrument and make the photographic exposure without changing the adjustment of the illumination eliminated the difficulty.

### 9. General Remarks

As the reader will have noticed, all of the above defects result in image shifts. If several are present simultaneously and they are observed only in the recorded image it is difficult, if not impossible, to determine their cause. In the present work it has been possible to sort out the various effects and to determine their cause individually through the use of telescopic observation of the image at high magnifications. This permits transitory image motions to be correlated with other incidental phenomena in the operation of the instrument. It is hoped that the presentation of a description of these defects in the above paragraphs will enable other electron microscopists to systematically eliminate them in their own particular instruments, which may not be provided with telescopic observation of the image. It is realized that the above list is not complete and, in particular, does not include

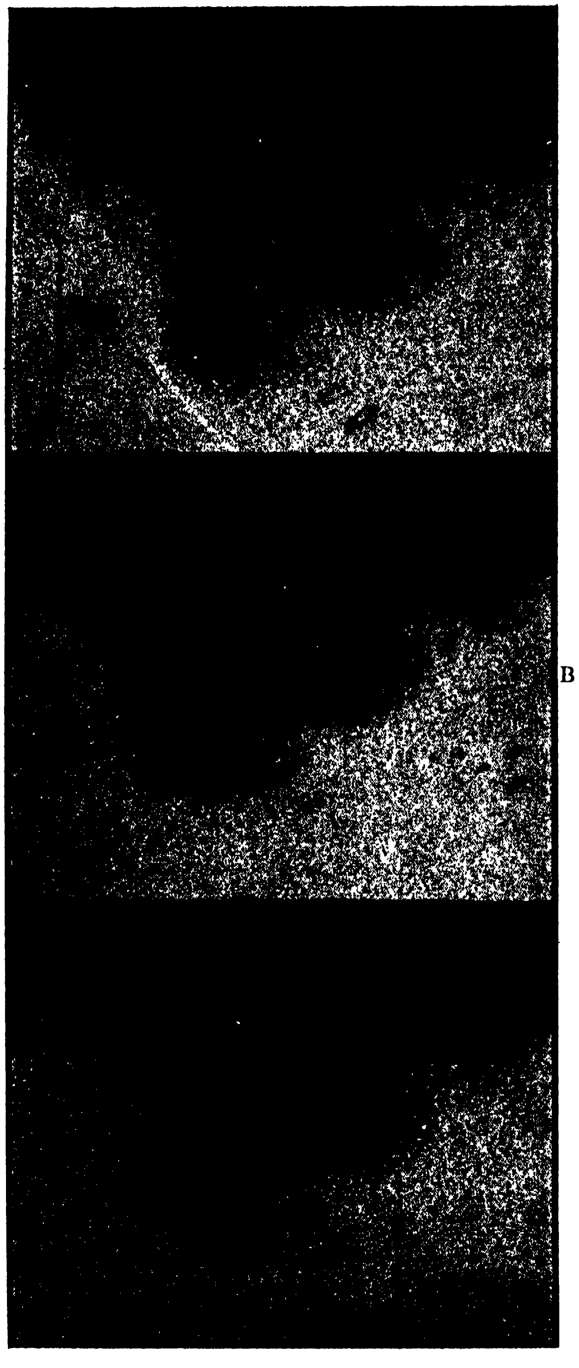

FIG. 32. High magnification focal series of alumina gel taken with compensated objective ($f=2.4$ mm). A. Underfocused image; B. Focused image; C. Overfocused image.

a description of the methods of identifying specific defects in the electrical supplies. The latter can be easily deduced, however, from a study of the normal operation of the instrument.

## X. OBJECTIVE APERTURE

Throughout the development of the electron microscope there have been many differences of opinion with regard to the necessity and value of a physical limiting aperture in the objective. The present work, which was carried out entirely without an aperture, has shown conclusively that such an aperture is not necessary for the demonstration of resolving powers at the 10A level. On the other hand, it has become apparent that lack of contrast at exact focus is at present the major limiting factor in the resolution of extremely fine structures of organic materials. A few attempts, which were made in the course of the present work, to establish the value of a limiting aperture in this particular problem were not conclusive.

## XI. CONCLUSION

It is demonstrated that the Fresnel diffraction fringes which are present in extra-focal images

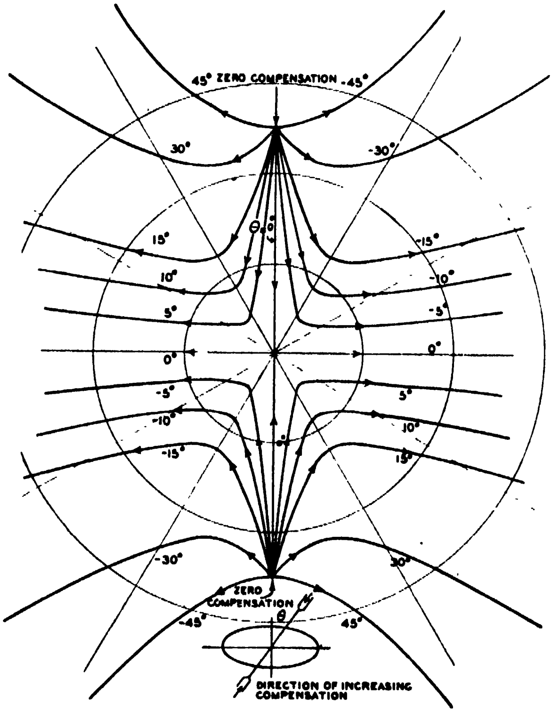

FIG. 33. Variation of orientation and magnitude of residual asymmetry with magnitude of compensating field for various angles between the principal axes of the original field and the compensating field.

obtained with small angular aperture of illumination provide a sensitive criterion of the degree of symmetry possessed by an electron microscope objective. It is shown further that the use of such a criterion makes the correction of asymmetries a relatively straightforward and simple matter. The image quality obtained with a corrected lens (Figs. 31 and 32) has been consistently and obviously higher than that obtained with the best uncorrected lenses.[1] While it has not been possible to make a precise measurement of the best resolving power achieved it is believed to lie in the range of values predicted theoretically for the lenses used.

The observed contour fringes are found to correspond to the Fresnel diffraction pattern for the edge of a partly transparent screen which introduces a phase delay in the coherently transmitted wave. The phase delay, arising from the inner potential of the screen, and the empirically observed greater intensity of the edge wave in the shadow, account for the observed dissimilarity of the contours for underfocusing and overfocusing.

Since the technique of obtaining symmetry in the properties of the image corrects asymmetries owing to external causes as well as those produced by defects in the lenses and since this compensation is not independent of instrument adjustment it appears, at present, that the attainment of high resolving power in a particular instrument requires the individual attention of the electron microscopist responsible for its operation. A number of practical suggestions have been included in the above discussion in the hope that they will assist the interested electron microscopist in the recognition and elimination of some of the more common instrumental difficulties which he may encounter.

---

## APPENDIX I

### Field Variation and Electron Paths for Elliptical Permanent Magnet Ring

If $q$ is the magnetic moment per unit length of the magnetic ring, $a$ (along the $x$ axis) is the major axis, and $b=a(1-\epsilon^2)^{\frac{1}{2}}$ (along the $y$ axis) is the minor axis, the scalar potential variation in the plane containing the major axis is

$$\psi(\xi,0,\zeta)=\frac{q\zeta}{a}\int_{-1}^{1}\frac{(1-\epsilon^2\xi_0^2)^{\frac{1}{2}}d\xi_0}{(1-\xi_0^2)^{\frac{1}{2}}[(\xi_0-\xi)^2+(1-\epsilon^2)(1-\xi_0^2)+\zeta^2]^{\frac{3}{2}}}. \tag{4}$$

Here $\zeta=z/a$, $\xi=x/a$, $x$ and $z$ being the coordinates of the reference point. For the meridional plane containing the minor axis,

$$\psi(0,\eta,\zeta)=\frac{q\zeta}{a}\int_{-1}^{1}\frac{(1-\epsilon^2\xi_0^2)^{\frac{1}{2}}d\xi_0}{(1-\xi_0^2)^{\frac{1}{2}}\{\xi_0^2+([(1-\epsilon^2)(1-\xi_0^2)]^{\frac{1}{2}}-\eta)^2+\zeta^2\}^{\frac{3}{2}}}, \tag{5}$$

$$\eta=y/a. \tag{6}$$

Near the axis a Taylor expansion of the potential yields

$$\psi=\Psi(\zeta)+\frac{1}{2}\left(\frac{\partial^2\psi}{\partial\xi^2}\right)(0,0,\zeta)\xi^2+\frac{1}{2}\left(\frac{\partial^2\psi}{\partial\eta^2}\right)(0,0,\eta)\eta^2+\cdots. \tag{7}$$

This is to be compared with the Taylor expansion for the corresponding axially symmetric system ($\epsilon=0$)

$$\psi_0=\Psi_0(\zeta)-\tfrac{1}{4}\Psi_0''(\zeta)r^2+\cdots, \tag{8}$$

where

$$\Psi_0(\zeta)=\frac{\pi q\zeta}{a(1+\zeta^2)^{\frac{3}{2}}},\quad \Psi_0'(\zeta)=\frac{\pi q}{a}\frac{(1-2\zeta^2)}{(1+\zeta^2)^{5/2}}. \tag{9}$$

For small values of $\epsilon$ the differences of corresponding coefficients in the two expansions are simply proportional to $\epsilon^2$:

$$\frac{\Delta\Psi'}{\Psi_0'}=\frac{1}{\Psi_0'}(\Psi'-\Psi_0')=\frac{\epsilon^2}{4}\frac{4\zeta^4-10\zeta^2+1}{(1+\zeta^2)^{7/2}}, \tag{10}$$

$$\frac{1}{\Psi_{0\max}'}\Delta\left(\frac{\partial^2\psi}{\partial\xi^2}\right)=\frac{1}{\Psi_{0\max}'}\left(\frac{\partial^2\psi}{\partial\xi^2}+\frac{\Psi_0''}{2}\right)=\frac{3\epsilon^2\zeta}{(1+\zeta^2)^{9/2}}\left(\frac{1}{4}-\frac{27}{16}\zeta^2+\frac{\zeta^4}{4}\right), \tag{11}$$

$$\frac{1}{\Psi_{0\max}'}\Delta\left(\frac{\partial^2\psi}{\partial\eta^2}\right)=\frac{1}{\Psi_{0\max}'}\left(\frac{\partial^2\psi}{\partial\eta^2}+\frac{\Psi_0''}{2}\right)=\frac{3\epsilon^2\zeta}{(1+\zeta^2)^{9/2}}\left(\frac{11}{4}-\frac{57}{16}\zeta^2+\frac{\zeta^4}{4}\right), \tag{12}$$

and hence

$$\frac{1}{\Psi_{0\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}+\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)=\frac{3}{4}\frac{\epsilon^2\zeta}{(1+\zeta^2)^{9/2}}(12-21\zeta^2+2\zeta^4), \tag{13}$$

$$\frac{1}{\Psi_{0\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}-\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)=-\frac{15}{8}\frac{\epsilon^2\zeta}{(1+\zeta^2)^{9/2}}(4-3\zeta^2). \tag{14}$$

The equations of motion of the electrons in the elliptical field are, in the paraxial approximation

$$\frac{\partial^2\xi}{\partial t^2}=\frac{e}{mca}\left(\dot\eta\Psi'-\frac{\partial^2\psi}{\partial\eta^2}\dot\zeta\eta\right);\quad \ddot\eta=\frac{e}{mca}\left(\frac{\partial^2\psi}{\partial\xi^2}\dot\zeta\xi-\dot\xi\Psi'\right);\quad \frac{\partial^2\zeta}{\partial t^2}=0. \tag{15}$$

Here dots indicate differentiation with respect to the time. The equations of motion may be converted into the path equations

$$\eta''=\frac{\ddot\eta\dot\zeta-[(\partial^2\zeta/\partial t^2)\dot\eta]}{\dot\zeta^3}\cong\frac{\ddot\eta}{\dot\zeta^2}=\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left(\frac{\partial^2\psi}{\partial\xi^2}\xi-\xi'\Psi'\right), \tag{16}$$

$$\xi''=\frac{[(\partial^2\xi/\partial t^2)\dot\zeta]-[(\partial^2\zeta/\partial t^2)\dot\xi]}{\dot\zeta^3}\cong\frac{(\partial^2\xi/\partial t^2)}{\dot\zeta^2}=\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left(\eta'\Psi'-\frac{\partial^2\psi}{\partial\eta^2}\eta\right), \tag{17}$$

since $\dot\zeta=(2e\Phi/m)^{\frac{1}{2}}/a$ where $\Phi$ is the accelerating potential of the electrons. Primes indicate differentiation with respect to $\zeta$. Equations (16) and (17) may be combined into a single equation:

$$(\xi+i\eta)''+i\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left[\Psi'(\xi+i\eta)'-\left(\frac{\partial^2\psi}{\partial\xi^2}\xi+i\frac{\partial^2\psi}{\partial\eta^2}\eta\right)\right]=0 \tag{18}$$

or

$$(\xi+i\eta)''+i\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left[\Psi_0'(\xi+i\eta)'+\frac{\Psi_0''}{2}(\xi+i\eta)\right]$$
$$=-i\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left\{\Delta\Psi'(\xi+i\eta)'-\left[\xi\Delta\frac{\partial^2\psi}{\partial\xi^2}+i\eta\Delta\frac{\partial^2\psi}{\partial\eta^2}\right]\right\}. \tag{19}$$

Introduce now the new independent variable

$$u=(\xi+i\eta)e^{-i\chi};\quad \chi=-\int_{-\infty}^{\zeta}\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi_0'd\zeta. \tag{20}$$

The differential Eq. (19) now becomes:

$$u''+\frac{e\Psi_0'^2}{8mc^2\Phi}u=-i\left(\frac{e}{2mc^2\Phi}\right)^{\frac{1}{2}}\left\{\Delta\Psi'\left(u'-i\left[\frac{e}{8mc^2\Phi}\right]^{\frac{1}{2}}\Psi_0'u\right)-e^{-i\chi}\left[\xi\Delta\frac{\partial^2\psi}{\partial\xi^2}+i\eta\Delta\frac{\partial^2\psi}{\partial\eta^2}\right]\right\}=R(\zeta). \tag{21}$$

The corresponding homogeneous equation,

$$u_0''+\frac{e\Psi_0'^2}{8mc^2\Phi}u_0=0, \tag{22}$$

has the particular solution $u_\alpha$ with the initial conditions $u_\alpha=0$, $u_\alpha'=-a/f$ for $z=z_F$; for $z=-\infty$, $u_\alpha=1$.

Consider now a ray incident parallel to the axis, unit distance from it, and in a meridional plane with the azimuth $\varphi$. In the zero approximation its coordinates are then given by

$$u=u_\alpha e^{i\varphi};\quad \xi=u_\alpha\cos(\varphi+\chi);\quad \eta=u_\alpha\sin(\varphi+\chi). \tag{23}$$

The deviation of the ray passing through the deformed lens in the plane of focus ($z=z_F$) is then[11]

$$\Delta u=\frac{f}{a}\int_{-\infty}^{\zeta_F}Ru_\alpha d\zeta. \tag{24}$$

Here, to obtain a first approximation, the coordinates in Eq. (23) are to be substituted for $u$, $\xi$, and $\eta$ in the expression $R(\zeta)$ from Eq. (21). It is desirable to refer this displacement to the plane in which the corresponding ray for the symmetrical lens traverses focus. The coordinates are then given by

$$\Delta\xi_\varphi+i\Delta\eta_\varphi=\Delta ue^{-i(\varphi-\chi_a)};\quad \chi_a=-\int_{-\infty}^{\zeta_F}\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi'd\zeta. \tag{25}$$

$\chi_a$ is the total rotation of the image. $\Delta\xi_\varphi$ now represents the deviation parallel to the meridional plane, $\Delta\eta_\varphi$ that at right angles thereto. Substituting $R$ from Eq. (21) in Eq. (24),

$$\Delta\xi_\varphi+i\Delta\eta_\varphi=-\frac{2if}{a}e^{i\chi_a}\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\int_{-\infty}^{\zeta_F}\left[\Delta\Psi'\left(u_\alpha'u_\alpha-i\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi'u_\alpha^2\right)\right.$$

$$\left.-e^{-i(\varphi+\chi)}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}\cos(\varphi+\chi)+\Delta\frac{\partial^2\psi}{\partial\eta^2}\sin(\varphi+\chi)\right)u_\alpha^2\right]d\zeta. \tag{26}$$

$$\Delta\xi_\varphi=\frac{f}{a}\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi_{\max}'\left\{2\sin\chi_a\int_{-\infty}^{\zeta_F}\frac{\Delta\Psi'}{\Psi_{\max}'}u_\alpha u_\alpha'd\zeta\right.$$

$$2\cos\chi_a\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi_{\max}'\int_{-\infty}^{\zeta_F}\frac{\Psi'\Delta\Psi'}{\Psi_{\max}'^2}u_\alpha^2d\zeta+\sin\chi_a\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}+\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)d\zeta$$

$$\cos2\varphi\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}-\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)\sin(2\chi-\chi_a)d\zeta$$

$$\left.-\sin2\varphi\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}-\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)\cos(2\chi-\chi_a)d\zeta\right\}. \tag{27}$$

---

[11] See e.g., E. P. Adams, *Smithsonian Mathematical Formulae* (Smithsonian Institution, Washington, D. C., 1922), Formula 8.410.

$$\Delta\eta_\varphi=\frac{f}{a}\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi_{\max}'\Bigg\{-2\cos\chi_a\int_{-\infty}^{\zeta_F}\frac{\Delta\Psi'}{\Psi_{\max}'}u_\alpha u_\alpha'd\zeta$$

$$-2\sin\chi_a\left(\frac{e}{8mc^2\Phi}\right)^{\frac{1}{2}}\Psi_{\max}'\int_{-\infty}^{\zeta_F}\frac{\Psi'\Delta\Psi'}{\Psi_{\max}'^2}u_\alpha^2d\zeta-\cos\chi_a\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}+\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)d\zeta$$

$$-\cos2\varphi\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}-\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)\cos(2\chi-\chi_a)d\zeta$$

$$+\sin2\varphi\int_{-\infty}^{\zeta_F}\frac{u_\alpha^2}{\Psi_{\max}'}\left(\Delta\frac{\partial^2\psi}{\partial\xi^2}+\Delta\frac{\partial^2\psi}{\partial\eta^2}\right)\sin(2\chi-\chi_a)d\zeta. \quad (28)$$

The distance between the focal plane and the plane in which the ray approaches closest to the axis is given by

$$\Delta z_F=-a\Delta\xi_\varphi/u_\alpha'=f\Delta\xi_\varphi; \quad (29)$$

$ar_0\Delta\eta_\varphi$, $r_0$ signifying the distance of the ray from the axis in image space, on the other hand, gives the deviation from the axis at the point of closest approach. Equations (27) and (28) were evaluated by numerically solving Eq. (22) for $u_\alpha$ and performing the indicated quadratures. The results are shown in Table I and Fig. 18.

## APPENDIX II

### Compensation of Objective Asymmetries

Equation (7), representing the axial potential for any pole-piece assembly with two meridional planes of symmetry passing through the $\xi$ and $\eta$ axes, may be written

$$\psi=\Psi_0+\left(\frac{\partial^2\psi}{\partial\xi^2}\right)\xi^2+\left(\frac{\partial^2\psi}{\partial\eta^2}\right)\eta^2+\cdot$$

$$=\Psi_0+\frac{1}{2}\left[\frac{\partial^2\psi}{\partial\xi^2}+\frac{\partial^2\psi}{\partial\eta^2}\right](\xi^2+\eta^2)+\frac{1}{2}\left[\frac{\partial^2\psi}{\partial\xi^2}-\frac{\partial^2\psi}{\partial\eta^2}\right](\xi^2-\eta^2)+\cdots. \quad (30)$$

The last term in this expression is responsible for the astigmatism of imaging pencils refracted by the system.

Assume now that a second asymmetry is introduced, e.g., by a pair of iron screws placed symmetrically with respect to the axis. Let the principal axes of this "compensating" system ($\xi_1$, $\eta_1$) form an angle $\Theta$ with the $\xi$, $\eta$ axes:

$$\xi_1=\xi\cos\Theta-\eta\sin\Theta,\quad \eta_1=\xi\sin\Theta+\eta\cos\Theta,\quad \xi_1^2-\eta_1^2=\xi^2\cos2\Theta-2\xi\eta\sin2\Theta-\eta^2\cos2\Theta. \quad (31)$$

The total asymmetry term resulting from the superposition of the two fields is now

$$\Delta\Psi=A[\xi^2(1-k\cos2\Theta)-2k\xi\eta\sin2\Theta-\eta^2(1-k\cos2\Theta)], \quad (32)$$

where

$$A=\frac{1}{2}\left(\frac{\partial^2\psi}{\partial\xi^2}-\frac{\partial^2\psi}{\partial\eta^2}\right);\quad k=\left(\frac{\partial^2\psi_1}{\partial\xi_1^2}-\frac{\partial^2\psi_1}{\partial\eta_1^2}\right)\Big/\left(\frac{\partial^2\psi}{\partial\xi^2}-\frac{\partial^2\psi}{\partial\eta^2}\right).$$

The subscript 1 refers to the compensating system. If the factor $k$, normally a function of $\zeta$, is a constant, perfect compensation is possible. This occurs, of course, for $\Theta=0$ and $k=1$ and corresponds to a compensating field whose asymmetry terms are, except for sign, identical throughout with those of the original field.

If the factor $k$ is not a constant, the adjustment of $\Theta$ and the magnitude of $k$ (for a short magnetic or for an electrostatic lens) will still bring about correction, though now the imagining pencils can be made stigmatic only in the first order. The image formation in such systems is analogous to the formation of an image focused sharply in two perpendicular directions by two cylindrical lenses with their axes at right angles to each other. For a long magnetic lens compensation will generally be incomplete, since the adjustment of the orientation and the magnitude of an arbitrary compensating field will not suffice to balance both the isotropic and the anisotropic component of the astigmatism resulting from the original field. Below the case of the short lens, for which a single, effective, value of $k$ can be defined, will be treated.

Since, in practice, the orientation of the asymmetry in the original pole pieces is initially either unknown or known only approximately, the principal axes of the compensating field first introduced will, in general, form an angle $\Theta$ different from zero with the principal axes of the original field. It is hence of interest to know how the asymmetry in the image will change with the value of $k$ for different values of $\Theta$.

For any value of $k$ and $\Theta$ the principal axes ($\xi_2$, $\eta_2$) of the resultant field (determining the directions of maximum focal deviation or most pronounced defocusing fringes in the image) will be rotated relative to the principal axes $\xi$, $\eta$ of the original field by an angle $\vartheta$:

$$\xi=\xi_2\cos\vartheta-\eta_2\sin\vartheta,\quad \eta=\xi_2\sin\vartheta+\eta_2\cos\vartheta. \tag{33}$$

Substituting this relation in Eq. (32) and adjusting $\vartheta$ so that the coefficient of $\xi_2\eta_2$ vanishes leads to

$$\Delta\Psi=A(1-2k\cos 2\Theta+k^2)^{\frac{1}{2}}(\xi_2{}^2-\eta_2{}^2), \tag{34}$$

$$\tan 2\vartheta=-k\sin 2\Theta/(1-k\cos 2\Theta). \tag{35}$$

Here the coefficient in Eq. (34) measures the asymmetry of the resultant field (or the value of the eccentricity factor $\epsilon^2$), $\vartheta$ the rotation of the direction of maximum lens action (or of the orientation of the most pronounced fringes) as $k$ (or the compensating field) is increased from zero to the given value. These quantities are plotted, for a series of values of $\Theta$, the angular deviation between the principal axes of the two superposed fields, in the polar diagram shown in Fig. 33. Each curve corresponds to a range in $k$ from 0 to 2; arrowheads indicate the direction of increasing $k$.

Correction takes place only if $\Theta$ is less than 45° in absolute value. If this condition is fulfilled, increasing the compensating field from zero results in an initial reduction in the degree of asymmetry and a subsequent increase. The value of $\vartheta$ passes simultaneously from 0 to $\mp(\pi/2-|\Theta|)$ if the sign of $\Theta$ is $\pm$. Only for $\Theta=0$ is full correction attained; for $|\Theta|=5°$ the asymmetry can be reduced to less than a fifth, for $|\Theta|=10°$, to a third, and for $|\Theta|=15°$, to a half.

# An Investigation of a Method for the Analysis of Smokes According to Particle Size[1]

WILLIAM N. LIPSCOMB,[2] T. R. RUBIN,[3] AND J. H. STURDIVANT
*California Institute of Technology, Pasadena, California*[4]

(Received August 2, 1946)

An electrical precipitation method for the analysis of smokes according to particle size has been investigated. A thin stream of smoke particles moving under laminar conditions in a wind tunnel of rectangular cross section is electrically charged in a small region. The charged particles are then precipitated by the uniform field existing between the charged upper plate and the grounded lower plate of the wind tunnel as a long track along the lower plate. The size-frequency distributions of the particles precipitated at various points on the lower plate were determined from measurements on enlargements of electron-microscope photographs of samples of the smoke precipitated at various points. The agreement between theory and experiment is fair, but the range of sizes of the particles precipitated at a given point is rather large.

## INTRODUCTION

THE use of a precipitation method for the estimation of sizes of smoke particles was first described by Rohmann.[5] His apparatus consisted of a wind tunnel of rectangular cross section with an electric field between the negatively charged upper plate and the grounded lower plate. The smoke was introduced into the wind tunnel through a small tube and was charged in a small region by a corona discharge from a point. The charged particles were precipitated by the uniform field as a track about 5 cm in length. The size of the particles was measured with an optical microscope and compared with the particle radius calculated from the theory of precipitation of charged spherical particles in a uniform field. Rohmann did not report the size-frequency distributions of the particles precipitated at various points, but only the average size in the densest region of the precipitate. No statement was made regarding the regularity of shape of the metallic oxide particles in the smokes which he used for his investigation. Rohmann mentions two difficulties encountered in his experiments. The first was the difficulty of obtaining laminar gas flow in the wind tunnel; even in the absence of a charging corona he was forced to work with gas velocities of nearly 40 cm/sec. in order to obtain a stable thread of smoke. The second difficulty was the disturbance of the thread of smoke by the electrical wind which accompanies corona discharge; he was therefore constrained to use comparatively small charging currents.

The present investigation consists of a more extensive study of the precipitation method for the analysis of smokes according to particle size. A modified form of the apparatus described by Rohmann was used. The rectangular wind tunnel was redesigned in order to give essentially laminar flow at gas velocities of approximately 10 cm/sec. Since the point corona was found to be unsatisfactory, other methods of obtaining charging currents were investigated. The electron microscope was used to record the sizes of particles precipitated at various points in the apparatus. Had the separation of the smoke particles proved more satisfactory a much more rapid method was to be used (based on calibration with the electron microscope results) for the determination of the size-frequency distribution function; this proposed method consisted of measurement of the current carried by the charged smoke particles to small metal collectors mounted in the plane of the lower plate and insulated from it. Because the results were not completely satisfactory, however, only the studies of various charging devices, representative size-frequency distribution curves, and com-

parisons of experimental results with theoretical precipitation curves are presented here.

## APPARATUS

A diagram of the precipitation apparatus is shown in Fig. 1. The smoke, which was contained in a large flask, was forced by means of compressed air first through a short length of small-bore glass tubing (to reduce turbulence) and then into the entrance tube *T*. This tube extended through the entrance duct *D* to the rectangular precipitation chamber *C*. In order to minimize turbulence the entrance duct was provided with a honeycomb baffle *B* made from short lengths of Cellophane soda straws. Further reduction of turbulence was obtained by placing a box in front of the entrance duct in the position indicated in the plan and elevation of Fig. 1. The

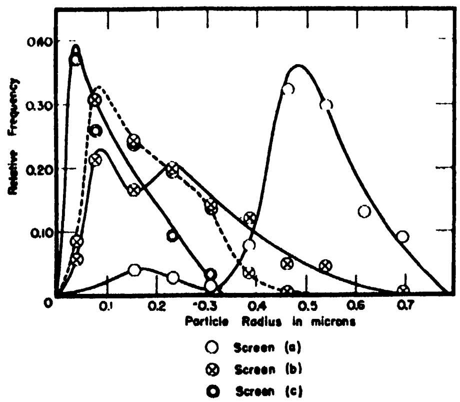

FIG. 4. Size-frequency distributions of particles in a rosin smoke charged by means of a plate coated with rayon flock fibers.

precipitation chamber consisted of two parallel brass plates *P* separated by lucite strips. The upper plate, which was charged to about −4 kv, was insulated from the entrance and exit ducts by bakelite strips *E*. The various charging devices which were tested were placed above or in the plane of an aperture *S* in the upper plate, and were surrounded by an air-tight insulator to prevent air from entering around the charging region. The lower plate was provided with a metallic collector *H* which was mounted in the plane of this plate and insulated from it. This collector was made movable along the direction of wind flow in order to measure, by means of a galvanometer, the iron currents emitted by the charging device as a function of the position of the collector. The air-stream outlet consisted of two sections which ended finally in a large circular cross-section. A four-bladed fan, run from a variable speed motor, was placed just inside the outlet section *N*; this fan produced air velocities at the center of the precipitation

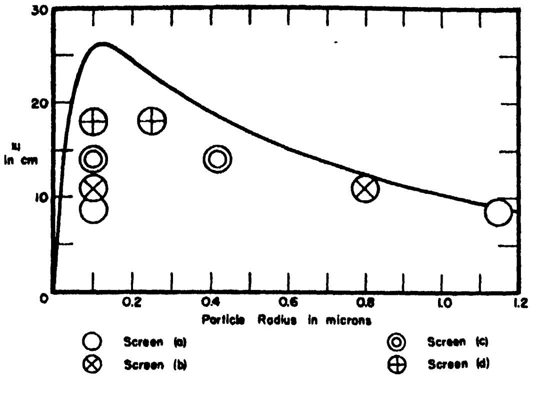

FIG. 5. Average particle radius as a function of point of precipitation; charging device was a heated filament.

chamber of 8 to 25 cm/sec. The velocities which were used in the runs described below were 12 to 15 cm/sec.

A uniform downward current of ions of about $10^{-8}$ ampere/cm$^2$ must be obtained in order to charge the smoke particles. Of the large number of devices which were tested for this purpose, the three most promising were investigated in detail

TABLE I. Summary of experimental results.

Run 1; Charging device: heated filament

| Screen | Particles measured | $x_i$ in cm | Position of maxima in microns |
|---|---|---|---|
| (a) | 176 | 8.7 | 0.1<br>1.15 |
| (b) | 146 | 11.0 | 0.1<br>0.5, 1.1<br>(Average, 0.8) |
| (c) | 195 | 14.0 | 0.1<br>0.42 |
| (d) | 99 | 18.0 | 0.1<br>0.25 |

Run 2; Charging device: cotton cloth

| Screen | Particles measured | $x_i$ in cm | Position of maxima and half width at half maximum, in microns |
|---|---|---|---|
| (a) | 196 | 6.5 | 0.08±0.05,<br>0.69±0.13 |
| (b) | 265 | 12.0 | 0.25±0.08 |
| (c) | 248 | 15.0 | 0.17±0.10 |

Run 3; Charging device: rayon flock fibers

| Screen | Particles measured | $x_i$ in cm | Position of maxima in microns |
|---|---|---|---|
| (a) | 77 | 4.0 | 0.16<br>0.48 |
| (b) | 229 | 6.0 | 0.08<br>0.23 |
|  | 452 | 6.0 | 0.09<br>(0.2 to 0.3) |
| (c) | 97 | 8.6 | 0.05 |

by studies of the size-frequency distribution of the smoke particles precipitated at various points in the apparatus. The first (Run 1) consisted of a small heated Nichrome coil which was supported by a short quartz rod and jacketed by a Pyrex compressed air cooler. Immediately below this coiled filament was placed a wire screen (15–50 meshes/in.$^2$) which was allowed to remain at "floating" potential. The filament was heated by means of a filament transformer and was maintained at a potential of about −5 kv. The second charging device (Run 2) consisted of a small area (1 cm×2.5 cm) of cotton bird's-eye toweling which was placed in contact with a metal plate at −4 to −10 kv. The third charging device (Run 3) consisted of a small aluminum plate maintained at −14 kv and covered sparsely with rayon flock fibers (about 250/cm$^2$) attached normal to it.[6] This third charging device gave the most nearly reproducible and uniform charging conditions of all of those which were tested.

For studies with the electron microscope, collodion-covered screens were placed on the lower plate of the precipitation apparatus at various distances from the charging region. These screens were 6-mm circles cut from 350-mesh brass screen, and were coated with a collodion film about 0.1 micron in thickness.

## EXPERIMENTAL PROCEDURE

The wind velocity $v_0$ was measured in the following manner: a thin stream of smoke was allowed to flow down the center of the precipitation chamber. A disturbance was given to the stream by a slight movement of the inlet tube, and the time required for this disturbance to move a known distance was measured.

The ion current in the charging region was measured at various positions by means of the movable collector plate; it was found to be fairly uniform and limited to a small region. The extent of the charging region, extrapolated to the height of the smoke stream above the lower plate, divided by the velocity of the stream was taken as the time of charging, $t$. The average ion current per unit area in the charging region was taken as the ion current density, $i$.

The rosin smokes were prepared by heating about 70 mg of rosin in a small copper pan; the rosin condensed into a smoke consisting of approximately spherical particles of radius $0.05 < a < 3$ microns. The smoke was collected in the large flask and was forced into the apparatus by a slow stream of compressed air. When the charging and deflecting potentials were turned on, the smoke stream was observed to curve down slightly and fan out into a curtain of smoke dropping to the lower plate. The smoke thus deposited a narrow track of rosin on the lower plate where, for the purpose of electron microscopy, the small collodion-covered collectors were placed.

Photographs were taken of the smoke deposits on the collodion-covered screens with the use of the electron microscope designed at the California Institute of Technology by Professor W. V. Houston and Dr. J. H. Bradner, and the RCA electron microscope at the Department of Physics of the University of California at Berkeley. Enlargements of the electron microscope photographs were made to a total linear magnification of about 6000. For spherical particles the diameter was measured; for elliptical and slightly irregular particles the average of the largest and smallest diameters was taken. Nearly all of the rosin smoke particles were approximately spherical except for the larger particles obtained in Run 1, in which the heated filament was used as a charging device. These highly irregular particles were divided into spherical or approximately elliptical sections and measured as independent parts. Although this idealization is clearly not a good approximation, a convenient method of comparing particle sizes was obtained by this method. There is no satisfactory treatment of the law of fall for particles of irregular shape. From the measurements of particle size, the size-frequency distribution curves were prepared by plotting the number of particles of a given size as ordinate against the radius of the particle in microns as abscissa, and then drawing a smooth curve through the points.

## RESULTS

The size-frequency distribution curves obtained in the three runs are shown in Figs. 2a, 2b, 3, and 4. The experimental results are summarized in Table I. On Screen (b) of Run 1 two maxima appeared for $a > 0.3$ microns whereas the theory required only the one shown by most of the other experimental results. The average of these two peaks was taken. It is to be noted that the numbers of particles of given size determining parts of this and some of the other distribution curves are too small to yield satisfactory statistical distributions. As a result the method of interpolation by which some parts of the curves should be obtained is not unambiguous. The photographed area of Screen (b) of Run 3 was divided into two parts, and the particles on these two parts were counted separately in order to determine whether the result-

---

[6] Flock is a preparation of textile fibers cut to uniform, short lengths. In order to prepare this charging device the required density of flock was placed on a grounded conducting plate. The aluminum plate, wet with Glyptal, was suspended above the grounded plate and charged to about −15 kv in order to deposit the fibers in an erect position on the charged plate. The potential was left on until the Glyptal hardened.

ing size-frequency distribution curves were in satisfactory agreement. The results, shown in Fig. 4 and Table I are in good agreement, but it is quite clear that a large number of particles must be counted before satisfactory distributions are obtained.

The experimental results are compared with the theoretical curves, calculated as described in the Appendix, in Figs. 5, 6, and 7. The numerical expressions from which the curves were calculated are, for Run 1,

$$x_i = \frac{1660a_\mu}{(1+0.082/a_\mu)Q} \text{ where } Q = 123a_\mu{}^2 + 23a_\mu;$$

for Run 2,

$$x_i = \frac{1840a_\mu}{(1+0.082/a_\mu)Q} \text{ where } Q = 157a_\mu{}^2 + 82a_\mu;$$

and, for Run 3,

$$x_i = \frac{1840a_\mu}{(1+0.082/a_\mu)Q} \text{ where } Q = 476a_\mu{}^2 + 39a_\mu,$$

where $a_\mu$ is the particle radius in microns. The agreement between the curves and the experimental points is not too good. However, the general character of the theoretical curves is reproduced by the experiments, for example, the precipitation of both large and small particles at a given point as required by the theory appears to be verified.

In order to test whether the original smoke sample itself contained an abnormally large number of small particles, the whole thread of smoke was swept repeatedly across a collodion-covered screen by variation of the corona potential, until a satisfactory density of particles was obtained. Electron microscope photographs of this sample did not show a predominant number of particles of radius less than 0.2 micron; the size-frequency distribution curve for the unseparated smoke showed a single maximum at about 1 micron.

Considerable experimental difficulties were encountered in the use of the various charging devices. The filament heated the charging region considerably, and even though approximate thermal equilibrium had been reached before the run was started some slight thermal unsteadiness in the precipitation conditions persisted. The cotton cloth charging device produced results which were quite unreproducible; however, no variations in the charging conditions were usually observed during a single run. The conducting plate covered with the rayon flock fibers was probably the most satisfactory charging device which was tested. These fibers undoubtedly retained their relative orientation for successive runs better than did the cloth fibers. The appearance of the track of rosin precipitated on the lower plate was very similar for successive runs with the flock fiber charging device, although a series of five successive runs under as nearly the same conditions as possible gave results which agreed rather poorly.

The reasons for this poor agreement probably include (a) variations in the initial charges on the particles, (b) turbulence in the wind flow in the tunnel, (c) irregularities in the particle shape, (d) fluctuations in the charging current, and (e) statistical variations in the charging. The effects of variation of the initial charges of the particles were estimated by measurement of the maximum deflection of the smoke stream in a uniform field in the absence of the precipitating current. The maximum deflection observed corresponded to a maximum initial charge of $\pm 8e$ on a particle of radius 0.5 micron, or $\pm 34e$ on a particle of radius 2 microns. Turbulence is extremely difficult to eliminate completely, and its effect was apparent on careful visual observation under the best conditions which we obtained; it may have been caused, in part, by electrical wind effects. Fluctuations in the charging current of 1 to 2 percent were detected with a probe which was connected to an electrometer circuit. The effect of irregularities in the shapes of the particles and of statistical variations in charging could not be estimated.

## ACKNOWLEDGMENT

Our thanks are due Professor Linus Pauling, who suggested this study, for his interest, advice, and encouragement. We are also indebted to Mr. George Standart for assistance with part of the experimental work, and to Dr. R. V. Langmuir and Mr. R. Rau of the California Institute of Technology, Mr. A. E. Smith of the Shell Development Company, and Mr. A. W. Einarsson of the University of California at Berkeley

for their assistance in helping us to obtain electron microscope photographs.

## APPENDIX: THEORETICAL SECTION

A particle which has a radius $a$ and charge $Qe$ and is swept along a horizontal rectangular channel (see Fig. 8) between two charged plates has a downward velocity $v'$ because of the gravitational and electrostatic forces, $mg+E_0Qe$;

$$v'=\frac{mg+E_0Qe}{6\pi\eta a}\left(1+\frac{A\lambda}{a}\right), \tag{1}$$

where $\eta$ is the viscosity of the gas; $A$ is the Cunningham constant[7]; and $\lambda$ is the mean free path of the gas molecules.

The problem of the gas velocity at any point in a tube of rectangular cross section has been solved by Cornish.[8] In a tube with cross-sectional width $c$ and height $d$ in which the velocity on the axis ($y=z=0$) is $v_0$, the velocity of gas flow along any line parallel to the axis is

$$v=v_0\frac{\left[\frac{1}{4}-\frac{y^2}{d^2}-\frac{8}{\pi^3}\left(\frac{\cosh\frac{\pi z}{d}}{\cosh\frac{\pi c}{2d}}\cos\frac{\pi y}{d}-\frac{1}{3^3}\frac{\cosh\frac{3\pi z}{d}}{\cosh\frac{3\pi c}{2d}}\cos\frac{3\pi y}{d}+\cdots\right)\right]}{\frac{1}{4}-\frac{8}{\pi^3}\left(\frac{1}{\cosh\frac{\pi c}{2d}}-\frac{1}{3^3\cosh\frac{3\pi c}{2d}}+\cdots\right)} \tag{2}$$

The horizontal distance, $x_i$, from the point at which the particles are charged to the point at which they strike the lower plate may then be shown, by integration of the equation $dx=(v/v')dy$, to be

$$x_i=\frac{6\pi\eta a v_0}{(mg+E_0Qe)\left(1+\frac{A\lambda}{a}\right)}\frac{2l^2}{d}\left(1-\frac{2l}{3d}\right)$$
$$\times\left\{1+\frac{32}{\pi^3\cosh\frac{\pi c}{2d}}\left[1+\frac{32}{\pi^3\cosh\frac{\pi c}{2d}}\right]\right.$$
$$\left.\times\left[1-\frac{d^2\left(1-\cos\frac{\pi l}{d}\right)\cosh\frac{\pi z}{d}}{2\pi l^2\left(1-\frac{2l}{3d}\right)}\right]+\cdots\right\}, \tag{3}$$

where $l$ is the height above the lower plate at which the stream of particles is charged. For the conditions under which the experiments were carried out $E_0Qe\gg mg$ and $z=0$, and an adequate approximation to Eq. (3) is

$$x_i=\frac{6\pi\eta a v_0}{E_0Qe\left(1+\frac{A\lambda}{a}\right)}\frac{2l^2}{d}\left(1-\frac{2l}{3d}\right). \tag{4}$$

This equation would be suitable for calculation if we knew the number of charges, $Q$, as a function of the particle radius and known or measurable quantities.

A theory of the charging of a spherical particle of radius $a$ and dielectric constant $K$ passing through a downward current of ions has been derived by Rohmann[8] under the assumptions that (1) diffusion of charges to the particle is negligible, (2) electrical image forces between an ion approaching a particle and the particle are negligible, and (3) all of the incident ions give up their charge to the particle. His expression for the charge $Q_fe$ acquired in time $t$ by an initially uncharged particle may be written in the form

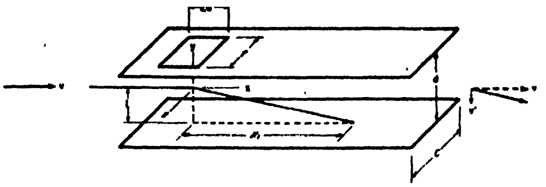

FIG. 8.

$$Q_fe=\left(1+\frac{2(K-1)}{K+2}\right)E_1a^2\frac{\pi it}{E_1+\pi it}, \tag{5}$$

where $i$ is the ion current per unit area and $E_1$ is the field intensity in the charged region.

No satisfactory theory has been developed for the initial stage of the charging of a spherical particle of low dielectric constant by diffusion. The final stage of diffusion charging was investigated theoretically and experimentally by Arendt and Kallmann.[9] Their work, and also the experimental work of Deutsch[10] and Schweitzer[11] showed that the saturation charge taken up by oil drops of radius from 0.1 micron to 10 microns in a space charge of the order of $10^6$ charges/cm$^3$ is proportional to the particle radius. Ladenburg[12] pointed out that in the process of precipitation of smoke particles in a charging field there are two distinct charging mechanisms, one, important for the larger particles, giving a charge proportional to $a^2$ as described in the preceding paragraph, and another, important for the smaller particles, giving a charge proportional to $a$. This second mechanism is called diffusion charging although it includes, in addition to ordinary diffusion of ions to the particle, the effect of image forces on the charge approaching the dielectric surface of the particle and the effect of the net charge on the diffusion of ions to the particle. We have assumed that the number of charges diffusing to a particle of radius $a$ in a time $t$ and in an ion atmosphere of volume density $f$ is

$$Q_d=Cfta. \tag{6}$$

The value of the proportionality constant was determined to be $C=0.07$ by extrapolation to zero time of the experimental curves for the charging of oil drops as a function of time, as given by Arendt and Kallmann.[9] Unfortunately, Arendt and Kallmann did not obtain data for times less than about 4 min., and consequently the constant $C$ cannot *a priori* be regarded as determined even to the correct order of magnitude for the time intervals of interest ($t\sim0.2$ sec.). We shall, nevertheless, use the resulting expression for calculation of $Q_d$ because our results described above indicate that the resulting term in the

[12] R. Ladenburg, Ann. der Physik [5] **4**, 863 (1930).

charging law is approximately correct, and is almost certainly of the correct order of magnitude. Since the ion density is given by the relation $f=i/(E_1ue)$, where $u$ is the mobility of the ions, Eq. (6) therefore becomes

$$Q_de=0.07iat/E_1u. \tag{7}$$

In the absence of a complete mathematical treatment of the charging process, we shall write the expression for the total charge at a time $t$ on a spherical particle of radius $a$ in the form

$$Qe=Q_fe+Q_de, \tag{8}$$

where $Q_fe$ and $Q_de$ are given by Eqs. (5) and (7), respectively. In this and the preceding equations the effect of the comparatively small initial charge on the particle has been omitted. Although the two charging processes are probably not independent, and the expressions for the two processes therefore not strictly additive, it may be pointed out that because of the different dependence of the two processes on the particle radius, Eq. (7) represents the important term for the smaller particles, whereas Eq. (6) represents the important term for the larger particles.

The value of $Qe$ from Eq. (8) may be substituted into Eq. (4) in order to calculate the distance along the direction of gas flow from the center of the charging region to the point of precipitation of a particle of radius $a$. In this calculation we have made the additional assumption that the charging, which occurs over the distance $v_0t=2a'$ (Fig. 8), may be approximated by complete charging at a point at the center of the charging region.

In some of the experiments the field in the charging region was considerably higher than that between the deflecting plates of the rectangular precipitation chamber. The average field in the charging region in this case was calculated from an approximate solution of the two-dimensional potential distribution by expansion in rectangular harmonics. For the case (Run 3, above) in which this treatment was applied, the field thus calculated was about 7 percent smaller than that obtained from the relation $E_1=-V_1/d$, where $V_1$ is the potential of the upper plate of the rectangular tube. The effect of space charge in decreasing the field intensity in the charging region was small enough to be neglected.

# Dislocation Theory as Applied by N.A.C.A. to the Creep of Metals

A. S. Nowick and E. S. Machlin
*Aircraft Engine Research Laboratory, Cleveland, Ohio*

(Received September 9, 1946)

An equation for the steady-state rate of creep of pure annealed polycrystalline metals is derived through dislocation theory and the theory of rate processes. The rate of generation of dislocations is shown to be the rate-determining process. A specific mechanism for the generation of a dislocation is presented, from which the heat and entropy of activation of the process are expressed in terms of physical constants of the material. In addition the lowering under stress of the potential energy barrier, which yields the stress-dependent term, is given in terms of constants of the material and a "back-stress" term. The creep equation thus obtained is found to be in good agreement with data in the literature.

## INTRODUCTION

Creep of metals is generally subdivided into three stages, as shown in Fig. 1. The initial stage, in which the slope of the elongation-*versus*-time curve (the rate of creep) is rapidly decreasing, is commonly designated the primary or transient stage; secondary or steady-state creep refers to the straight-line portion of the creep curve. After a sufficient length of time, the rate of creep increases in the region designated the tertiary stage.

The criterion generally used to evaluate the creep property of a given material at a particular stress and temperature is the steady-state creep rate. One of the first attempts to analyze steady-state creep by other than empirical methods was by Kanter.[1] Later, Kauzmann[2] applied Eyring's theory of liquid flow, which is a special application of the theory of rate processes, to the steady-state flow of metals. The problem of creep has also been attacked by the use of the theory of dislocations. A survey of results obtained thus far by this approach is reported by Seitz and Read.[3] Although these three treatments predict equations for the steady-state creep rate that show the correct dependence on stress and temperature, quantitative predictions cannot be

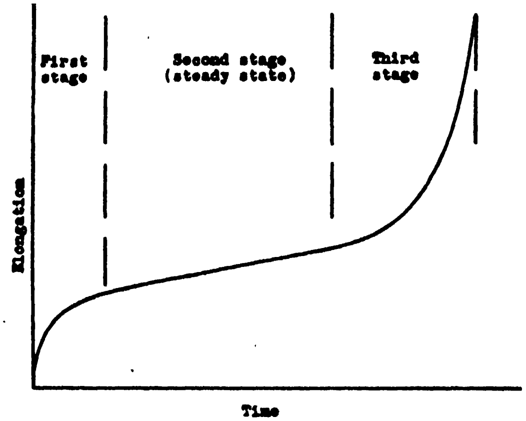

FIG. 1. A typical creep curve showing the three stages.

made from them as to how physical and structural constants of materials affect creep rate. Furthermore, difficulties were encountered in attempting to explain the large negative entropy of activation that experimental data showed.

This report derives an equation for the steady-state creep rate in terms of a specific dislocation mechanism which involves considering the generation of dislocations to be a rate process. The features of the theory of rate processes and of dislocation theory required for the development of the creep equation are first briefly reviewed; the derivation then follows.

The material contained herein was derived at the Cleveland laboratory of the N.A.C.A. and was originally presented as N.A.C.A. Technical Note No. 1039.

## THEORY OF RATE PROCESSES

The theory of rate processes,[4] as developed by Eyring and others, considers a reaction or any rate process to be the result of the crossing of a potential-energy barrier by molecules whose energies have exceeded a certain minimum value. The reaction consists of the formation of an "activated complex" capable of crossing the barrier followed by the passage of this complex over the barrier. The most important assumption is that the initial reactants and activated complexes are always in equilibrium. Application of thermodynamic and statistical mechanical considerations shows that the number $r$ of activated complexes passing over the barrier per second (or rate of reaction), per unit concentration of reactants is given by

$$r=\frac{kT}{h}\exp(-\Delta F_a/kT) \qquad (1)$$

in terms of Boltzmann's constant $k$, Planck's constant $h$, the absolute temperature $T$, and the free energy of activation per molecule, $\Delta F_a$.

The term $kT/h$ can be regarded as the effective frequency at which activated complexes cross over the barrier; the exponential factor represents the probability of formation of an activated complex. In the calculation of this probability term, the contribution due to the translational degree of freedom along the "reaction coordinate" (the most favorable reaction path on the potential-energy surface) has been disregarded because it is included in the factor $kT/h$. The free energy of activation $\Delta F_a$ is interpreted as an ordinary free-energy term and can be expressed by

$$\Delta F_a=\Delta H_a-T\Delta S_a, \qquad (2)$$

where the heat of activation per molecule $\Delta H_a$ is the height of the potential-energy barrier, and $\Delta S_a$ is the entropy of activation per molecule.

## DISLOCATION THEORY IN RELATION TO SLIP

Of several mechanisms suggested, the one that has been most successful in explaining the slip process is the theory of dislocations. This theory proposes that local deviations from a perfect lattice, called dislocations, exist in single crystals and that movement of dislocations through the stressed crystal produces slip. A dislocation consists in a stable arrangement of atoms such that, in a region of a few atomic distances, $n+1$ atoms in the slip direction face an adjacent parallel row of $n$ atoms across the slip plane. The point at which the atoms are one-half an atomic spacing "out of step" is called the center of the dislocation. The extension of the dislocation in the slip plane and normal to the slip direction is called the length of the dislocation. Two types of dislocations can exist: a dislocation is called positive if in the neighborhood of the center of the dislocation the compression is above the slip plane, and negative if the compression occurs

---

[4] S. Glasstone, K. J. Laidler, and H. Eyring, *The Theory of Rate Processes* (McGraw-Hill Book Company, Inc., New York and London, 1941), Chaps. I, IV, and IX.

below the slip plane. Positive and negative dislocations move in opposite directions under a given shear stress, but they produce the same net result in passing through the crystal, a relative translation of one atomic distance between the parts of the lattice above and below the slip plane.

Inasmuch as the passing of a dislocation out of the crystal lattice results in its loss, new dislocations must be generated in order for continuous plastic deformation to be possible. Because of the high energy required, the process generally takes place at regions of high stress concentration resulting from imperfections in the single crystals. The existence of such imperfections as a result of accidents of growth during the formation of single crystals is generally accepted, but the nature of the flaws that exist is still a matter of controversy. For example, the theory that single crystals are made up of a mosaic block structure is discussed by Seitz and Read. X-ray evidence indicates that the average spacing of the imperfections is of the order of 1 micron. The dynamic dislocation picture obtained is as follows: dislocations are generated under shear stress at the regions of high stress concentration, which will be called sources of dislocations. Upon generation, the dislocations are only a few atoms long because of the extremely low probability of generating a full-length dislocation (one whose length is of the order of the spacing between imperfections). As the dislocations move through the crystal under a shear stress, they increase in length and move in the slip plane and slip direction until they become stuck at an imperfection or in the vicinity of other dislocations.

Further details on the properties of dislocations as used to explain the qualitative aspects of plastic deformation are given by Seitz and Read.[3]

### DERIVATION OF THE CREEP EQUATION

In the analysis of the creep process, it will be assumed that creep as well as slip takes place by the motion of dislocations. If $L$ is the spacing between imperfections (in terms of the mosaic structure theory, the length of a mosaic block), we choose a cubic block of side $L$ and make two assumptions: (a) no "annihilation" (union of pairs of dislocations of opposite sign) takes place so that each dislocation passes completely through the block; (b) the block chosen is representative of the entire crystal in that it will shear at the same rate as any other similar block. This assumption follows from the requirement of a steady-state condition.

For the chosen block, the number of dislocations generated per second within the block must equal the number leaving the block per second, or

$$R_g N_s L^3 = N_d v L, \tag{3}$$

where $R_g$ is the rate of generation for a single generating source; $N_s$ is the number of sources per unit volume; $N_d$ is the number of dislocations per unit area that intersect a plane normal to the slip plane and containing the slip direction; and $v$ is the average velocity of the moving dislocations. Inasmuch as the displacement produced when a dislocation passes out of the block is equal to the lattice spacing $d_1$ between atoms in the slip direction, the shear rate $u'$ is given by

$$u' = \frac{1}{L}(N_d v L) d_1 = N_d v d_1. \tag{4}$$

The occurrence of slip bands at distances apart of the order of 1 micron indicates an average of about one source of dislocations for each block so that

$$u' = (d_1/L) R_g. \tag{5}$$

Up to this point, only creep of single crystals has been considered. In polycrystalline metals, it would appear that two types of creep are possible: creep within individual grains, and creep resulting from intergranular motion. As noted by Seitz and Read, present data on the effect of grain size on creep leave doubt as to the possibility of the occurrence of intergranular creep. For example, it has been shown[5] in work on copper of various grain sizes that there are no detectable differences in creep strength other than those resulting from oxidation. (Unfortunately this work was carried out only at a single temperature.) Creep in polycrystalline metals is therefore assumed to be predominately the result of deformation occurring within the individual grains by the motion of dislocations. If the

orientation of the grains is such that slip occurs in the plane of maximum shear stress, then, following Kauzmann, the strain rate $u'$ can be corrected to the tensile creep rate $u$ by an additional factor of about $\frac{2}{3}$. Such a factor would be of no consequence here because $d_1/L$ is known only in order of magnitude; accurate values cannot be given until more is known about the nature of the crystal imperfections. The tensile creep rate $u$ of a polycrystalline material can therefore be written approximately as

$$u=(d_1/L)R_g. \qquad (5')$$

In calculating the rate of generation $R_g$, the generated dislocation will be taken to be 1 atom long. A simple model for the generation of a positive dislocation at a right-hand source[6] is presented in Figs. 2(a) and (b). If atoms 1 and 2 are simultaneously displaced in the directions shown in Fig. 2(a) by large fractions of the lattice spacing, and atoms 3, 4, and 5 are moving in the slip direction as shown, the generation of a dislocation becomes possible. Before a dislocation will form, however, a rearrangement of the neighboring atoms must take place in order to achieve a stable configuration. Figure 2(b) shows the rearranged condition. The new positions of atoms 5 and 6 after rearrangement were found by using the approximate method of Taylor[7] in his discussion of the motion of a dislocation under stress. The contributions to the potential field in row $B$ by the neighboring rows $A$ and $C$ are taken to be sinusoidal with periods equal to the spacing of atoms 1 and 3 in row $A$ and atoms 2 and 4 in row $C$. Figure 2(c) shows that addition of the two sinusoidal potential functions gives a resultant potential function having four minima. Atoms 5, 6, and 7 can be expected to fall into the deepest of these minima if atom 5 had begun by oscillating to the left as in Fig. 2(a).

The displacement $\delta$ of atoms 1 and 2 will be some fraction $f$ of the atomic separation $d_1$ in the slip direction. A value of $f$ of somewhat less than $\frac{1}{2}$ makes it possible to form a stable configuration with a minimum activation energy.

The mechanism just presented is an example of a rate process where the "reactant" is the perfect lattice at the region of high stress concentration. The "activated complex" for a positive dislocation, which for brevity will be called a positive activated complex, can be taken as the configuration shown in Fig. 2(a) and the "product" as the dislocation after atomic rearrangement has taken place (Fig. 2(b)). If the fundamental assumption of rate-process theory that equilibrium exists between reactant and activated complex is made, the considerations involved in the theory of rate processes can be applied to the generation of dislocations. If $t$ is the average time for the activated complex to pass into final form, the rate of generation of positive dislocations $R_g^+$ can be expressed as

$$R_g^+=(1/t)P^+, \qquad (6)$$

where $P^+$ is the probability of formation of a positive activated complex at a right-hand source.

It has been shown[8] that if the displacement involved in the transition from the activated complex to the final state is on the order of $10^{-8}$ centimeter, the factor $1/t$ is approximately equal to $kT/h$. In the formation of a dislocation, this transition corresponds to passing from the configuration of Fig. 2(a) to that of Fig. 2(b), which clearly involves a displacement of this order of magnitude. Hence, $R_g^+$ is given approximately by

$$R_g^+=(kT/h)P^+. \qquad (7)$$

Similarly, for the rate of generation of negative dislocations,

$$R_g^-=(kT/h)P^-, \qquad (7')$$

where $P^-$ is the probability of formation of a negative activated complex at a right-hand source.

In order to simplify the calculation of $P^+$ and $P^-$, the generation of a dislocation will be treated as a "local shear" which takes place by means of thermal oscillations. The energy involved in this process will be calculated by the theory of elasticity. Furthermore, Hooke's law will be assumed valid for large strains. The use of these assumptions is necessary because the forces between individual atoms have not been evaluated in terms of physical constants, but it should be remembered that the approximations may be serious enough to lead to large errors in the results. The thermal atomic oscillations in Fig. 2(a) will be regarded as resulting in a local shearing of atoms 1, 6, and 2 producing a strain of $\delta/d_2$. Inasmuch as the elastic energy per unit volume for a shear stress $\tau$ is $\tau^2/2G$ where $G$ is the modulus of rigidity, and the volume of the

---

[6] A source of dislocations will be called a right-hand source if it generates dislocations to the right, and a left-hand source if it generates to the left. The sources are taken to be at "internal surfaces," for example, the edge of a surface of misfit between mosaic blocks.

[7] G. I. Taylor, Proc. Roy. Soc. (London) **A145**, 362 (1934).

[8] Glasstone, Laidler, and Eyring, reference 4, p. 189.

region of shear under consideration is twice the atomic volume $V$, the elastic energy involved is

$$W=V\tau^2/G. \tag{8}$$

Now, let $\tau_0$ be the local shear stress attained by atoms 1, 6, and 2 in Fig. 2(a). If the displacement $\delta$ is some fraction $f$ of $d_1$, application of Hooke's law to the displacement yields

$$\tau_0=Gxf, \tag{9}$$

where $x$ is defined as the ratio $d_1/d_2$. If the source of generation is under a stress $\tau_s$, as shown in Fig. 2, the energy $W_t$ to be attained thermally is, by (8)

$$W_t=(V/G)(\tau_0-\tau_s)^2. \tag{10}$$

Inasmuch as $\tau_s$ may be expected to be only a small fraction of $\tau_0$ for rigid materials, the term in $\tau_s^2$ may be neglected in the binomial expansion of $(\tau_0-\tau_s)^2$, so that, incorporating (9), we obtain

$$W_t=VGx^2f^2-2Vxf\tau_s. \tag{11}$$

In order to evaluate $\tau_s$, work-hardening must be considered. A crystal in the steady-state range of creep is generally work-hardened because deformation has taken place. From the nature of a dislocation it is clear that a stress field exists about it. By making use of this stress field, Taylor[7] has explained work-hardening on the basis of a "lattice" of stuck dislocations. Taylor's explanation is a static one and is applied only to determining the form of the stress-strain curve. In terms of a dynamic approach, the existence of a stress field about a dislocation leads to the concept suggested by Kochendörfer[9] that the lattice of stuck dislocations creates an inner stress field whose direction at the point of generation is opposite to the externally applied shear stress $\tau_e$ in the slip plane. The value of the inner stress field at the point of generation will be called the back stress $\tau_b$. The dynamic concept of hardening therefore consists in the formation of a lattice of stuck dislocations, which results in a back stress at the point of generation. This back stress lowers the effective shear stress at these points, and as a result the rate of generation, hence the creep rate, decreases. These considerations lead to the result that

$$\tau_s=q(\tau_e-\tau_b), \tag{12}$$

where $q$ is the stress concentration at the generating source. Inasmuch as $\tau_b$ is always less than $\tau_e$, the directions of $\tau_e$ and $\tau_s$ are the same.

In addition to the energy of local shear, the configuration of Fig. 2(a) involves a limitation of the movement of atoms 1, 2, 3, 4, and 5 to a particular crystallographic direction within a very small solid angle. If the probability of oscillation in this direction is $p$, the total probability of the configuration of Fig. 2(a) is

$$\begin{aligned}P^+&=p^5\exp(-W_t/kT)\\&=p^5\exp[-(VGx^2f^2-2Vxf\tau_s)/kT].\end{aligned} \tag{13}$$

Similarly the probability of forming a negative activated complex (the configuration of Fig. 2(d)) at a positive source is

$$P^-=p^5\exp[-(VGx^2f^2+2Vxf\tau_s)/kT], \tag{13'}$$

because $\tau_s$ is opposite to $\tau_0$ in this case. The applied stress $\tau_e$ therefore makes the generation of a positive dislocation more probable than the generation of a negative dislocation at a right-hand source.

If a negative dislocation is generated in the region under discussion, it would move to the left and out of the crystal without producing deformation if it were the only dislocation present. The last positive dislocation generated from this source, however, became stuck after moving through part of the crystal lattice; that is, all forces upon it were balanced. The generation of a negative dislocation at the point being considered will upset this equilibrium and attract the previous positive dislocation. As the two dislocations approach each other, the stress that each exerts on the other increases,[10] and a union takes place resulting in the annihilation of the two dislocations and restoration of a perfect lattice. The net rate of generation $R_g$ of positive dislocations that will eventually produce plastic deformation is $R_g^+-R_g^-$ or from Eqs. (7), (7′), (12), (13), and (13′)

$$\begin{aligned}R_g=\frac{2kT}{h}&\exp[-(VGx^2f^2+CT)/kT]\\&\times\sinh[2qVxf(\tau_e-\tau_b)/kT],\end{aligned} \tag{14}$$

where

$$C=-k\ln p^5. \tag{15}$$

---

[9] A. Kochendörfer, Zeits. f. Physik 108, 244 (1938).

[10] From the equation for the stress field about a dislocation; see Taylor, reference 7.

The equation for the net rate of generation of negative dislocations at a negative source is clearly identical with (14).

According to this derivation, it is now clear that the generation of a dislocation 2 atoms in length involves the simultaneous oscillation of twice as many atoms with sufficiently great energies. Thus, the probability of such a generation taking place can be neglected as compared with the probability of generating a 1-atom dislocation.

Comparison of (14) with Eqs. (1) and (2) now shows that the heat of activation (the height of the barrier for zero applied stress) and the entropy of activation are given, respectively, by

$$\Delta H_a = VGx^2f^2, \tag{16}$$

$$\Delta S_a = -C. \tag{17}$$

$C$ is always positive because $p$ is less than 1, so $\Delta S_a$ is negative.

When the expression (14) for $R_a$ is combined with the creep equation (5′), the complete equation for the steady-state creep rate $u$ becomes

$$u = \frac{2d_1}{L}\frac{kT}{h}\exp[-(VGx^2f^2+CT)/kT] \times \sinh[qVxf(\sigma-2\tau_b)/kT], \tag{18}$$

where the applied tensile stress $\sigma$ has been substituted for $2\tau_e$ assuming that slip in the individual grains occurs in the plane of maximum shear stress. For high values of $\sigma$, the hyperbolic sine function becomes an exponential, or in logarithmic form

$$\ln u = \ln\left(\frac{d_1kT}{Lh}\right) - \left(\frac{VGx^2f^2+CT}{kT}\right) + \frac{qVxf}{kT}(\sigma-2\tau_b). \tag{19}$$

## COMPARISON OF THEORETICAL AND EXPERIMENTAL CREEP EQUATIONS

The evaluation of the back stress $\tau_b$ as a function of $T$ and $\sigma$ is difficult and has not yet been accomplished. We will therefore compare the theoretical results with empirical equations. It has been found that a hyperbolic sine function represents the dependence of creep rate on applied tensile stress $\sigma$ for many polycrystalline materials[11] in agreement with Eq. (18). It has also been shown[12] that creep rates of a large number of materials can be represented in the form

$$\ln\frac{u}{T} = -\frac{a}{T} - b + \gamma\sigma, \tag{20}$$

where $a$ and $b$ are constants for a given material and $\gamma$ is a function of temperature but not of stress. If the notation is changed, (20) can be rewritten

$$\ln u = \ln\left(\frac{d_1kT}{Lh}\right) - \frac{A+BT}{kT} + \frac{\beta\sigma}{kT}, \tag{21}$$

where

$$A = ka,$$

$$B = kb + k\ln\frac{d_1k}{Lh},$$

$$\beta = \gamma kT.$$

The simultaneous validity of (19) and (21) requires that $\tau_b$ be a linear function of stress. In addition, the condition $\tau_b = 0$ for $\sigma = 0$ which should apply at least to annealed metals, yields

$$\tau_b = F(T)\sigma, \tag{22}$$

where $F(T)$ depends only on temperature and material parameters. Equation (21) shows that three factors determine the creep rate, the constants $A$ and $B$ and the temperature function $\beta$. Comparison of (21) with (19) shows that these factors are expressed in terms of physical constants of the material as

$$A = VG_0f^2x^2, \tag{23}$$

$$B = C - Vf^2x^2G_0\alpha, \tag{24}$$

$$\beta = qVxf(1-2F(T)), \tag{25}$$

where the modulus of rigidity $G$ has been taken in the approximate form

$$G \doteq G_0(1-\alpha T), \tag{26}$$

where $G_0$ is the modulus of rigidity at absolute zero.

It seems clear that the structure sensitivity of the creep property, which is particularly important in alloys, will be mainly due to the back

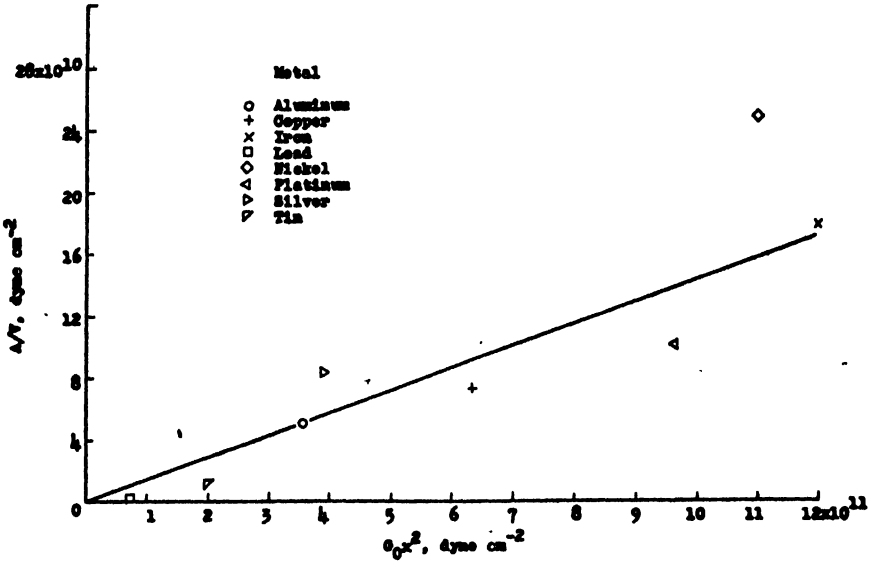

FIG. 3. Comparison of experimental data for factor $A$ with theory.

stress term and will therefore appear in the factor $\beta$.

## COMPUTATIONS AND PRECISION

Creep data were obtained from the literature[13] for a number of polycrystalline "pure" metals that had been annealed. The reproducibility of the creep data from the various sources is not known. The data were plotted up similarly to Dushman and the factors $A$, $B$, and $\beta$ obtained. The factor $d_1/L$ was taken as $10^{-4}$ for all materials.

Generally, the errors in $A$, $B$, and $\beta$ were estimated to be about $\pm 5\times 10^{-13}$ erg, $\pm 8\times 10^{-16}$ erg/°K, and ±30 percent, respectively.

Room temperature values of $G$ were used as approximations to $G_0$.

## RESULTS AND DISCUSSION

### The Factor A

In Fig. 3, $A/V$ is plotted against $G_0x^2$. The line drawn is the best straight line through the origin and generally represents the data within the estimated error of $A$. From Eq. (23) and the above discussion the slope of the line is $f^2$ and should be somewhat less than 0.25. Because the activation energy predicted on the basis of the validity of Hooke's law will be greater than the actual value, it can be expected that the theoretical prediction will be too high. The experimental slope from the straight line of Fig. 3 is 0.14. This agreement is good considering the assumptions made and variety of sources of data used. It gives further verification that the generated dislocation is only one atomic distance in length.

### The Factor B

The order of magnitude of the term $Vf^2x^2G_0\alpha$ of Eq. (24) which is $3\times 10^{-16}$ erg/°K, is within the experimental error of $B$, $\pm 8\times 10^{-16}$ erg/°K; this term can therefore be neglected in consider-

ation of the $B$ values. Therefore $B$ becomes equal to $C$, or from (17) to the negative of the entropy of activation $\Delta S_a$. The results obtained from the data are listed in Table I.

A correlation exists between the variation from the best straight line of data presented in Fig. 3 and the variation in $B$ values. The points above the line are all related to metals that have $B$ values less than 40 and those below the line to $B$ values greater than 40. From the method of plotting the data to obtain $A$ and $B$ values, a positive error in $A$ means a negative error in $B$. This correlation therefore indicates that the correct values of $B$ fall about their mean value more closely than the values in the table. In addition, errors in the substitution of $10^{-4}$ for $d_1/L$ and $kT/h$ for $1/t$ will enter into the $B$ factor. The entropy of activation $\Delta S_a$ therefore seems to be very closely the same for all materials considered. This is in agreement with the theory since the factor $p$ should be about the same for all materials.

The large negative value of the entropy of activation $\Delta S_a$ has previously been pointed out by Kauzmann and by Dushman, but satisfactory explanations for the magnitude of this factor could not be given. In terms of the present treatment, the large negative $\Delta S_a$ is accounted for by the restriction of direction of 5 atoms participating in the generation of an activated complex. A value of about $3\times 10^{-3}$ is obtained for $p$ when $C=40\times 10^{-16}$ erg/°K. The possibility that more than 5 atoms must be restricted in direction certainly exists, so that $p$ may be larger than the above value.

### The Factor $\beta$

For a large number of materials the temperature dependence of $\beta$ could be approximated by the function

$$\beta = C_1 \exp C_2 T,$$

where $C_1$ and $C_2$ are positive constants. This function was used to extrapolate to room temperature values.

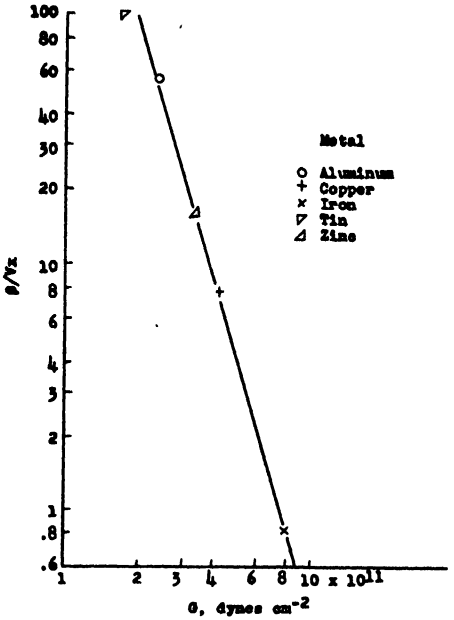

FIG. 4. Room temperature dependence of $\beta/Vx$ on the modulus of rigidity $G$.

The term $F(T)$ in (25) is related to the back stress $\tau_b$ which results from the internal stress field about a dislocation. This stress field is dependent on $G$. Therefore, $\beta$ at any given temperature was expected to be a function of $G$. Figure 4 shows that, for the materials shown, the $\beta$ values extrapolated to room temperature vary as $G^{-n}$ where $n$ is approximately 3.

## CONCLUSIONS

The analysis presented in this report shows that dislocations are generated by the formation of an activated complex configuration in a small region. Limitation of the direction of motion of a group of atoms results in a large negative entropy of activation for the process. When generated, the dislocations are probably just one atom long.

# Application of the Sliding Thermocouple Method to the Determination of Temperatures at the Interface of a Moving Bullet and a Gun Barrel*

E. L. ARMI,† J. L. JOHNSON, R. C. MACHLER, AND N. E. POLSTER
*Leeds and Northrup Company, Philadelphia, Pennsylvania*

(Received May 31, 1946)

Description is given of a set-up for the determination of temperatures at the frictional interface between a moving bullet and the bore in a caliber 0.50 gun barrel. Cathode-ray oscilloscope e.m.f.-time records, which were obtained from a traveling thermocouple junction formed by the bullet-bore interface, are interpreted (by use of a formula due to Jaeger) in terms of instantaneous temperatures. A calorimetrically measured value of the total frictional heat input caused by a bullet being pushed through a barrel section by means of a falling weight, is found to be in good agreement with the value of the heat input calculated from bore surface temperatures which were determined by the sliding thermocouple method.

## INTRODUCTION

DURING the course of an investigation on values of local heat input associated with the firing of individual rounds of ammunition in caliber 0.50 machine gun barrels, it became desirable to obtain an idea of the magnitude of that part of the heat which is caused by friction between bullet and bore, and also an idea of the bore surface temperatures which are reached during this frictional process, before the onset of heat input from the hot powder gases.

A falling weight apparatus with a usable free fall of 65-foot length was modified to drive bullets with fair velocity through a short length of barrel held in a suitable mounting. Making use of the fact that the frictional interface between bullet and bore is also an e.m.f.-generating interface, because of a difference in the thermoelectric potential of the two materials involved (gun steel, gilding metal), effective temperatures at the interface were determined from a measurement of the e.m.f. from this somewhat complex "sliding band thermocouple." Having found the approximate temperature-time curve of a point on the bore, it was easy to calculate the local frictional heat input into the barrel wall. On the other hand, this heat input was also measured directly by a calorimetric method, and thus a check was obtained on the results of the sliding thermocouple method.

Sliding thermocouple measurements were also carried out on caliber 0.50 barrels in actual firings, but the check against calorimetric heat input measurements had to be omitted in this case, because of the impossibility of separating the frictional heat input from that of the powder gases.

## FALLING WEIGHT APPARATUS

Figure 1 gives a view of the falling weight apparatus, with the carriage in raised position. Two taut wire rope guides reached up to a height of 65 feet above a solid concrete foundation. The carriage, sliding on four bearings, was pulled up by a rope and was dropped with the aid of an electromagnetic release mechanism. The weight of the carriage, including the steel bar at its bottom, amounted to 40 lb; occasionally, additional bars were clamped onto the carriage in order to increase the kinetic energy of the system. At the end of its fall the carriage hit a piston which in turn drove the bullet through a short length of barrel, held in a heavy steel base. Excess kinetic energy was taken up by lead stops of suitable size.

Electrical connection to the bullet was made by means of a shielded flexible cable soldered to the tip of the bullet; the grounded shield of the cable was connected to the barrel section. E.m.f.'s generated at the frictional interface were amplified in a Ballantine Decade Amplifier (Model 220) before being made visible on the screen of a DuMont cathode-ray oscillograph

---

* The work reported in this article was undertaken as part of contract OEMsr-536 between the Leeds and Northrup Company and the Office of Scientific Research and Development, under the supervision of Division One of the National Defense Research Committee.

† Now Director of Technical Department, Mica Insulator Company, Schenectady, New York.

(Type 175A). The latter was operated with single sweeps which were obtained from a DuMont low-frequency linear time base Generator (Type 215) and which were triggered by the closing of a contact shortly before the carriage hit the piston driving the bullet. Figure 1 shows the double spike on the carriage, which closed the sweep initiating circuit of the time base generator by connecting the two mercury pools in the reservoirs visible below the spikes.

Details of the construction of the barrel section holder can be seen in Fig. 2. (The thermocouple shown on the outside of the barrel section was used for the calorimetric measurements discussed under the heading "Theory of Calorimetric Measurements in Barrel Sections.") In most tests the barrel sections had special 0.500″/0.520″ rifling (bore diameter 0.500″ across lands, 0.520″ across grooves) instead of the regular 0.500″/0.510″ rifling of caliber 0.50 guns, in order to avoid contact of the bullets with the bottom of the grooves of the rifling; the generation of thermal e.m.f. was thereby restricted to the area of the top and (part of) the sides of the rifling bands ("lands"), and the interpretation of the records obtained became somewhat simpler. All barrel sections had at their entrance a forcing cone (origin of rifling) of standard taper.

## INTERPRETATION OF CRO TRACES OF THE INTERFACE THERMAL E.M.F.

Interpretation of the experimental data was greatly helped by a paper of J. C. Jaeger, on "Moving Sources of Heat and the Temperatures at Sliding Contacts,"[1] in which temperatures in a semi-infinite conductor are worked out for the motion of a band source of heat over the conductor, and this analysis is applied to the case where a slider moves with constant friction over a metallic surface. Jaeger shows that, for high

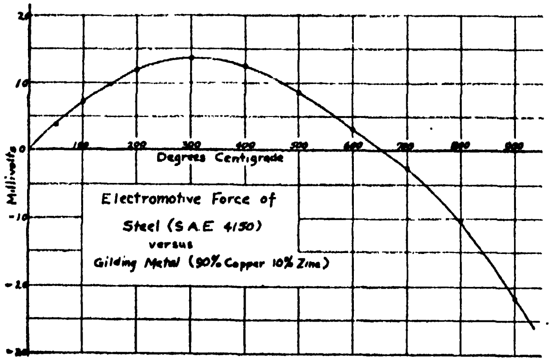

FIG. 3. E.m.f. calibration curve of gun steel *vs.* gilding metal.

sliding speeds and after a steady state is reached, the instantaneous temperature distribution over the surface of the metal in contact with the slider can be approximated by[2]

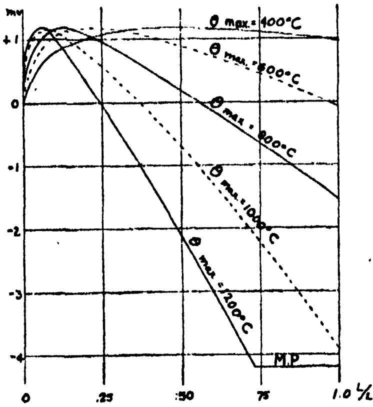
$$\theta/\theta_{\mathrm{max}} = (L/L_0)^{\frac{1}{2}}, \qquad (1)$$

where $\theta$ is the temperature rise on the surface of the metal, $L$ the distance back from the front edge of the "band source," and $L_0$ the total width of the "band source." It seems permissible, for a first approach to the solution of the problem, to assume that the conditions of the theory are satisfied to an acceptable degree in the case of a bullet sliding over the (spirally rifled) bore surface, whereby the frictional contact area corresponds to the heat-generating band of the mathematical analysis.

Matters become complicated by the behavior of the e.m.f.-temperature curve of the particular combination of metals in the sliding thermocouple (gun steel *vs.* gilding metal). Figure 3 shows a calibration curve taken on a sample thermocouple, the two wires of which were cut from a bullet jacket and a gun barrel, respectively. This curve, which has its maximum at about 300°C, is parabolic in its general shape; all e.m.f. readings are, therefore, essentially ambiguous since their correlated temperatures can lie either on the ascending or the descending branch of the calibration curve. It should also be kept in mind that the e.m.f. recorded is essentially an arithmetical average of the e.m.f.'s generated over the whole frictional interface area at the instant concerned; but, because of the nonlinearity of the e.m.f.-temperature curve, the temperature corresponding to the average of the e.m.f.'s is not at all identical with the average of the temperatures which cause the generation of these e.m.f.'s.

Figure 4, based on Eq. (1) and Fig. 3, gives curves of the e.m.f.'s which are generated locally along the frictional interface. Of course, these e.m.f.'s are never measured as such, since only the average over all locally generated e.m.f.'s is recorded on the CRO screen. Figure 5, above the designation "full contact," shows this average for several values of $\theta_{\mathrm{max}}$. However, it should be remembered that the "local" e.m.f.'s are actually averages too, namely over-all points which make contact with the bore on a particular circumference of the bullet. (It is therefore, in general, quite possible to find points which have temperatures in excess of the effective "maximum temperature.") Since the temperature in the frictional process is unlikely to exceed the melting point of the material of the bullet jacket (gilding metal), the curves for a fictitious $\theta_{\mathrm{max}} = 1200°$ have to stop at the e.m.f. corresponding to the temperature of that melting point (about 1050°C).

As long as the bullet is fully in contact with the bore surface, averaging of the e.m.f.'s takes place over the whole of the curves of Fig. 4. However, when the bullet is entering or leaving the barrel section, the average is taken over only that part of the curve which corresponds to actual contact with the bore. Figure 5 gives e.m.f.



LOCAL EMF ON MOVING INTERFACE THERMOCOUPLE
(COLD JUNCTION 25° C)

FIG. 4.

---

[2] J. C. Jaeger, reference 1, Eq. (14).

curves which were obtained by carrying out the averaging as indicated, for the bullet entering, traversing, and leaving the barrel section, with $X/L_0$ denoting the ratio between instantaneous length of contact and length of contact for a fully entered bullet. The relative length of the center part of the curve, designated "full contact," varies, of course, with the length of the barrel section used.

## COMPARISON BETWEEN THEORETICAL AND OBSERVED FORMS OF OSCILLOGRAM RECORDS

Figure 6 shows three frictional interface e.m.f. traces, together with theoretical curves for $\theta_{\max} = 825°C$ and 910°C, respectively, for a $3\frac{5}{8}$ in. long barrel section. Disregarding irregularities of detail, these traces are seen to conform well with the theoretical curves; in fact, it is almost surprising that in spite of the simplifications made for the computation of the theoretical curves, such satisfactory agreement with experimental work was achieved. The maximum temperatures ($\theta_{\max}$) encountered on these and other similar records are found to be between 800°C and 950°C.

Speculating on the causes for the irregularities in the traces, it can be said that the vibrations seen on most traces are probably caused by a longitudinal oscillation of the bullet; careful degreasing of bullet and barrel had the effect of accentuating this vibration as well as of raising the interface temperature. A local increase in frictional pressure causes additional heat development and, consequently, a rise in the interface temperature; it is therefore probable that some of the deviations from theoretical curves are due to variations of pressure. The passage of the crimped portion of the bullet jacket might be expected to be noticeable in the traces, and, indeed, the secondary peak in most exit traces may be attributed to it. Finally, since interface temperatures go up with an increase in the velocity of the bullet, the traces for 64-foot drops are seen to correspond to slightly higher temperatures than those for 32-foot drops. In the

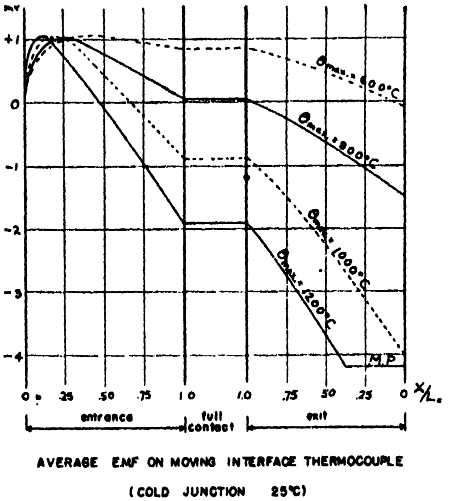


FIG. 5.

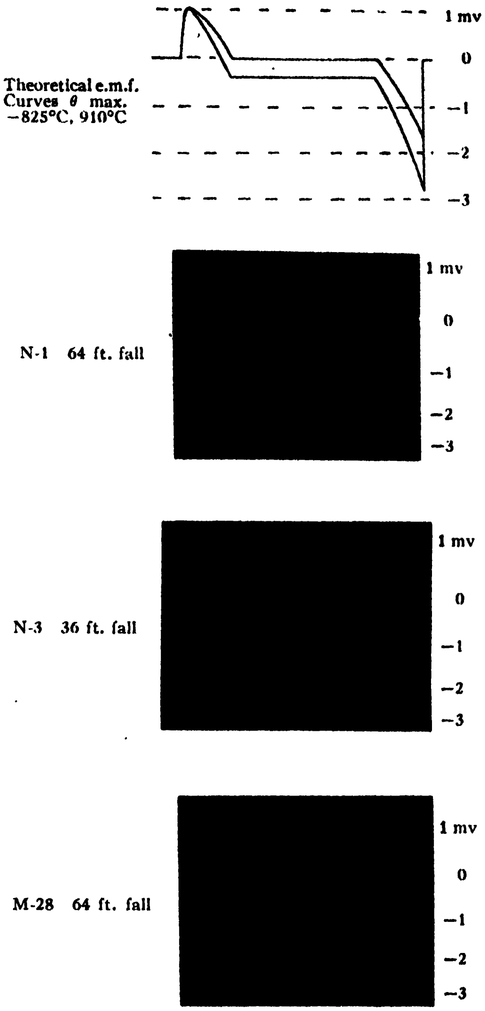

FIG. 6. Interface thermal e.m.f. traces taken with falling weight apparatus. Barrel section No. 4 (0.500"/0.520")—40-lb. carriage. Timing dot intervals 1/5000 sec. Oiled M2 bullets.

first approximation, the interface temperature rises with the square root of the velocity,[3] but, at higher temperatures the coefficient of friction decreases, and the interface temperature eventually levels off. In the case of drops with low initial kinetic energy, where the bullet velocity decreases appreciably during the travel through the barrel section, the e.m.f. traces observed were found to be distorted in accordance with the expected decline in the interface temperatures.

Figure 7 shows four records which were taken on a 2-in. long barrel section. These records are quite similar to those seen in Fig. 6, but, since they were taken on a much shorter barrel section, the flat central portion of the traces is correspondingly shortened. While the general agreement among traces which were taken under similar conditions is quite satisfactory, it is not surprising to find a number of minor variations between individual traces, due to small changes in local conditions between individual rounds.

## INTERFACE THERMAL E.M.F. TRACES FROM FIRED BULLETS

After the work with the falling weight apparatus had given encouraging results, an attempt was made to obtain records of the frictional interface e.m.f. for actually fired bullets. The problem of keeping an insulated wire attached to the tip of the moving bullet was considerably simplified when the barrels were cut down to only 6 in. of rifled length. Experiments undertaken with these short barrels gave quite satisfactory results.

Since it was found desirable to correlate the recorded instantaneous thermal e.m.f. with the position of the bullet, a simple apparatus was devised to record the time when the bullet passed through certain points. A number of hardened steel wires were placed at fixed distances in an insulated holder over the muzzle end of the shortened barrel. A disk mounted on a "harpoon" which extended from the front end of the bullet, touched and broke these steel wires in succession, as the bullet moved forward, and thereby closed and opened a circuit which applied a fixed voltage to the CRO. A leaf-spring contact, mounted at the rear end of the barrel receiver was automatically closed by the motion of the firing mechanism and thereby made to initiate a single sweep on the CRO; the closing and opening of the circuit through the bullet harpoon and the

---

[3] J. C. Jaeger, reference 1, Eq. (33).

steel wires, during the sweep, was used to obtain position-time records.

The electrical set-up for taking frictional interface e.m.f. traces during the firing was the same as that for the falling weight apparatus, with the above-mentioned contact on the barrel receiver taking the place of the spikes on the carriage and the twin mercury pools as switching device for the initiation of a single sweep on the CRO.

Traces obtained with a fired bullet are essentially similar to those from the falling weight apparatus, however, because of the much higher velocity of a fired bullet, fusing is found to occur over a considerable portion of the frictional area; the simple parabolic temperature distribution over the length of the area of contact, which is valid with a constant coefficient of friction, does therefore not hold for this case. Furthermore, since the CRO traces give records of e.m.f. *vs.* time rather than *vs.* travel, the traces obtained have to be redrawn with the use of position-time records, if records of e.m.f. *vs.* travel are desired.

## THEORY OF CALORIMETRIC MEASUREMENTS IN BARREL SECTIONS

In addition to the recording of interface thermal e.m.f.'s, the experimental set-up was well suited and easily adapted for calorimetric measurements of the amount of frictional heat transferred to the barrel wall. It appeared of interest to carry out such measurements and to compare the results obtained with heat input values which were calculated from bullet-bore interface temperature determinations.

A heat input $H$ per unit area of bore wall, in a given unit length of barrel (of annular cross section), causes a temperature rise $\theta_e$ throughout that length amounting to, after temperature equilibrium has been reached,

$$\theta_e = \frac{H}{bc\rho}\frac{1}{1+b/d}, \tag{2}$$

where $b$ is the thickness of the barrel wall in the section, $d$ the bore diameter, $c$ the specific heat of the barrel material, and $\rho$ its density.

The time required to reach thermal equilibrium throughout the barrel section varies approximately with the square of the thickness of the barrel wall,[4] and, *e.g.*, for a wall thickness of $\frac{1}{4}$ in., it is of the order of 2 sec.

While the reading of the "barrel calorimeter" is not affected by a continuous variation in the heat input over the length of the barrel, a discontinuity in the amount of the heat input, or a change in the cross section of the barrel, or any other "end effect" does influence the temperature in the cross section in which the measurement is taken. Thus, a temperature difference $\delta_e$, which is maintained at a distance $x$, causes a temperature difference $\delta$ in a cross section of thermal diffusivity $a^2$, after a time $t$, according to[5]

$$\delta/\delta_e = 1 - \mathrm{erf}(x/2at^{\frac{1}{2}}). \tag{3}$$

Therefore, although the calorimetric measurement cannot be made before radial temperature equilibrium has been attained, it is essential that the reading or recording be completed before any temperature difference due to axial flow becomes appreciable. *E.g.*, a value of $\delta/\delta_e = 0.0025$ is reached in steel after about 25 sec. with $x = 3$ in.; with $x = 1$ in., the same value is reached after slightly less than 3 sec.

Depending on the time required to carry out the temperature measurement (whether done manually or by some automatic recording equipment) the distance $x$ has to have a definite minimum value. *E.g.*, for heat input determinations in caliber 0.50 firings, the distance of a thermocouple from the end of the "calorimetric section" of reduced outside diameter could be kept as short as 1 in., when measurements were made with a Leeds and Northrup Speedomax A (electronic potentiometer recorder); this distance allowed a time of about 1 sec. between the establishment of radial temperature equilibrium and the beginning of a perceptible temperature decay in the section, caused by heat flow to the ends of the "calorimetric section."

The amount of heat received by any point on

---

[4] $$\theta/\theta_e = 1 + \sum_{n=1}^{\infty} (-1)^n \exp(-n^2\pi^2a^2t/b^2).$$

See H. S. Carslaw, *Mathematical Theory of the Conduction of Heat in Solids* (The Macmillan Company, London, 1921), second edition, Chap. IX.

[5] H. S. Carslaw, reference 4, Chap. III.

the bore during passage of a bullet is given by[6]

$$H=\left(\frac{kc\rho}{\pi}\right)^{\frac{1}{2}}\int_0^{\tau}\frac{\theta(t)}{(\tau-t)^{\frac{1}{2}}}dt, \qquad (4)$$

where $H$ is the heat input per unit area of bore, $k$ the thermal conductivity, $c$ the specific heat, $\rho$ the density of the barrel material, $\theta$ the temperature rise of the bore as a function of time $t$, and $\tau$ the total time of contact of the point concerned.

Assuming that it is permissible to approximate the temperature distribution over the contact area of the bullet with the bore by Eq. (1), which is valid for a "slider" moving under steady-state conditions, the temperature of a fixed point on the bore, during passage of the bullet, is given by:

$$\theta(t)=\theta_{\max}(t/\tau)^{\frac{1}{2}}. \qquad (5)$$

Substituting (5) into (4) and integrating, one obtains finally:

$$\theta_{\max}=\frac{2}{\pi^{\frac{1}{2}}}\frac{H}{\tau^{\frac{1}{2}}(kc\rho)^{\frac{1}{2}}}. \qquad (6)$$

## RESULTS OF CALORIMETRIC MEASUREMENTS

For heat input measurements in the falling weight apparatus, the "calorimetric section" had a length of 3⅝ in., with the couple peened in its center; no thermal insulation at the ends of the section was required. A special Leeds and Northrup mirror galvanometer recorder was used as recording equipment.

The frictional heat input values obtained by the "calorimetric section" method scatter rather widely, averaging 2.85 cal./cm² and 3.65 cal./cm² for drops from 64 feet and 32 feet height, respectively, when referred to the whole bore surface; when only the area of actual contact (assumed to consist of the top and about one-half of the sides of the lands) is taken into account, these values rise to 8.7 cal./cm² and 11.0 cal./cm², respectively, in a 0.500″/0.520″ rifled barrel section, at about 1¾ in. beyond the origin of rifling.

When these heat input values are substituted in Eq. (6), with $(kc\rho)^{\frac{1}{2}}=0.31$ cal./°C cm² sec.$^{\frac{1}{2}}$ (for steel) and a length of contact $L_0=2.0$ cm, values of $\theta_{\max}$ between 950°C and 1000°C are obtained for either case (with bullet velocities of about 60 ft./sec. and 40 ft./sec., respectively). These temperatures are somewhat higher than those calculated from sliding thermocouple records (800°C to 950°C); however, in view of the simplifying assumptions made for the calculations and of the various uncertainties involved, the agreement can be considered quite satisfactory. Furthermore, the errors in the temperatures calculated are in the direction to be expected; while Eq. (4) is based on the assumption of linear heat flow from the bore surface into the barrel, heat actually is generated over only a fraction of the bore surface (top and about one-half of sides of lands) in barrels used for this work, and it spreads from there two-dimensionally, with the effect that a lower temperature than with strictly linear flow is required at the contact area in order to produce a given heat input; this effect increases rapidly with duration of the time of contact, and is therefore more pronounced for 32 foot drops than for 64 foot drops.

Concluding, it may be said that frictional temperature determinations by means of the sliding thermocouple method gave satisfactory results in an application where no other known methods of temperature measurement could be used.

---

# Carbide Structures in Carburized Thoriated-Tungsten Filaments

C. W. HORSTING
*Tube Department, Radio Corporation of America, Harrison, New Jersey*

(Received April 16, 1946)

A wide variety of carbide structures is described, as found in the surface layer of carburized thoriated-tungsten filaments. Their origin is traced back to carburizing conditions and subsequent processing during tube making. A frequently occurring laminated carbide structure is found to contain less carbon than $W_2C$. The thyratron relay method of carburizing control is critically reviewed. Abnormal filament current in manufactured tubes is explained as due to surface conditions which cause changes in thermal emissivity.

THE application of carburized tungsten-filament cathodes is a well-known practice in radio tube manufacture, especially in the power tube field where high electron emission is required at high voltages. By the use of this method, longer filament life and higher operating temperatures are possible because, it is claimed, the emission-causing thorium layer at the filament surface adheres more firmly to the tungsten-carbide surface than to the pure tungsten surface.[1]

During the production of power tubes, the tungsten filaments are partially converted into tungsten carbide by heating them electrically in a hydrocarbon atmosphere to a temperature of about 2200°C. The hydrocarbon is decomposed at the hot filament surface to produce free carbon which diffuses into the tungsten, forming tungsten carbide. The degree of carburization is limited by the fact that the mechanical strength of the filament decreases rapidly with increasing carbon penetration. In practice, therefore, the carburizing reaction has to be stopped accurately at a predetermined penetration.

For this purpose, and chiefly because of the high speed of the carburizing reaction, a thyratron-controlled relay is often employed to cut off the heating current and, thus, stop the reaction after the desired amount of carbide has been formed. The fact that tungsten carbide has a higher electrical resistance than tungsten is utilized to determine the action of the relay. Since carburization is allowed to take place at a constant heating current, a rising voltage appears across the filament terminals as the resistance of the filament increases. The thyratron-operated relay is adjusted to function at a desired point on the rising voltage curve. Ideally, this point corresponds to a constant degree of carburization.

However, under certain circumstances hitherto unknown, filaments were produced which showed abnormal properties. The main difficulty encountered was too large a spread of the cold-resistance and the hot-resistance values of the finished tubes and inconsistent correlation between cold and hot resistance values.

In order to determine the reasons for these variations, the following investigation was carried out. At the start of the investigation, the main questions could be briefly stated as follows: Why does the theoretically well-founded method of thyratron control fail to produce tubes with constant filament properties? What are the circumstances under which the thyratron control fails? Is the resistance-control method unsuitable? What secondary phenomena may be causing the discrepancies?

In order that answers to these questions could be obtained, filaments having abnormal characteristics were collected and analyzed metallographically as to their microstructure. A wide variety of structures was found. Partial cross sections of two of these filaments are reproduced in Figs. 1 and 2. Figure 1 shows a filament which was found to be normal, whereas Fig. 2 shows a filament with normal cold resistance, but with low hot resistance, and a resultant filament current 6 to 7 percent above the value normally occurring at the specified operating voltage.

It has been well-known that different structures and forms of tungsten carbide can be produced under different circumstances. W. P.

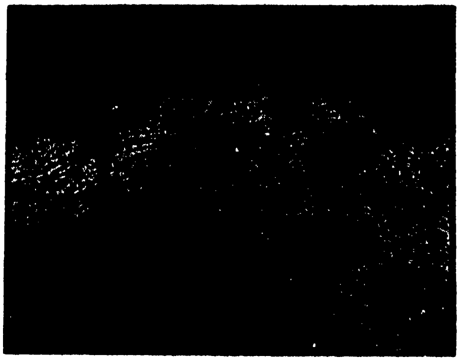

FIG. 1. Normal carbide structure. Magnification 250×.

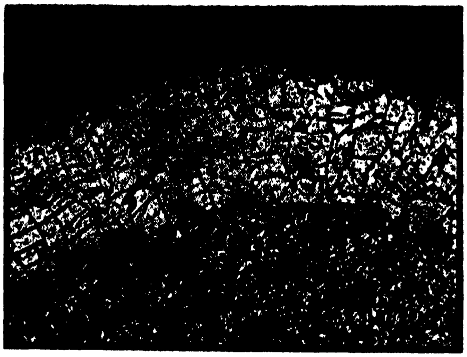

FIG. 2. Abnormal carbide structure. Magnification 250×.

Sykes,[2] K. Becker,[3,4] B. T. Barnes,[5] M. R. Andrews,[6] and others have reported on a variety of carbide structures, but the relation between the different carbide formations present in carburized tungsten filaments and their origination from the carburizing process had hitherto not been established. Consequently, efforts were made to reproduce under laboratory conditions the formations found in filaments and, thus, to determine the factors that produced them.

For that purpose the apparatus shown in Fig. 3 was constructed. With this apparatus, a U-shaped filament can be electrically heated in a hydrogen atmosphere to which can be added a controlled amount of hydrocarbon vapor by means of a specially devised carburetor. The current through the filament is controlled by means of a Variac auto-transformer. The carburizing time is regulated by a time switch which operates a relay switch in the main circuit. Such filaments carburized with this apparatus gave accurate reproduction of carbide formation and of electrical resistance.

One of the first filaments produced with this apparatus had a carbide structure as shown in Fig. 4. About half of the carbide shell consists of a laminated carbide formation similar to the one found in the normal filament. The other half is of a massive structure. By changing the hydrocarbon content of the hydrogen gas, it was possible to change the proportions of the two formations in the carbide shell at will. By lowering the hydrocarbon content, more of the laminated structure appeared and, simultaneously, more time was required for a certain depth of penetration of the carbide, whereas increasing the hydrocarbon content had the opposite effect. Figures 5a, b, and c show three different samples which were carburized to the same depth but with increasing hydrocarbon concentrations.

Because it is not possible to reproduce photomicrographs of all the cases found, a graphical reproduction of the whole range of structures obtained with a wide variation of hydrocarbon concentrations is given in Fig. 6. As a key to the interpretation of Fig. 6, a graphic picture corresponding with the photograph shown in Fig. 4 is given in Fig. 7. It will be explained later on how the concentration-penetration diagrams were arrived at. In Fig. 6, the diagrams of carbon

concentration *versus* penetration correspond to the structures shown at the left.

Figure 6a shows the effect produced by carburizing a filament in an atmosphere rich in hydrocarbon. A carbon deposit covers the surface, and two massive carbide phases are separately visible. The inner one is almost pure $W_2C$, whereas the outer one is WC. The concentration-penetration diagram for this sample is shown on the right.

Figure 6b is the same but without the carbon deposit.

Lowering the hydrocarbon content somewhat more prevents the formation of the second solid phase, the result of which is shown in Fig. 6c.

In Fig. 6d, we see the appearance of the laminated phase which was found in the normal filament; Figs. 6e–6h show the effects of reducing the hydrocarbon content further. The massive structure decreases until only widely spaced laminated material is formed at the very lowest hydrocarbon concentration.

The fact that the laminated structure is connected with a low hydrocarbon concentration, and the massive structure with a higher one, suggests that the laminated material contains less carbon than the massive $W_2C$ phase.

In addition, we know that where only laminated material is formed, the layers become wider as the hydrocarbon content of the carburizing atmosphere decreases.

Combination of these two facts leads to the conclusion that the change in character which we observed in the laminated phase in Fig. 4 actually shows us a concentration gradient of decreasing carbon content from the massive phase toward

suggests that the carbon deposit at this side of the gradient starts at 3.16 percent. The sharp line of demarcation between the laminated phase and the core suggests that the gradient does not end in a zero carbon concentration, but abruptly drops from a certain value to zero or some very small value.

In order to test the idea of a gradient, it was reasoned that a gradient of reverse character should be produced if carbon were removed from a previously carburized filament. This was done by heating such a filament in moist hydrogen. Figure 8b shows the results obtained. Figure 8a shows the original structure. The partial removal of carbon from the filament produced a laminated layer near the surface of the filament. It is clearly visible in the cross section that the laminations are widest near the surface where even a small decarburized layer is visible. The gradient on the inside of the remaining $W_2C$ section is, of course, of decreasing carbon content toward the core. The opposite character of the inward and outward gradients is clearly visible in Fig. 8b.

The explanation of the concentration-penetration diagrams in Fig. 6 is based on the following considerations and experiments.

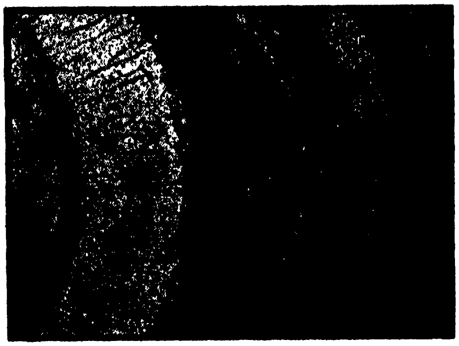
If we briefly review the theory of diffusion in solids, it does not seem to be difficult to explain the structures which are reproduced in Fig. 6.

If diffusion occurs in a binary system, and the components show mutual solubility in all proportions, one can generally expect a smooth concentration-penetration curve showing a gradual concentration decrease from the surface inward and ending in a zero concentration of the penetrating element at some distance from the surface.

However, in case limited solubility occurs, an area of co-existent phases separates the solubility fields in the phase diagram. If diffusion takes place in such a system, a sharp break in the concentration-penetration curve can be expected. The concentration drop at this break corresponds to the difference in solute content of the co-existent phases at the temperature involved, while the absolute concentrations on either side of the break are equal to the solute contents of the two co-existing phases.

In the somewhat more complicated case where compounds are formed between the components of the binary system, several areas of co-existence may occur, which are separated by more or less wide areas of solid solubility. Corresponding to each area of co-existence, a sudden break in the concentration-penetration curve must be expected. Each area of solid solubility corresponds to a gradient of gradually changing concentration.

Let us now consult the available data on the system tungsten-carbon and see what has to be expected in view of the above (see Fig. 9). Two compounds occur between tungsten and carbon, $W_2C$ and WC, the first containing 3.16 percent carbon, the other 6.12 percent carbon. Starting



a b

FIG. 8. Carbide shells. a, before, b, after, partial decarburization in wet hydrogen. Magnification 175×.

from the tungsten side of the diagram and only considering solids, we find successively:

1. A very narrow field of solid solubility of carbon in tungsten (W. P. Sykes reports a maximum solubility of 0.05 percent carbon in tungsten at 2400°C).
2. A co-existent phase area.
3. A narrow field of solid solubility around the stoichiometric $W_2C$ composition.
4. A co-existent phase area.
5. The compound WC with no solid solubility field.
6. An area of co-existence between WC and graphitic carbon.

If we apply the afore-mentioned theory to these data, we can expect the shape of the concentration-penetration curve for carbon diffusing into tungsten to be as indicated in Fig. 10. It is obvious, of course, that the complete sequence of concentration changes from the surface inward can occur only if sufficient carbon is available at the surface, and that the relative amounts of the different formations will depend upon the diffusion velocities within those formations and the degree of equilibrium reached during the diffusion reaction.

The concentration gradient within the solid solution range is, for simplicity's sake, indicated as a straight line. It will generally be a curved line which may be convex or concave to a larger or lesser degree depending on carburizing conditions. With this diagram as a basis, it is comparatively simple to construct the concentration-penetration diagrams, which are given in Fig. 6. If, on the basis of the above analysis, we reconsider the laminated gradient, it becomes clear that this material must be identified with the solid solution range of tungsten in $W_2C$. In order to explain its laminated character we have to invoke Sykes' claim that the solubility of tungsten in $W_2C$ decreases with temperature and that the tungsten-rich phase precipitates out on cooling from the diffusion temperature. Heavier layers are formed where more tungsten was in solution, while the wider spacing of the layers occurring simultaneously, may be attributed to the higher precipitation temperature. That no precipitation seems to occur where excess carbon is dissolved in $W_2C$ would indicate that the solubility of carbon in $W_2C$ does not decrease with temperature or that it is small and shows no pronounced effect on precipitation.

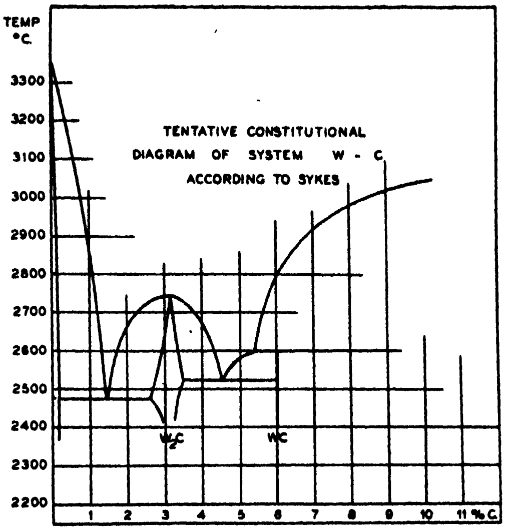


FIG. 9. Tentative constitutional diagram of tungsten carbon (used with permission).

The existence of the carbon concentration gradient, not only in the laminated region, but also in the massive carbide, was made plausible by a series of micro hardness tests. Successive tests, starting from the center of the wire outward toward the surface, were made with a Tukon hardness tester on a sample like the one shown in Fig. 4 containing both the massive and the laminated material. The core was found to be of uniform hardness. A sudden sharp increase in hardness occurred at the demarcation line between core and carbide shell followed by increasing hardness throughout the laminated zone. A maximum hardness was found just inside the massive zone, while the hardness again decreased from there to the surface. The increase in hardness throughout the laminated part of the shell confirms the gradient in this part; the relative amount of $W_2C$ increases. But the hardness distribution in the massive material also indicates an increasing carbon content toward the surface, for it is known that $W_2C$ attains its maximum hardness at the stoichiometric composition. Excess carbon, however, again lowers the hardness.

Finally, a direct carbon analysis of the laminated material was made in order to establish definitely its carbon content. At the same time

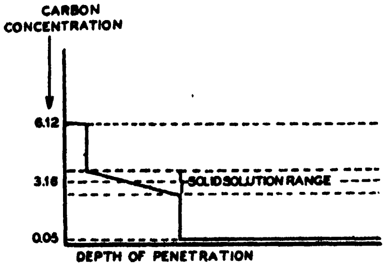

FIG. 10. Theoretical concentration-penetration curve for the diffusion of carbon into tungsten.

an attempt was made to determine the solubility limit of tungsten in $W_2C$ or, what amounts to the same thing, the carbon concentration at the carbide-side of the sharp interface between the carbide shell and the core. If carburization is carried out at the lowest hydrocarbon concentration which will allow formation of laminated material, and the temperature is sufficiently high to guarantee a diffusion reaction which is essentially "carbon-limited," it is safe to assume that equilibrium conditions are closely approached and that whatever gradient is formed is so small as to be negligible. The concentration-penetration diagram of this laminated material is indicated in Fig. 6h, and the whole carbide shell is of a widely spaced laminated character which does not show any evidence of a gradient. This material was produced and analyzed.

The carbon analyses were carried out with the aid of a high vacuum carbon analysis system which was built on the principle first described by Yensen,[7] later improved by Ziegler,[8] and redesigned by Wooten and Guldner[9] and others. The process, briefly described, utilizes a sample weighing about 10 milligrams which is heated in a vacuum to 1000°C and then burned in an excess of purified oxygen. After the $CO_2$ formed is frozen out in a liquid-air trap, the excess oxygen is removed by means of a vacuum pump. The $CO_2$ is then permitted to expand into a known volume. The $CO_2$ pressure at room temperature then furnishes the data required for a calculation of the carbon content of the sample under analysis.

At the same time, cross sections were made of the immediately neighboring part of the filament; the relative areas of the carbide shell and the tungsten core were measured by the use of a planimeter on the tracing of the enlarged cross-section image. This information made it possible to calculate the carbon content in the shell.

Results are given in Table I.

From the results obtained it can be seen that the carbon content is lower than 3.16 percent, as expected and, furthermore, that the equilibrium condition mentioned above was closely approached. This is borne out by the fact that the values obtained are fairly constant, even though the samples were carburized to different depths. We have assumed the average value of 2.45 percent carbon to be the one corresponding to the solubility limit of tungsten in $W_2C$, and the diagrams in Fig. 6 are drawn accordingly.

If we compare Sykes' tentative curves (Fig.9) with the result of our experiment, it seems that the value of 2.45 percent is somewhat low. However, the diffusion method is one of the most sensitive ones for the investigation of solid solubility limits, and Sykes' constitution diagram does not claim great accuracy in this region.

During the study of the decarburization process, it was found that the conditions shown in Fig. 8b could be produced only by high speed decarburization, that is, in wet hydrogen where oxygen is present to react with the carbon and remove it quickly from the filament surface as CO or $CO_2$ gas. In dry hydrogen, decarburization is much slower, and the massive $W_2C$ layer almost entirely disappears as a result of the carbon penetrating inward before a visible gradient toward the outside is established. A general survey of the stages of decarburization reactions is given in Fig. 11.

Decarburization in high vacuum is still slower than in pure hydrogen and needs a higher temperature. In high vacuum only a very limited amount of gas is present for the carbon to react with and simple evaporation may become necessary. Furthermore, it was found that the diffusion velocity of carbon in tungsten is considerably lower in a vacuum than in the presence of hydrogen. However, the same pattern of de-

carburization stages can generally be observed. Cross sections of filaments decarburized in a vacuum by high temperature flashing showed decarburized surface layers.

Referring to the structure of the normal filament as reproduced in Fig. 1, it can now be seen that this type of carbide formation was probably produced by decarburization. The hydrocarbon content of the hydrogen gas used during carburization was found to be too high for direct formation of laminated material. It follows, therefore, that decarburization must have taken place during the exhaust cycle when the filament was heated to a high temperature. In practice the duration of this cycle was found to be determined by the speed with which a certain degree of vacuum was obtained. This means that the filament was heated in the presence of gas and that the time varied with circumstances determining the degassing speed of the tube parts. Varying degrees of decarburization can easily be explained this way. If, in addition to that, the carbide formation during carburization does not produce constant results, as was found caused by improper dosing of the hydrocarbon in the hydrogen, it follows that a wide variety of carbide structures must be expected.

Varying amounts of carbide, of course, would cause differences in the values of cold resistance and of filament current (hot resistance). But why should two filaments having the same values of cold resistance have different values of filament current? This phenomenon was theoretically explained as follows: The cold resistance of a filament depends upon the amount of $W_2C$ formed, but it does not matter where in the filament this $W_2C$ is present. It may be on the surface as in the case of a freshly carburized filament; or it may be under the surface as in the case of a decarburized filament. Therefore, two filaments can have the same cold resistance, but different surface conditions.

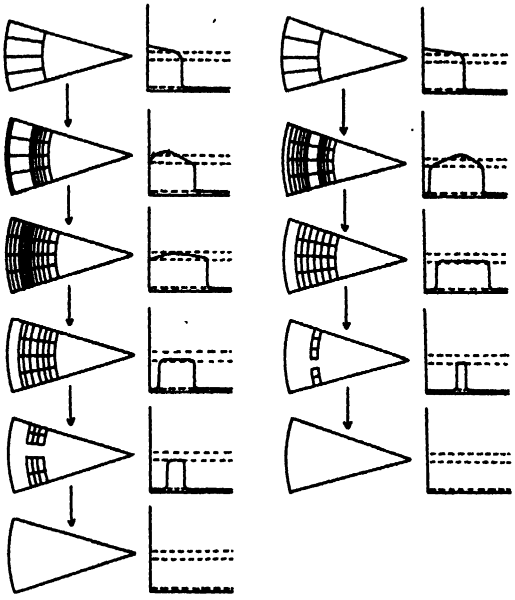

FIG. 11. Series showing effects of progressive decarburization: a, in dry hydrogen; b, in wet hydrogen.

When, however, these filaments are both put on the same operating voltage, as is done during tube operation, the one with the tungsten surface, having a lower heat emissivity, will have a higher temperature, a higher hot resistance, and a lower filament current than the one with the tungsten carbide surface, which has a higher heat emissivity.

The fact that surfaces intermediary between almost pure tungsten and total tungsten carbide as extremes may occur, due to decarburization on exhaust, opens the possibility of a range of hot resistances, corresponding to each cold resistance value. Thus, the cold resistance-*versus*-filament current diagram becomes an area instead of a line.

For confirmation of this theory, special tubes were built containing two identical tungsten filaments having the same initial cold resistance. One of the filaments was carburized under circumstances which guaranteed the formation of the massive $W_2C$ phase. The other filament was overcarburized and, subsequently, decarburized in wet hydrogen to exactly the same cold re-

TABLE II.

sistance as the first filament. When these two filaments were operated in series, the decarburized filament showed a visibly higher temperature.

Measurements made on the separate filaments are given in Table II.

These data show that the purposely decarburized filament has the lowest filament current and the highest temperature at a fixed operating voltage. In this case the difference in filament current values at 2000°C amounts to about 4 percent.

If we were to operate the filaments at 14.3 volts, the temperature difference is 30°C. Furthermore, these data agree with Barnes' results,[5] *i.e.* that the total emissivity of tungsten carbide is higher than that of tungsten for the same temperature of operation.

This is an appropriate place to return to our first question as to why the thyratron control sometimes failed to produce filaments of constant cold resistance, because the answer was also found to be differences in surface conditions. A filament with a surface having total emissivity higher than average will produce a lower than normal temperature for normal input. Translated into terms of hot resistance this means that a lower temperature corresponds to the hot resistance at which the thyratron relay is set to act. This in turn requires that overcarburization must take place if the necessary hot resistance is to be reached. A filament of higher than normal cold resistance is the result.

Two cases of abnormally high emissivity of filaments were encountered. The first one occurred when helical filaments were oxidized heavily during the forming operation and then were reduced by flashing them in a hydrogen atmosphere. This procedure produced a very rough surface. In the second case, the hydrocarbon content of the carburizing atmosphere was so great that a carbon deposit was formed on the surface of the filament.

From the above investigations, the following conclusions can be drawn:

1. Thyratron control for the carburization of thoriated-tungsten filaments is an excellent method, provided the filaments to be carburized have uniform surface conditions, and provided a strict control of the hydrocarbon content in the hydrogen atmosphere is maintained.
2. The character of the carbide formations obtained during carburization and decarburization can be explained on the basis of the theory of diffusion and the characteristics of the carbon-tungsten phase diagram.
3. The amount of decarburization which occurs during tube manufacture has an important effect on the uniformity of the electrical filament characteristics of tubes.
4. The hot-to-cold resistance ratio of a filament is greatly influenced by the surface condition of the filament.

# Creep Deflections in Columns

JOSEPH MARIN*
*School of Engineering, The Pennsylvania State College, State College, Pennsylvania*

(Received August 22, 1946)

The determination of column deflections and column buckling loads has been considered for many years. The available theories, however, do not provide for materials which creep with time under constant loads. For the design of structural members made of these materials, a consideration of creep may be of practical importance. Plastics, concrete, and some metals creep at normal temperatures while other metals creep only at high temperatures and at stress values beyond the yield point. A consideration of creep in the design of some structures appears appropriate in view of the modern developments in plastics and the presence of high stress values which are sometimes beyond the yield stress. This paper gives a rational theory for predicting creep deflections in columns. A special case using this theory is applied to the interpretation of some preliminary tests of an aluminum alloy.

## INTRODUCTION

THE usual concept of failure in columns by elastic instability must be modified if the material creeps. For columns made of materials that creep, critical buckling loads are smaller than the elastic buckling loads since the progressive lateral creep deflections must be considered. It is necessary therefore to modify our definition of the critical buckling load and to define the buckling load as that load which will produce a large lateral deflection at the end of a specified time. To determine these loads, a theory will be developed giving the creep deflections in a column in terms of the load, column dimensions, material constants, and time. These theoretical deflections will then be compared with the corresponding experimental values.

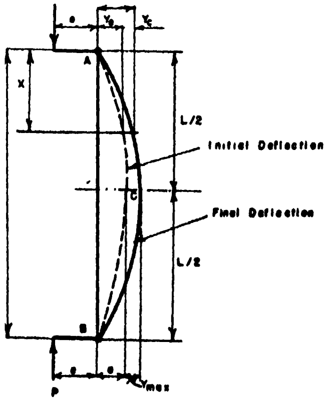

FIG. 1. Pin-ended column subjected to an eccentric load.

## GENERAL THEORY FOR COLUMN DEFLECTIONS

Columns having cross sections with at least one axis of symmetry will be considered. The column $AB$ is free at the upper end $A$, and at the base $B$, and is loaded eccentrically with a load $P$ in the plane of symmetry (Fig. 1). Initially, an elastic lateral deflection $y_e$ is produced at a distance $x$ from point $A$. This initial deflection will include the elastic deflection plus the initial creep deflection as shown in Fig. 2. Actually the column deflects so that $AB$ rather than $AC$ represents the initial elastic and creep deformation and beyond $B$ for a short period of time the deflections are represented by the curve $BD$. Beyond point $D$ the experimental deflection-time relation $DE$ was found to be linear. It will be assumed in this theory that the actual deflection curve $ABDE$ is replaced by $ACE$. To determine the lateral deflection ($y=y_e+y_c$) at a time $t$, a theory for defining

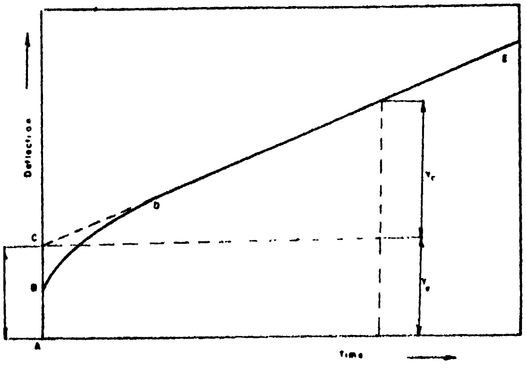

FIG. 2. Deflection-time relation.

---

* Professor of Engineering Mechanics.

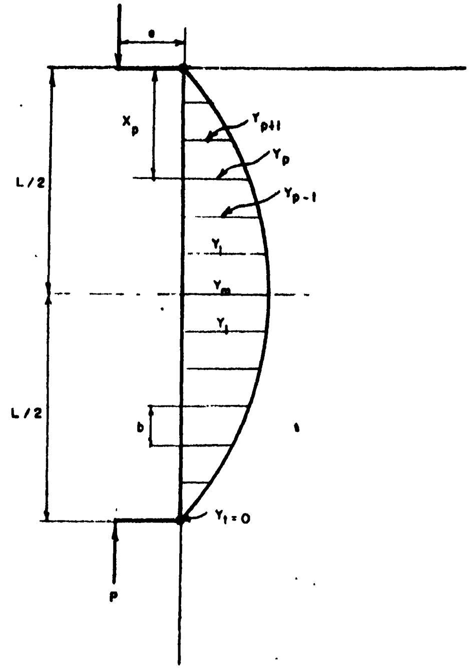

FIG. 3.

creep deflection in bending corresponding to the elastic theory for deflection must first be obtained.

A theory for the creep deflection in bending has been proposed by the writer in the form of a differential equation for the creep deflection $y_c$ in terms of the moment $M$ and time $t$.[1] It was shown by this theory that

$$(D/t)(d^2y_c/dx^2)=M^n. \qquad (1)$$

In Eq. (1), $D$ corresponds to the flexural rigidity $EI$ in the elastic theory. Its value for a rectangular cross section is

$$D=\frac{1}{A}\frac{(2b)^n(h/2)^{2n+1}}{(2+1/n)^n}, \qquad (2)$$

where $A$ and $n$ = experimental creep constants,

$b$ = the width of the section,
$h$ = the depth of the section.

Equation (1) is based on the log-log creep stress law $C=AS^n$ where $C$ is the assumed constant rate of creep strain and $S$ is the unit stress.

The moment $M$ in terms of the load $P$ at a time $t$ is, from Fig. 1,

$$M=-P(e+y)=-P(e+y_e+y_c), \qquad (a)$$

where $e$ = the eccentricity of the load. Substituting the value of the moment $M$ from Eq. (a) in Eq. (1), the differential equation for the creep deflection $y$ at a distance $x$ is

$$(D/t)(d^2y_c/dx^2)=-P^n(e+y_e+y_c)^n. \qquad (3)$$

In this equation $x$, $y_e$, and $y_c$ are variables. These three variables can be reduced to the necessary two by expressing the initial deflection $y_e$ in terms of $x$. For this purpose the shape of the curve $AB$ can be assumed with reasonable accuracy. This assumption is similar to that used in the analysis of buckling problems in the elastic case using the Rayleigh method. For the present problem the shape of the curve $AB$ will be assumed as a sine function. That is, the value of $y_e$ in terms of $x$ will be assumed as

$$y_e=a\sin\frac{\pi x}{L}, \qquad (b)$$

where $a$ = the initial deflection at point $C$ in the column and $L$ = the length of the column.

Placing the value of $y_e$ from Eq. (b) in Eq. (3) and noting that $y=y_e+y_c$, the differential equation for the total deflection $y$ as a function of the distance $x$ becomes

$$\frac{d^2y}{dx^2}=-\frac{a\pi^2}{L^2}\sin\frac{\pi x}{L}-\frac{P^nt}{D}(e+y)^n. \qquad (4)$$

The values of $n$ in Eq. (4) must be assumed as odd integers since the creep stress law $C=AS^n$ must apply for compressive and tensile values of $S$ in the case of bending where both types of stress exist.[2] That is, Eq. (4) must be solved for values of $n=1, 3, 5\cdots n$, where $n$ is an odd number. A direct solution of Eq. (4) for $y$ in terms of $x$ could not be found. One method of attack using numerical integration is given in Appendix 1. A general method of solution is developed in this paper by using a trial and error

[2] J. Marin, "Mechanics of creep for structural analysis," Trans. A.S.C.E. Vol. 108, 470 (1943).

procedure. This method is similar to the one used by Holzer[3] for the determination of natural frequency of vibration of multi-mass systems. The procedure used is to replace the differential Eq. (4) by an equivalent system of difference equations. To do this, consider the column divided into a number of segments $N$ of length $b=L/N$ (Fig. 3). The ordinates to the deflection curve will be designated by $y_m, y_1 \cdots y_p$, as shown in Fig. 3. The second derivative of $y$ with respect to $x$, $d^2y/dx^2$, at any section where $x=x_p$, is given approximately by the equation:

$$\left(\frac{d^2y}{dx^2}\right)_{x=x_p}=\frac{1}{b^2}(y_{p+1}-2y_p+y_{p-1}). \tag{5}$$

Placing the value of $d^2y/dx^2$ from Eq. (4) in Eq. (5) and solving for $y_{p+1}$,

$$y_{p+1}=2y_p-y_{p-1}-F_p+Q(e+y_p)^n, \tag{6}$$

where

$$F_p=(b^2a\pi^2/L^2)\sin(\pi x_p/L), \tag{7}$$

and

$$Q=b^2P^nt/D. \tag{8}$$

Denoting the deflection at the mid-section of the column by $y_m$ and at the end by $y_t$ and writing Eq. (6) for each section successively,

$$\left.\begin{aligned} y_1&=y_m-\tfrac{1}{2}[F_m+Q(e+y_m)^n],\\ y_2&=2y_1-y_m-[F_1+Q(e+y_1)^n],\\ y_3&=2y_2-y_1-[F_2+Q(e+y_2)^n],\\ y_{p+1}&=2y_p-y_{p-1}-[F_p+Q(e+y_p)^n],\\ y_t&=2y_{t-1}-y_{t-2}-[F_{t-1}+Q(e+y_{t-1})^n],\end{aligned}\right\} \tag{9}$$

where

$$F_m=\frac{b^2a\pi^2}{L^2}\sin\frac{\pi x_m}{L},\quad F_1=\frac{b^2a\pi^2}{L^2}\sin\frac{\pi x_1}{L}. \tag{10}$$

The method of applying Eqs. (9) to determine column deflections for a given load $P$ at a time $t$ is as follows:

1. From the column dimensions, material constants $A$ and $n$, time $t$, and load $P$, determine the value of $Q$ by Eq. (8).
2. Using the value of the elastic deflection for the approximate value of $a$ and for different values of $x$ determine the values of $F_1, F_2 \cdots F_p$.
3. Assume a value for $y_m$ and, by Eqs. (9), determine successively values of $y_1$ to $y_t$. The value of $y_t$ should be zero if the correct value of $y_m$ was assumed.
4. Repeat Item 3 until small positive and small negative values of $y_t$ are obtained. Then by interpolation the correct value of $y_m$ can be calculated.

The above calculations can be repeated for various values of $P$ and $t$. These data can then be used to determine the load deflection curves with the time $t$ as a parameter (Fig. 4).

For the aluminum alloy tested in this investigation it was found that $n=1$ is a good approximation. As shown in the following, the solution of Eq. (3) is greatly simplified when $n=1$.

## SPECIAL THEORY FOR COLUMN DEFLECTIONS WHEN $n=1$

By Eqs. (3) and (b) for $n=1$,

$$\frac{D}{t}\frac{d^2y_c}{dx^2}=-P\left(e+a\sin\frac{\pi x}{L}+y_c\right), \tag{c}$$

or

$$\frac{d^2y_c}{dx^2}+k^2y_c=-k^2a\sin\frac{\pi x}{L}-k^2e, \tag{11}$$

where $k^2=Pt/D$.

It can be shown that the solution of this differential equation is

$$y_c=C_1\sin kx+C_2\cos kx+\frac{a\sin\pi x/L}{\dfrac{\pi^2}{k^2L^2}-1}-e. \tag{12}$$

Boundary conditions can be used to determine the constants $C_1$ and $C_2$. Since $y_c=0$ when $x=0$, from Eq. (12),

$$C_2=e. \tag{d}$$

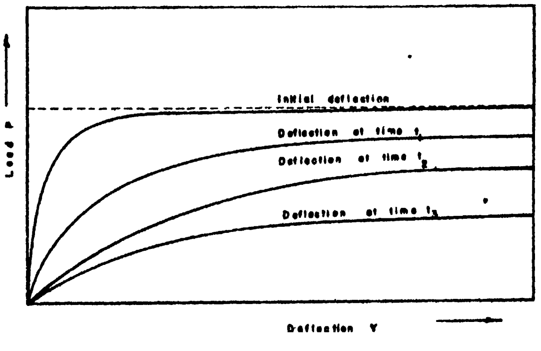

FIG. 4. Load-deflection relations.

---

[3] J. P. Den Hartog, *Mechanical Vibrations* (McGraw-Hill Book Company, Inc., New York, 1940), p. 225. See also Dana Young, "Inelastic buckling of variable section columns," paper presented at the Annual Meeting of the A.S.M.E., Dec. 1944.

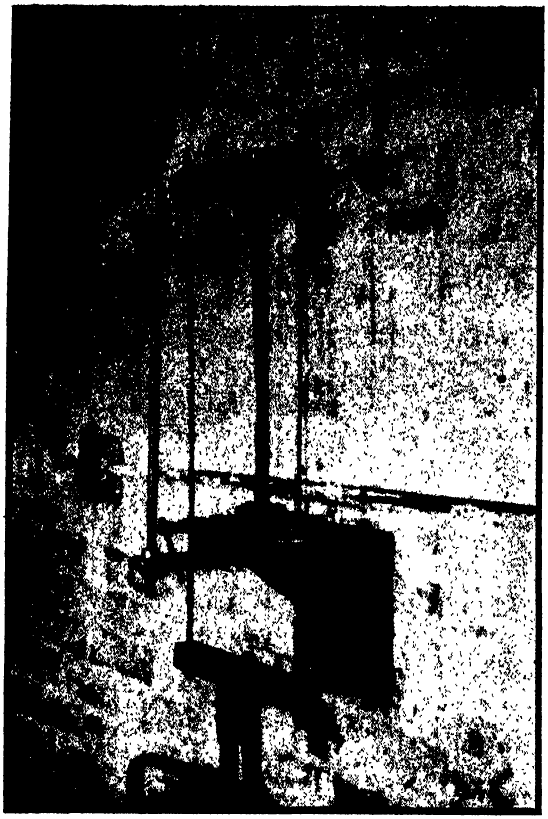

FIG. 5. Creep buckling apparatus.

The deflection $y_e$ also equals zero when $x=L$, or from Eq. (12),

$$C_1=\frac{e(1-\cos kL)}{\sin kL}. \tag{e}$$

Substituting the values of $C_1$ and $C_2$ from Eqs. (d) and (e) in Eq. (12) the creep deflection is

$$y_e=\frac{\sin kx}{\sin kL}(1-\cos kL)e+e\cos kx-e+\frac{a\sin\pi x/L}{\dfrac{\pi^2}{k^2L^2}-1}. \tag{13}$$

By inspection the maximum creep deflection is for a value of $x=L/2$, or

$$y_{\max}=e\left(\sec\frac{PtL^2}{4D}-1\right)+\frac{aPtL^2/D}{\pi^2-\dfrac{PtL^2}{D}}. \tag{14}$$

If it is assumed that the initial deflection $y_e$ is entirely the elastic deflection at the center of the column, then it can be shown by the usual elastic theory that,

$$y_e=e\sec[(PL^2/4EI)]^{\frac{1}{2}}-e. \tag{15}$$

The total deflection at the center ($y_T$) is equal to the creep deflection ($y_{\max}$), as given by Eq. (14), plus the elastic deflection, as given by Eq. (15). That is, by Eqs. (14) and (15),

$$y_T=e\left[\sec\frac{PtL^2}{4D}+\sec[(PL^2/4EI)]^{\frac{1}{2}}-2\right]+\frac{aPtL^2/D}{\pi^2-\dfrac{PtL^2}{D}}. \tag{16}$$

The maximum moment produced in the column at a time $t$ is,

$$M_{\max}=P(y_T+e). \tag{17}$$

The maximum bending stress with $n=1$ is the same as for the elastic case or equal to $M_{\max}c/I$, where $I=$ the moment of inertia of the cross section and $c=$ the distance to the outer fiber. In addition to the bending stress, there is an axial compressive stress equal to the load divided by the area or $P/A$. Then the maximum stress is

$$S_{\max}=\frac{P}{A}+\frac{M_{\max}c}{I}. \tag{18}$$

Using values of $M_{\max}$ and $y_T$ from Eqs. (16) and (17) in Eq. (18), the maximum stress is

$$S_{\max}=\frac{P}{A}+\left(\frac{Pc}{I}\right)\left[e\sec(PtL^2/4D)+e\sec[(PL^2/4EI)]^{\frac{1}{2}}-e+\frac{aPtL^2/D}{(\pi^2-PtL^2/D)}\right]. \tag{19}$$

TABLE I. Physical properties of 3S-H aluminum alloy.

| | |
|---|---|
| Yield strength (0.2 percent set) (pounds per square inch) | 25,000 |
| Ultimate strength (pounds per square inch) | 29,000 |
| Elongation (percent in 2 inches) (one-half inch round specimen) | 10 |
| Hardness (Brinell—500 Kg) | 55 |
| Modulus of elasticity (pounds per square inch) | 10,300,000 |
| Modulus of rigidity (pounds per square inch) | 3,800,000 |

Equation (19) corresponds to the secant formula obtained in the elastic theory and it can be used to determine maximum stresses in columns accompanied by creep.

## EXPERIMENTS ON ECCENTRICALLY LOADED COLUMNS

The columns tested were supported and loaded as shown in Fig. 5. The load was applied to the column specimens by a hanger supplied with a universal joint to prevent bending, and provision was made for rigidly fixing the lower end of the column. The lateral creep deflections were measured by a Federal dial reading to 1/10,000 inch. Precautions were taken for placing the column initially vertical and the dial pointer horizontal. The material tested was an aluminum alloy designated as 3S–H by the Aluminum Company of America and the properties of this material, as supplied by Mr. R. L. Templin, Chief of Tests of this Company, are given in Table I.

Tension and pure bending creep tests also were made on this material at room temperatures.[1] The tension creep tests showed that the creep rate-stress relation was a straight line on a log-log plot. That is, the variation between the stress $S$ and constant creep rate $C$ is:

$$C = AS^n, \tag{20}$$

where $A$ and $n$ are experimental constants.

The values of $A$ and $n$ as determined by the tension tests were reported[1] as $A = 6.51 \times 10^{-12}$ and $n = 1.18$. A reconsideration of this data shows that a value of $n = 1$ and $A = 2.5 \times 10^{-11}$ is also a good approximation. The value of one for the constant $n$ is selected since this simplifies the theoretical interpretation of the test results. The pure bending creep tests showed that Eq. (1) gives a reasonably good approximation for this material.

The column specimens used were about one-half inch square, and most of them were about 15 inches in length. To prevent local yielding the bases of the columns were increased in size. Various values of the eccentricity $e$ and load $P$ were used for the eight columns tested, as is shown in Table II. Table II also lists the average dimensions and slenderness ratios for the mem-

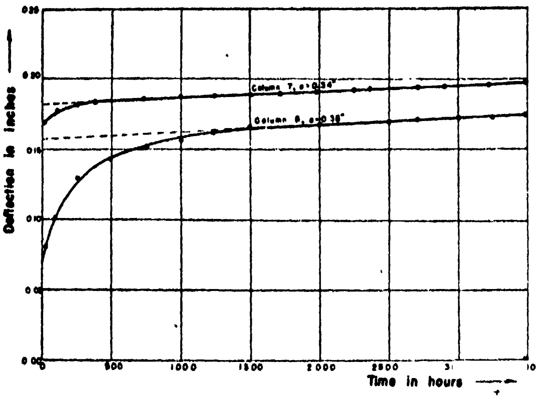

FIG. 8. Deflection-time relations for columns 7 and 8.

bers used. For each experiment, lateral deflections were measured at a point near the upper end of the column, as shown in Fig. 5. An approximate value of the initial elastic and creep deflections was noted for each member. Creep deflection readings were recorded at varying intervals of time and deflection-time plots are shown for the various specimens in Figs. 6–8. Each test covered a time period of at least 500 hours and two specimens covered a time of 3000 hours. After the first 24 hours the creep rate became almost constant so that readings were taken only once a day. The creep rate was constant for all columns except No. 3 which failed by buckling at the end of 70 hours (Fig. 7). For a number of the specimens tested the applied moment was maintained constant by decreasing the load and increasing the eccentricity.

## INTERPRETATION OF TEST RESULTS

A comparison between the theoretical and experimental deflection values can be made by determining both the creep deflections and creep rates using each method. The creep deflection given by Eq. (14) also represents the maximum theoretical creep deflection for the column of Fig. 5. For example, to determine the theoretical creep deflection at 500 hours in the case of column 2, it is necessary to substitute in Eq. (14) the values of $e=0.79$ inches, $P=143$ lb., $t=500$ hr., $L=28$ in., $D=I/A=2.08\times 10^8$, and $a=0.364$ in. Then the theoretical creep deflection $y_{max}=0.042$ in. The values of the theoretical deflections for other columns are given in Table III.

The actual deflections were not measured at the ends of the columns so that it is necessary to correct these deflections in order to compare them with the theoretical values. To do this the creep deflection curve is assumed to be a sine curve. The corrected values of the measured creep deflections are listed in Table III for comparison with the theoretical values. The values of the creep rates, as obtained by theory and experiment, are also given in Table III for purposes of comparison.

## CONCLUSION

In view of the preliminary nature of these tests and the approximations made in the theory, the agreement between the theoretical and experimental creep values as given in Table III is quite satisfactory. There is need, however, for further research on this problem before a definite conclusion can be reached.

## ACKNOWLEDGMENTS

The author wishes to express his thanks to R. L. Templin, Chief of Tests of the Aluminum Company of America for the aluminum used in these tests and for control test data supplied. The experimental data of this paper was taken from a Master's Thesis by R. C. DeHart performed under the direction of the writer.

## APPENDIX 1

An alternate method for the solution of Eq. (1) is given in the following. The value of $y_e$ is first assumed to be $y_e=ix^2$. The constant $i$ can be determined by noting that $y_e=a$ when $x=L$ (Fig. 9) or $i=a/L^2$. That is,

$$y_e=(a/L^2)x^2, \tag{f}$$

TABLE III. Comparison of theoretical and experimental values.

| 7 | 53.8 | 0.34 | 0.018 | 0.029 | 0.060 | 0.097 |
| 8 | 60.0 | 0.38 | 0.018 | 0.037 | 0.060 | 0.123 |

*Note:* For columns 1 to 5 creep deflections are for $t=500$ hours. For columns 7 and 8 creep deflections are for $t=3000$ hours.

where $a$ = the initial deflection at $B$ and $L$ = the length of the column. For the column in Fig. 9 the moment is

$$M=Py'=P(e+y_{\max}+a-y_c-y_e). \qquad \text{(g)}$$

Placing the value of $y_e$ from Eq. (f) and the value of $M$ from Eq. (g) in Eq. (1),

$$d^2y_c/dx^2=(k_1y_c+k_2x^2+k_3)^n, \qquad (21)$$

where

$$k_1=-P(t/D)^{1/n}, \quad k_2=\frac{-aP}{L^2}(t/D)^{1/n},$$

and

$$k_3=(e+y_{\max}+a)P(t/D)^{1/n}.$$

Placing

$$u=k_1y_c+k_2x^2+k_3 \qquad \text{(h)}$$

in Eq. (18),

$$d^2u/dx^2=k_1u^n+2k_2. \qquad \text{(i)}$$

Integrating Eq. (i) and separating the variables,

$$\int\frac{du}{(u^{n+1}+k_4u+k_5)^{1/2}}=k_6\int dx, \qquad (22)$$

where

$$k_4=(2k_2/k_1)(n+1),$$
$$k_5=-(k_3)^{n+1}-(n+1)(2k_2k_3/k_1),$$
$$k_6=[(n+1)/(2k_1)]^{1/2}.$$

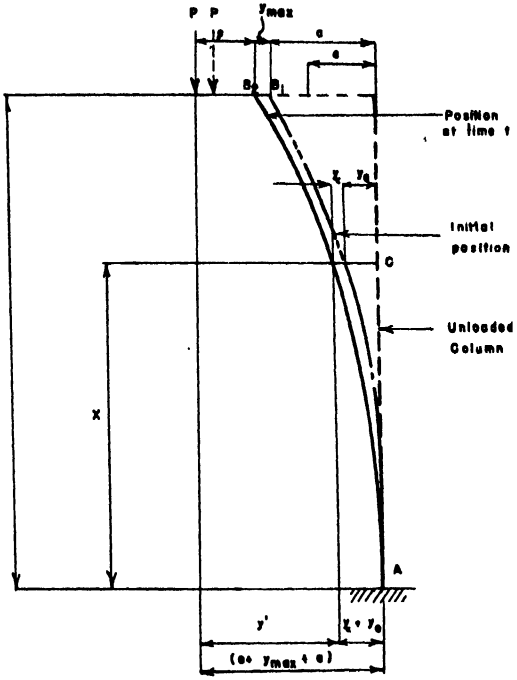

FIG. 9. Deflection of column fixed at one end and free at the other.

Equation (22) can now be solved for particular values of $n$ by using numerical integration methods. For a value of $n=1$, Eq. (22) can be integrated directly, or

$$u^2+k_4u+k_5=(e^{k_6x+k_7}-x-k_4/2)^2, \qquad (23)$$

where $k_7$ is a constant of integration.

Replacing $u$ by its value in terms of $x$ and $y$ as given by Eq. (h), the equation for the deflection $y_c$ can be obtained.

# Effects of Magnetic Field on Oscillations and Noise in Hot-Cathode Arcs*

J. D. Cobine and C. J. Gallagher**
*Radio Research Laboratory, Harvard University, Cambridge, Massachusetts*

(Received April 11, 1946)

The voltage disturbances in hot-cathode arcs are markedly affected by a magnetic field transverse to the normal flow of current. The normal plasma oscillations can be suppressed and the noise level above 1 Mc/sec. greatly increased. The oscillations appear to be transmitted to the electrodes by electrons whose velocity is modulated by the plasma ion oscillations as they travel directly from cathode to anode. The effect of the magnetic field is to remove these electrons from the current reaching the anode. A critical value of magnetic field will suppress the oscillations and reduce the noise to a minimum. As the magnetic field is further increased the high frequency noise level increases. The high frequency noise level also increases if the pressure decreases, or if a lighter gas is used. The noise level is independent of the plasma volume. The effect of the magnetic field is to build up a region of high ion density in a narrow region near the electron source. Plasma oscillations with continuous spectrum are generated in this region of high density and high density gradient.

## INTRODUCTION

Occasionally mention is made of the fact that gas discharge tubes are "noisy," where "noise" is taken to mean any objectionable fluctuating voltage, such as random noise or oscillations.

Many investigators have reported the existence of oscillations in the voltage appearing between the electrodes of gaseous discharge.[1] The oscillations so observed appear to be of three types, *viz.*, oscillations of electrons and of positive ions in the plasma, and relaxation oscillations. The former appear to be characteristic of the discharge (current, pressure, geometry, nature of gas), while the latter are dependent on both the discharge and the external circuit conditions. Observations and analysis of the plasma oscillations have been made by Tonks and Langmuir.[2] These workers showed theoretically that the frequency of the plasma oscillations increases with increasing positive-ion density. The frequencies of these oscillations have been studied in narrow ranges from 1000 kc/sec to 1000 Mc/sec.

No systematic study of the random noise developed by gaseous discharges has been reported in the literature although gas tubes have been used as random noise generators in acoustical testing,[3] and Tonks and Langmuir[2] mention the existence of a continuum in the voltage output of their discharge tube. Recently the authors have reported a study of random noise and oscillations in hot-cathode arcs.[4] In this study it was shown that the random noise could be explained as the result of random fluctuations of space charge at the electrodes.

FIG. 2. Effect of magnetic field on noise and oscillations of hot-cathode gas triode (RCA 884).

The present paper presents a further study of noise and oscillations in gas discharges when placed in a magnetic field. A transverse magnetic field is shown to produce two new effects, namely, the suppression of oscillations and the complete alteration of the noise spectrum.

## EXPERIMENTAL TECHNIQUE

The voltage fluctuations can be studied effectively by means of spectrum analyzers which measure amplitude and frequency characteristics of the oscillations and random noise. The frequency range from 25 c.p.s. to 9 Mc/sec. could be continuously studied with three heterodyne-type analyzers having band widths sufficiently small that the continuous noise spectrum remained essentially uniform over the region under observation.[5] Thus, the analyzers measured the r.m.s. voltage over a small band of frequencies. Since the r.m.s. noise power in a uniform spectrum is proportional to the band width, all measurements could be referred to a common band width, arbitrarily chosen as 1 kc/sec. The measurements of the spectra under various conditions are presented in db referred to a zero db level of $10\mu v/(\text{kc/sec.})^{\frac{1}{2}}$. Precautions were taken to insure that the input impedance of each analyzer was sufficiently high to avoid "loading" the gas tube output circuit and thus distorting the spectrum being measured. The discharge tube being studied was connected in series with a non-inductive resistance and a regulated power supply. The fluctuation voltage was measured directly between the tube electrodes. The data presented were obtained from both commercial tubes and tubes of experimental design.

## EXPERIMENTAL RESULTS

### Oscillations

Much information about the oscillations was conveniently obtained by studying characteristics of type 884 tubes (hot-cathode, argon-filled gas triode). As has been shown previously,[4] the voltage between anode and cathode contains two oscillations superimposed on a background of random noise. These oscillations are not harmonically related.

When a magnetic field is applied transverse to the normal direction of current flow the effect on each oscillation is quite different as shown in Figs. 1 and 2. The effect of the magnetic

Magnetic flux density = 860 gauss

FIG. 3. Effect of pressure on spectrum of argon tube.

field on the lower frequency oscillations is indicated in Section B of these figures, where it is seen that as the magnetic field increases, the amplitude first increases and then decreases without any change in frequency. With sufficiently high field (approx. 150 gauss), this oscillation disappears completely. Oscillation C undergoes a more complicated series of changes. The peak shifts toward higher frequencies, with marked broadening. Figure 2, Section C, shows the amplitude of the peak and its spectrum measured between frequencies whose amplitudes are 6 db below those of the peak.

For the strongest magnetic fields, the peak becomes so broad that a discrete oscillation cannot be detected. The numbers on the figure indicate the spectrum levels measured at the corresponding magnetic field in Section E. The behavior of these oscillations is typical of all the hot-cathode arcs studied.

The disappearance of these oscillations was studied in an experimental tube with an oxide-coated cathode and a small plane anode three inches from it. The cathode was partly surrounded by a metal shield to define an electron beam, the limits of which could be plainly seen at a few hundred microns pressure. Under these conditions the discharge space was filled with plasma and the two characteristic oscillations were observed in the voltage spectrum. When a magnetic field was applied so as to deflect the beam of electrons away from the anode, the low frequency oscillation disappeared. The oscillation reappeared at reduced amplitude if the beam was directed against the glass wall of the tube so that electrons coming directly from the cathode were reflected to reach the anode. It is not possible to eliminate this oscillation in any tube in which the electrons could reach the anode directly in spite of the magnetic field. Thus, this oscillation is a positive-ion plasma oscillation whose energy is transmitted to the external circuit by velocity modulation of the electron beam passing directly from cathode to anode. Tonks and Langmuir[2] have shown that the plasma oscillations have zero group velocity and cannot transmit energy directly to the external circuit.

Unlike the plasma oscillation, the second type of oscillation has been observed at all currents, even down into the "Townsend" discharge region where no plasma exists.[4] Similar oscillations have been observed by Ballantine[6] in vacuum tubes containing mercury as a residual gas (pressures less than 1 micron). Since these oscillations appear under conditions in which no plasma is present, as well as under plasma conditions, the most promising explanation appears to be that proposed by Ballantine, *i.e.*, the oscillations are those of positive ions in the potential minimum at the cathode. If these are "cathode" oscillations, the magnetic field has the effect on frequency that might be expected, since the electron density increases near the cathode due to the bending of the electron paths in the magnetic field. The increase in density would cause a deepening of the potential well, with consequent increase in oscillation frequency. The broadening of the peak is more difficult to explain.

## Noise

As shown in Fig. 1, the oscillations are superimposed on a continuous background of random noise. The effect of the magnetic field is first to

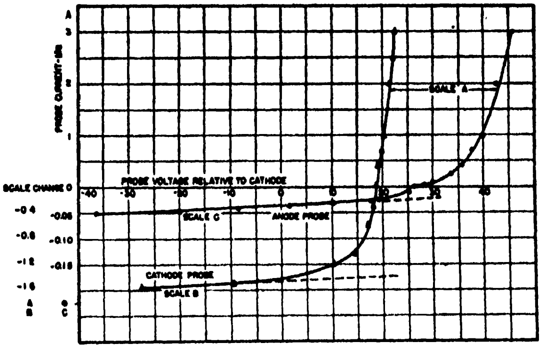
FIG. 5. Effect of probe current on noise at cathode probe.

decrease and then increase the noise level over the entire spectrum. In no case where the magnetic field is equally strong at cathode and anode is the low frequency noise increased above the zero field value. On the other hand the high frequency noise can be increased markedly over the zero field value (Sections A and D, Fig. 2). The noise level in the high frequency region increases continuously up to the point where the magnetic field is strong enough to extinguish the discharge. The ultimate noise voltage level at 5 Mc/sec. may be 100 times the zero field level.

The noise level is also affected by gas pressure. With the discharge in a strong magnetic field, the noise increases continuously as the pressure is reduced, to the point where the pressure is too low for the discharge to be maintained in the presence of the field. Figure 3 shows a series of typical spectra obtained with an argon-filled experimental tube with a field of 860 gauss at the cathode. It will be noted that there is no "hump" in these spectra. This characteristic was noted for all tubes in which the electrode structure was such that the field was strong at one electrode only. In this case, the hump which is present at lower fields is obliterated by the high level of the low frequency noise.

The discharge current does not greatly effect the shape of the spectrum, if arc conditions are fully established. Both high and low frequency noise increase with increasing currents by a factor of not more than 3 when the arc current increases by a factor of 100. The noise is also substantially independent of the plasma volume, which was varied by a factor of 2000.



Magnetic flux density =800 gauss at cathode
Cathode current =20 ma
Argon at 85 microns

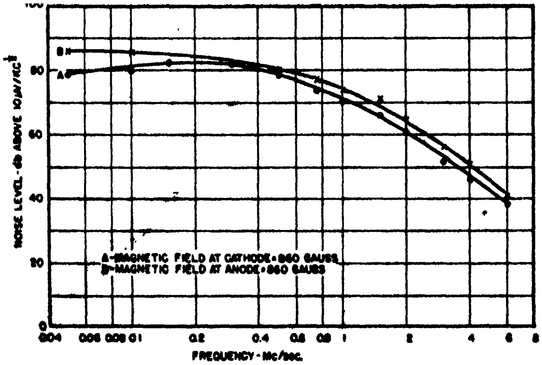
FIG. 6. Probe characteristics of experimental tube (Figs. 4 and 5).

The effect of different gases on the noise was studied. The general shape of the spectra is the same for all of the gases used, including helium, argon, xenon, and mercury. The high frequency noise (above 1 Mc/sec.) decreased as the atomic weight increased. No definite trend was noted in the low frequency noise. The results of these studies are summarized in Table I. The peak-to-peak voltage was measured on a wide-band oscilloscope. The peak-to-peak voltage is of the order of 85 percent of the arc drop. The arc drop itself is roughly proportional to the ionization potential of the gas used.

It was found that the amount of noise voltage measured between either cathode or anode, and an auxiliary probe electrode was highly dependent on the current collected by the probe. For these measurements, the main discharge was maintained between cathode and anode. The cathode-anode current and noise voltage were unaffected by the variations in the probe current. Two probes were used—one near the cathode and the other near the anode. The magnetic field was applied at the cathode and was perpendicular to the plane of the cathode probe. For each probe the noise was measured between probe and anode and probe and cathode. Figures 4 and 5 show the noise level at three frequencies as a function of probe current. The volt-ampere characteristics of the probes are shown in Fig. 6.

In all cases the noise was very low when the probe was made sufficiently negative that only positive-ion current was drawn. In general, the noise increases only when the probe begins to draw electron current. The noise at the cathode probe changes very gradually with current. The noise at the anode probe changes very abruptly when appreciable electron current is drawn. With magnetic field, the noise reaches its greatest value when the probe potential is such as to repel all but the fastest electrons. For these probe currents, conditions are such that very little noise is developed in the space charge region adjacent to the probe, since without the magnetic field, it has been shown that the maximum noise at the probe is developed only when its voltage is such as to accelerate electrons.[4]

Since the plasma acts as a "virtual" cathode with respect to the anode, it seemed probable that placing the magnetic field at the anode should produce the same effect on the noise spectrum as a field at the cathode. The experiment was tried, and the results were as expected (Fig. 7). In fact, the noise with the field at the anode was actually of higher level than that produced by a field at the cathode. Placing the magnetic field at any other position in the discharge decreased the over-all noise level, *i.e.*, the magnet had to be placed at a source of electrons to produce the high level noise. It has been observed elsewhere that the light from the discharge fluctuates with a "light" noise spectrum identical in shape with that of the electrical noise spectrum.[7] The light fluctuations were studied with a photo-cell. This effect was also noted in our investigation.



Argon at 85 microns
Anode current = 20 ma

FIG. 7. Noise spectrum of experimental tube for magnetic field at cathode (A) and at anode (B).

With a sufficiently strong magnetic field at the cathode, there is a narrow region of intense illumination adjacent to the cathode. Numerous experiments with fixed and moving probes show that the positive-ion density is abnormally high in the region close to the cathode when the magnetic field is applied. The positive-ion density was measured by the method of Langmuir and Mott-Smith.[8] For example, in one tube the positive-ion density near the cathode changed from $0.6\times10^{10}$ ions/cm$^3$ to $3.0\times10^{10}$ ions/cm$^3$ upon application of the magnetic field.

## DISCUSSION

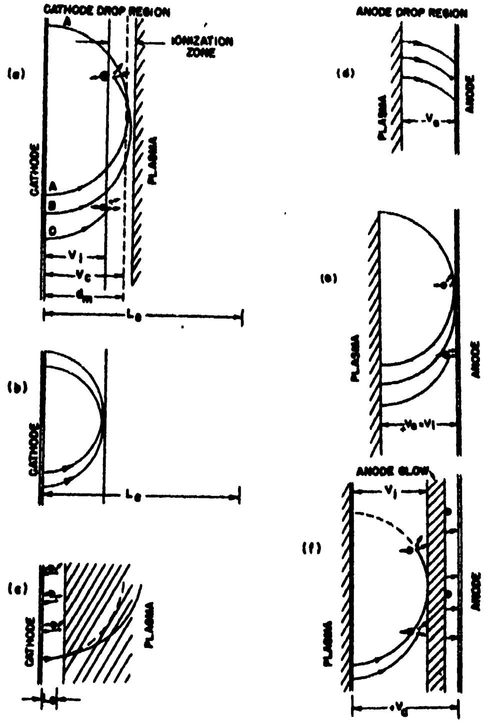
It is apparent that the generation of noise in the presence of the magnetic field is closely related to the space charge conditions at the cathode, or in particular, to the increased positive-ion density mentioned above. That the magnetic field must increase the positive-ion density in a narrow region near the cathode can be seen by considering Fig. 8. This figure presents a picture of the processes at a plane cathode and anode where each is in a strong magnetic field. The trajectory of an electron which does not collide with any atoms (A of Fig. 8a) will return to the cathode. The path will be determined by the electric and magnetic fields. In a uniform magnetic field, with plane electrodes and with no space charge or initial velocity, the path is cycloidal. If the electric field is distorted by

---

[7] Observed by Dr. R. W. Engstrom, Radio Corporation of America, Lancaster, Pennsylvania.

[8] I. Langmuir and H. Mott-Smith, Gen. Elec. Rev. 27, 449 (1924).

space charge, a direct calculation of the path is not possible unless a relation between electric field and distance is known. Thomson has shown that the paths in the dark space of a glow discharge in a transverse magnetic field are similar in form to cycloids.[9] It is probable that the paths do not differ greatly in the hot-cathode arc. If the pressure is such that the electrons make most of their collisions when near the point of maximum distance from the cathode, it is apparent that an intensely ionized zone will be found at this distance. If there is a very small spread in the initial velocities of the electrons, this zone will be very narrow. At higher pressures, the electrons will ionize much closer to the cathode, and the magnetic field will have little effect. Also, since the electric field is greater, the projected path will extend farther from the cathode (Fig. 8c). As the pressure is reduced, the point of maximum ionization moves out along the trajectory. At the same time, the maximum in the trajectory moves nearer the cathode because of the smaller electric field. At very low pressures the ionization must be occurring in a very narrow region, since reduction of the pressure makes it more and more probable that a collision will not occur until the electron has passed the maximum in the trajectory. In this portion of the path the electron is losing energy to the field. Thus, the electron must ionize before it reaches the point where its energy is less than the ionization potential (B of Fig. 8a). In the limiting case, immediately preceding extinction of the discharge, the zone of ionization must be very narrow. This picture assumes that most of the ionization results from single collisions. Multiple ionization, although certainly occurring, is not favored under conditions of low pressures. Such cumulative ionization as does occur would broaden the ionization zone.



(a) Cathode region, pressure = few hundred microns
A = trajectory of electron making no collisions
B = trajectory of electron making collision as it leaves ionization zone
C = trajectory of electron making collision as it enters ionization zone
(b) Cathode region, same pressure as (a), magnetic flux density = cut off value

$V_i$ = ionization potential of gas
$V_c$ = cathode drop of potential
$d_m$ = mean distance of ionization zone from cathode
$V_a$ = anode drop of potential

FIG. 8. Details of electron paths with transverse magnetic field.

It is also possible for the magnetic field to establish a narrow zone of ionization at the anode. Possible space charge conditions are shown in Fig. 8 (d, e, f). If the anode drop is negative, electrons coming from the plasma are retarded, and little ionization occurs near the anode (Fig. 8d). If the anode drop is positive and slightly greater than the ionization potential, space charge conditions are similar to those at the cathode, since the plasma acts as a source of electrons (Fig. 8e). If the anode is small, a second ionized zone may be formed adjacent to it (Fig. 8f).

Dr. Felix Bloch suggested during the course of this research that the source of the increased noise is in the region of high space-charge density, where the ions in each element of volume can oscillate with a frequency determined by the local ion density, as in the plasma oscillations studied by Tonks and Langmuir. Since the ion density varies greatly over this region, a wide range of frequencies would be present instead

---

[9] J. J. Thomson, *Conduction of Electricity through Gases* (Cambridge University Press, London, 1933), third edition, Vol. II, p. 333 ff.

of the single characteristic frequency of the plasma. Tonks and Langmuir have shown that the plasma type oscillation can take place if the mean distance between ions is less than the Debye distance. For the ion densities and temperatures observed here, the Debye distance is several orders of magnitude greater than the interionic spacing. An unpublished analysis by Drs. Felix Bloch and Robert Weinstock[10] indicates that the highly ionized region may be as thin as $5\times10^{-5}$ cm and is capable of generating frequencies as high as 250 Mc/sec.

Additional evidence for the effect of the narrow ionization zone in producing the noise may be found in some additional experiments with oxide-coated cathodes. A number of commercial tubes were found deficient in high frequency noise unless the cathodes were properly treated to insure good emission. As might be expected, the arc drop was higher than for a normal tube at the same current. The higher arc drop is known to result in sputtering of the cathode materials which have much lower ionization potentials than argon. (Ionization potential of barium = 5.19 volts.) These sputtered atoms can be ionized over a broad region beginning close to the cathode. Thus, if there is an appreciable density of sputtered atoms, there will be a marked broadening of the ionization zone, with consequent lowering of the ion-density peak. This principle of the variation of high frequency noise level with cathode activation was used in designing an instrument for production testing of commercial tubes.

ACKNOWLEDGMENT

The authors wish to acknowledge the generous assistance of Dr. J. H. Van Vleck and Dr. Felix Bloch for many consultations during the course of this research. Acknowledgment is also made to Dr. Martin Freundlich and Mr. Stanley Ruthberg who built most of the experimental tubes used for these studies.

# Numerical Solution of Axisymmetrical Problems, with Applications to Electrostatics and Torsion

GEORGE SHORTLEY, *Mendenhall Laboratory of Physics, Ohio State University, Columbus, Ohio*

ROYAL WELLER, *Naval Ordnance Laboratory, Washington, D. C.*

PAUL DARBY,* *Mendenhall Laboratory of Physics, Ohio State University, Columbus, Ohio*

AND

EDWARD H. GAMBLE,** *Mendenhall Laboratory of Physics, Ohio State University, Columbus, Ohio*

(Received September 19, 1946)

Numerical methods are given for solution of axisymmetrical problems involving the partial differential equation

$$\frac{\partial^2\psi}{\partial z^2}+\frac{\partial^2\psi}{\partial\rho^2}+\frac{K}{\rho}\frac{\partial\psi}{\partial\rho}=0,$$

where $\rho$ is the radial coordinate and $z$ the coordinate parallel to the axis. The various values of $K$ which occur in physical situations are discussed, and common iteration methods for handling these problems are given. For Laplace's equation, $K=1$. For the Stoke's stream function, $K=-1$, but it is pointed out that for numerical work a new function, called the *flow-disturbance function*, having $K=3$, is more tractable. Similarly a new function with $K=5$, the *stress-concentration function*, is much easier to compute than the usual stress function ($K=-3$) for the case of the torsion of a circular shaft of varying diameter. The methods are illustrated by computation of the equipotentials for an electron lens, and by a complete computation of the stresses and strains in a particular grooved circular shaft under torsion.

## 1. INTRODUCTION

THIS paper represents an extension of the numerical methods for handling partial differential equations in two dimensions, which were developed in recent work on "Numerical Solution of Laplace's and Poisson's Equations, with Applications to Photoelasticity and Torsion."[1] For the basis of some of the methods used in the present paper, reference should be made to this previous work. On the other hand, the method of extrapolation developed in Section 6 of the present paper is an improvement over that previously given, and can be used in the solution of Laplace's and Poisson's equations in two dimensions as well as in the cases discussed here.

An axisymmetrical problem is essentially two-dimensional, since the functions which arise depend only on the coordinate $z$, measured parallel to the axis, and the radius $\rho$, measured normal to the axis, and are independent of the azimuthal angle $\varphi$. The differential equations which govern many functions of technical interest are of the form

$$\frac{\partial^2\psi}{\partial z^2}+\frac{\partial^2\psi}{\partial \rho^2}+\frac{K}{\rho}\frac{\partial\psi}{\partial\rho}=0, \qquad (1)$$

which we abbreviate to

$$\Delta'\psi+(K/\rho)\psi_\rho=0. \qquad (1')$$

Here the constant $K$ takes on the following values:

$K=1$, Laplace's equation, applicable to the potentials of axially symmetric electrostatic, magnetostatic, and gravitational fields; and the steady flow of heat, electric current, and ideal fluid. This case is discussed in Section 7, with an application to an electron-lens system.

$K=-1$, Stoke's stream function, which is constant along a stream line in the steady flow of heat, electric current, and ideal fluid. This function, while it satisfies simpler boundary conditions than the potential, has the disadvantage for numerical work of rapid variation with $\rho$; for a unidirectional stream it varies as $\rho^2$. Hence it is preferable to introduce a new function, the *flow-disturbance function*, which is the stream function divided by $\rho^2$. This function is constant in regions free from disturbance and satisfies the above equation with

$K=3$; the use of the flow-disturbance function for numerical work is exactly analogous to the use of the stress-concentration function which is discussed in detail in this paper.

$K=-3$, a function which governs the stresses in a circular shaft of varying diameter. We introduce a new function, the *stress-concentration function*, more suitable for numerical work, which satisfies the equation with

$K=5$; the use of the stress-concentration function is the subject of Sections 8–10 of this paper.

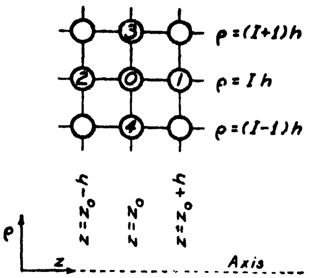

FIG. 1. Notation for an ordinary point of the net.

Because these problems differ only in the value of $K$ in (1), the methods of numerical solution will be similar and can be discussed without specifying the value of $K$.

It is well to point out at this time that any numerical integration of an elliptic partial differential equation in two or more dimensions is bound to be very tedious and time-consuming if high accuracy is desired simply because of the number of net points which must be used. The more irregular the boundaries, the more points which must be used if accuracy is to be obtained in the vicinity of the irregularities. But it seems important to know that a computation can be carried through numerically when required, and to investigate the most expeditious manner of making the computation. The procedures given below and in reference 1 are believed to contain most of the formal tricks for speeding up the computations which have been discovered to date and to constitute the best available computational scheme. It is hoped that some day high speed electronic computing equipment will be developed with sufficient internal-memory capacity to handle data on a large net; in this case it may be advisable to ignore tricks, use the simplest possible improvement formula at each point, and let the machine work somewhat

These three papers have been combined in the Ohio State University Engineering Experiment Station Bulletin No. 107 (1940); revised, 1942. In these papers will be found complete references to earlier work.

longer, or to use some non-iterative procedure such as a direct numerical solution of the difference equations.

## 2. THE ITERATION PROCEDURE

We first replace the continuum of points $(z, \rho)$ by the discrete set of points at the intersections of a net of intervals $h$:

$$z=0,\ \pm h,\ \pm 2h,\ \pm 3h,\ \cdots,$$
$$\rho=0,\ h,\ 2h,\ \cdots,\ Ih,\ \cdots.$$

The differential equation is then replaced by a difference equation which relates the value of $\psi$ at one point to its values at neighboring points. The solution of the difference equation is then an approximation to the solution of the differential equation—the finer the net, the better the approximation.

For example, consider the five numbered points in the diagram (Fig. 1). Denote the function values at these points by $\psi_0$, $\psi_1$, $\psi_2$, $\psi_3$, and $\psi_4$. At the point 0 $(z=z_0,\ \rho=Ih)$, Eq. (1′) may be written as

$$\Delta'\psi_0+(K/Ih)\psi_{\rho 0}=0$$

or

$$h^2\Delta'\psi_0+(K/I)h\psi_{\rho 0}=0. \tag{2}$$

Now on any quadric surface passing through the five function values $\psi_0, \cdots, \psi_4$, the following relations are satisfied:

$$h^2\Delta'\psi_0=-4\psi_0+\psi_1+\psi_2+\psi_3+\psi_4,$$
$$h\psi_{\rho 0}=\tfrac{1}{2}\psi_3-\tfrac{1}{2}\psi_4.$$

Hence the differential equation (2) is approximated—to the accuracy with which the function $\psi$ is representable by a quadric in the region containing these five points—by the difference equation

$$-4\psi_0+\psi_1+\psi_2+\psi_3+\psi_4+(K/I)(\tfrac{1}{2}\psi_3-\tfrac{1}{2}\psi_4)=0 \tag{3}$$

or

$$8I\psi_0=2I\psi_1+2I\psi_2+(2I+K)\psi_3+(2I-K)\psi_4. \tag{4}$$

This difference equation holds at all ordinary points of the net, but needs modifications, which will be considered later, at points near the axis or near a material boundary.

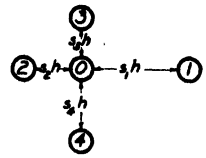
The iteration procedure, originated by Liebmann,[1] for finding the function values which satisfy this difference equation at all net points, proceeds as follows: Start with any arbitrary "trial" function $\psi$—a guess. Then go over the points of the net, in some definite order, replacing the $\psi$ value at each net point by a new value calculated from (4) in terms of the values at neighboring points. This will give an "improved" function $\psi'$. In calculating the improved value at a given point, the previously altered values are used whenever they are available. This procedure is then iterated. Successive traverses of the net give successively functions $\psi', \psi'', \psi''', \cdots$ which approach the true solution of the difference equation in a manner to be considered in Section 6.

We shall now consider modifications of the difference equation (3), necessary at points near the axis or near a boundary, and modifications leading to more rapid convergence. The essence of the iteration procedure is that at any point the difference equation, solved for $\psi_0$ as in (4), may be used as an "improvement formula." A proof of convergence, by this process, to the exact solution of the difference equation, and a method of investigating the rate of convergence, are developed in reference 1. This theory assumes that the improvement formula expresses the value at a point as a *true weighted average* of the neighboring values, *with all weights positive.* We note that the coefficient of $\psi_0$, in (4) and the following improvement formulas, equals the sum of the coefficients of the neighboring values $\psi_1$, $\psi_2$, $\cdots$. A little experimentation shows that if negative coefficients are permitted, the procedure may not converge, so we reject any improvement formula which involves negative coefficients and attempt to replace it by an alternative formula in which all the coefficients are positive.

## 3. IMPROVEMENT FORMULAS

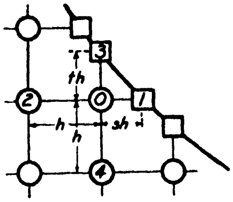
The following formulas are derived by passing a quadric through $\psi_0, \psi_1, \psi_2, \cdots$ which is required to satisfy the differential equation at point 0. The mechanism for accomplishing this is discussed in Appendix 1. Certain of the coefficients in these formulas, as well as in (4), become negative for high $K$ and low $I$ values. Formulas with negative coefficients may be used for interpolation but not for improvement. Modifications necessary to eliminate these negative coefficients will be considered later for each $K$ value separately. *In each diagram below, the coordinate axes are assumed to run as in Fig. 1, with the symmetry axis horizontal and below the diagram, and with coordinates $z=z_0$, $\rho=Ih$, for the point 0.*

*Unequal spacing:*



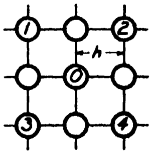
$$\left(\frac{2I}{s_1s_2}+\frac{2I+K(s_4-s_3)}{s_3s_4}\right)\psi_0=\frac{2I}{s_1(s_1+s_2)}\psi_1+\frac{2I}{s_2(s_1+s_2)}\psi_2+\frac{2I+Ks_4}{s_3(s_3+s_4)}\psi_3+\frac{2I-Ks_3}{s_4(s_3+s_4)}\psi_4. \tag{5}$$

*Point near boundary:*



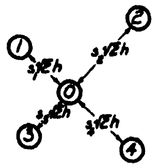
$$\left(\frac{2I}{s}+\frac{2I+K(1-t)}{t}\right)\psi_0=\frac{2I}{s(1+s)}\psi_1+\frac{2I}{1+s}\psi_2+\frac{2I+K}{t(1+t)}\psi_3+\frac{2I-Kt}{1+t}\psi_4. \tag{6}$$

*Diagonal formula:*



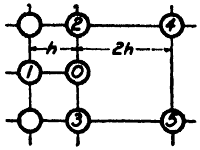
$$8I\psi_0=(2I+K)\psi_1+(2I+K)\psi_2+(2I-K)\psi_3+(2I-K)\psi_4. \tag{7}$$

*Diagonal formula, unequal spacing:*

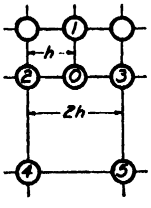


$$\left(\frac{2I+K(s_4-s_1)}{s_1s_4}+\frac{2I+K(s_3-s_2)}{s_3s_2}\right)\psi_0=\frac{2I+Ks_4}{s_1(s_1+s_4)}\psi_1+\frac{2I+Ks_3}{s_2(s_2+s_3)}\psi_2+\frac{2I-Ks_2}{s_3(s_2+s_3)}\psi_3+\frac{2I-Ks_1}{s_4(s_1+s_4)}\psi_4. \tag{8}$$

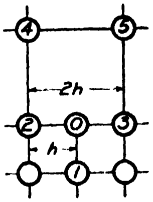
*Change of net spacing:*



$$16I\psi_0=4I\psi_1+(5I+3K)\psi_2+(5I-3K)\psi_3+I\psi_4+I\psi_5; \tag{9}$$

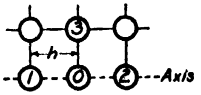


$$(32I+8K)\psi_0=(8I+8K)\psi_1+(10I+K)\psi_2+(10I+K)\psi_3+(2I-K)\psi_4+(2I-K)\psi_5; \tag{10}$$

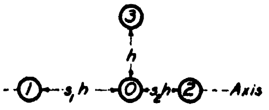


$$(32I-8K)\psi_0=(8I-8K)\psi_1+(10I-K)\psi_2+(10I-K)\psi_3+(2I+K)\psi_4+(2I+K)\psi_5. \tag{11}$$

*Axis points* (obtained from a quadric, even in $\rho$, which satisfies the differential equation everywhere):

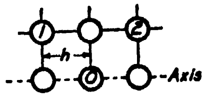


$$(2K+4)\psi_0=\psi_1+\psi_2+(2K+2)\psi_3; \tag{12}$$



$$\left(1+K+\frac{1}{s_1s_2}\right)\psi_0=\frac{1}{s_1(s_1+s_2)}\psi_1+\frac{1}{s_2(s_1+s_2)}\psi_2+(1+K)\psi_3. \tag{13}$$

*Axis point, diagonal* (obtained from the linear solution $\psi=\psi_0+Az$; not to be used except for interpolation):



$$\psi_0=\tfrac{1}{2}(\psi_1+\psi_2). \tag{14}$$

## 4. NINE-BLOCK FORMULAS

As explained in reference 1, the convergerce of the iteration procedure is much more rapid if we improve, not one point at a time, but a block of points all at once. A block of nine points is the maximum that can be handled conveniently. In the case of Laplace's equation, the use of nine-blocks was found to cut the labor by a factor of 3.5, and the saving of time is of the same order of magnitude for these axially symmetric problems.

The idea is to find improved values for all the nine circled points of Fig. 2 in terms of the values at the surrounding points, marked by squares. We start by writing the difference equation (4) for each of the nine points in terms of its neighbors. Elimination of the $\psi$ values at points $b$, $B$, $c$, $d$, $D$ then leaves a formula for $\psi_0$ in terms of only the outside points $e$, $E$, $f$, $F$, $g$, $G$, $m$. This formula gives an improved value for $\psi_0$ in which the difference equation is satisfied simultaneously at all nine points of the block. The coefficients in this improvement formula are fifth-order polynomials in $I$ and $K$ (see Appendix 2), so we give in Tables I and II the numerical values needed for $K=1$ and $K=5$. These tables give the coefficients by which each of the 12 boundary points are to be multiplied to get the improved center-point value. The coefficients given for points $F$, $G$, $m$, $g$, and $f$ are each to be used twice.

After the center value $\psi_0$ has been determined in this way, the four corner values $d$, $D$, are determined from it and the outside values at $e$, $E$, $m$, $n$, $N$ by using the diagonal formula (7); finally the side points $b$, $B$, $c$ are obtained from the ordinary improvement formula (4). In this way improved values for all nine points of the block are filled in without using any of the old values at these points.

## 5. USE OF THE DIFFERENCE FUNCTION

A great saving in labor is achieved by carrying out operations, not on the function $\psi$ itself, but on the "difference function," which represents the change in $\psi$ with one traverse. We suppose that the net has been completely laid out, the improvement formula for each point and a definite order of traversing the points and blocks decided on, and the initial trial function chosen. Suppose that the net were traversed several times, to obtain successively the improved functions $\psi'$, $\psi''$, $\cdots$. We call the change in function value at each point, $\delta=\psi'-\psi$, the *difference function*. Let $\delta'$ be the next change or difference: $\delta'=\psi''-\psi'$. Then if, after one traverse, we compute $\delta$ at each point by subtraction, we can compute what the next change $\delta'$ will be by applying our improvement formulas directly to $\delta$. For, application of the improvement process to $\psi$ gives $\psi'$, application to $\psi'$ gives $\psi''$, application to the difference $\delta=\psi'-\psi$ will give the difference $\delta'=\psi''-\psi'$.

Hence after *one* traverse, we can compute all successive changes which $\psi$ will undergo by operating on the difference function $\delta$ in place of operating on $\psi$ itself. There are a number of factors which make it much simpler to work with the difference function than with $\psi$. First, the difference function usually has fewer significant figures than has $\psi$. Second, the boundary values of the difference function are all zero; this gives many zero terms in the improvement formulas. Finally, we know the value to which the difference function will converge after a large number of improvements, *viz.*, to the value *zero* at each point, because of the zero boundary values. This convergence to zero takes place in a regular manner which permits convenient extrapolation.

If the successive difference functions are denoted by $\delta=\psi'-\psi$, $\delta'$, $\delta''$, $\delta'''$, $\cdots$, the final solution of the problem for this net will be obtained by the addition

$$\Psi=\psi'+\delta'+\delta''+\delta'''+\cdots. \qquad (15)$$

## 6. EXTRAPOLATION

As discussed in reference 1, it is possible to find certain functions with zero boundary values which, when improved, will be reduced to a constant fraction of themselves without being changed in shape. Such a function is called a characteristic function of the improvement process. The different characteristic functions are denoted by $\phi^{(1)}$, $\phi^{(2)}$, $\phi^{(3)}$, $\cdots$. On improvement these go over to

$$\phi^{(1)\prime}=\lambda_1\phi^{(1)}, \quad \phi^{(2)\prime}=\lambda_2\phi^{(2)}, \quad \text{etc.}$$

The $\lambda$ values (characteristic values) will all be less than unity, and one of them, say $\lambda_1$, will be the largest. It is now possible to make a sort of Fourier expansion of the actual difference function $\delta$ in terms of the characteristic functions,[2] i.e.,

$$\delta=a_1\phi^{(1)}+a_2\phi^{(2)}+a_3\phi^{(3)}+\cdots.$$

On improvement this becomes successively

$$\begin{aligned}\delta'&=a_1\lambda_1\phi^{(1)}+a_2\lambda_2\phi^{(2)}+a_3\lambda_3\phi^{(3)}+\cdots,\\ \delta''&=a_1\lambda_1^2\phi^{(1)}+a_2\lambda_2^2\phi^{(2)}+\cdots,\\ \delta'''&=a_1\lambda_1^3\phi^{(1)}+a_2\lambda_2^3\phi^{(2)}+\cdots, \quad \text{etc.}\end{aligned}$$

Thus after $k$ improvements, the coefficients of the various characteristic functions in $\delta$ are decreased by factors $\lambda^k$. After a time only the function with the highest characteristic value will remain, and $\delta^{[k]}$ will become a fairly smooth, pillow-shaped, one-signed function decreasing uniformly by a factor $\lambda_1$ at each iteration. At this stage one has

$$\begin{aligned}\delta^{[k]}&=c\phi^{(1)},\\ \delta^{[k+1]}&=\lambda_1c\phi^{(1)},\\ \delta^{[k+2]}&=\lambda_1^2c\phi^{(1)}, \quad \text{etc.}\end{aligned}$$

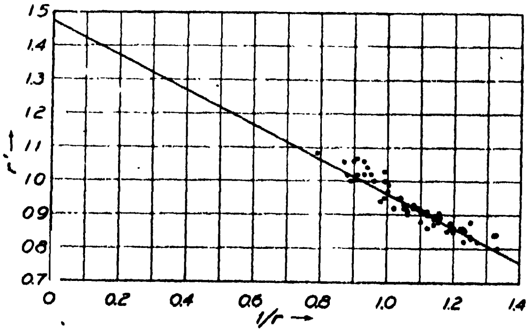

FIG. 3. Extrapolation. Plot of ratios in Eq. (18) for first extrapolation on net shown in Fig. 7. The straight line has the equation $r'=1.475-0.513(1/r)$ so $\lambda_1\approx0.914$, $\lambda_2\approx0.561$, and the right member of Eq. (19) becomes $-13\delta^{[k-1]}+26\delta^{[k]}$.

---

[2] This statement is not mathematically rigorous, but is adequate for the practical application of the extrapolation scheme. For discussion of this point, see the first paper of reference 1.

so that

$$\delta^{[k]}+\delta^{[k+1]}+\delta^{[k+2]}+\cdots$$
$$=c\phi^{(1)}(1+\lambda_1+\lambda_1^2+\cdots)=\delta^{[k]}/(1-\lambda_1),$$

which furnishes the evaluation of the infinite sum occuring in (15).

This was the method of extrapolation contemplated in reference 1. But is it not necessary to wait for all characteristic functions except $\phi^{(1)}$ to become small before extrapolating. For a fine net ($\lambda$ values close to unity), it will cut the labor by a large factor if we can extrapolate when *two* of the functions, $\phi^{(1)}$ and $\phi^{(2)}$, remain of importance. Let us suppose that we have improved the difference function $k$ times and that we may write

$$\begin{aligned}\delta^{[k-2]}&=c_1\phi^{(1)}+c_2\phi^{(2)},\\ \delta^{[k-1]}&=\lambda_1c_1\phi^{(1)}+\lambda_2c_2\phi^{(2)},\\ \delta^{[k]}&=\lambda_1^2c_1\phi^{(1)}+\lambda_2^2c_2\phi^{(2)},\quad\text{etc.}\end{aligned}\tag{16}$$

Let us define two successive ratios by

$$r=\delta^{[k-1]}/\delta^{[k-2]};\quad r'=\delta^{[k]}/\delta^{[k-1]}.\tag{17}$$

If $c_1\phi^{(1)}$ and $c_2\phi^{(2)}$ are eliminated from these two ratios, we find that if (16) are satisfied, then

$$r'=(\lambda_1+\lambda_2)-\lambda_1\lambda_2(1/r).\tag{18}$$

Hence we can test whether a net has reached the stage where the differences obey fairly well the relations (16) by computing $r$ and $r'$ at various points and plotting $r'$ against $(1/r)$. If (16) are exactly obeyed, these points will fall on a straight line of slope $(-\lambda_1\lambda_2)$ and intercept $(\lambda_1+\lambda_2)$. This plot will not only tell whether (16) are approximately valid, but will determine the values of $\lambda_1$ and $\lambda_2$ to use in the extrapolation. Such a plot is given in Fig. 3 by way of illustration.

With characteristic values determined as above for the net as a whole, the values of $c_1\phi^{(1)}$ and $c_2\phi^{(2)}$ at any point are fixed by any two successive $\delta$'s of (16). Algebraic manipulation shows that if (16) are obeyed, then

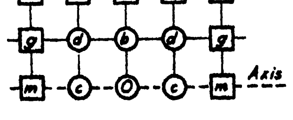

FIG. 4. A nine-block split by the axis.

$$\delta^{[k-1]}+\delta^{[k]}+\delta^{[k+1]}+\delta^{[k+2]}+\cdots$$
$$=\delta^{[k-1]}\frac{1-\lambda_1-\lambda_2}{(1-\lambda_1)(1-\lambda_2)}+\frac{\delta^{[k]}}{(1-\lambda_1)(1-\lambda_2)}.\tag{19}$$

Hence the extrapolation proceeds as follows: Suppose that we have computed

$$\begin{gathered}\psi,\ \psi',\\ \delta,\ \delta',\ \delta'',\ \cdots,\ \delta^{[k-2]},\ \delta^{[k-1]},\ \delta^{[k]},\end{gathered}\tag{20}$$

and believe that the differences are proceeding regularly enough to try an extrapolation under the assumption of (16). Compute $r$ and $r'$ for all points of the net which give enough significant figures to be useful in $\lambda$-value determinations. Make a plot like Fig. 3; from it determine $\lambda_1$ and $\lambda_2$. Compute the coefficients $(1-\lambda_1-\lambda_2)/(1-\lambda_1)(1-\lambda_2)$ and $1/(1-\lambda_1)(1-\lambda_2)$ in (19). Then compute the extrapolated function value $\Psi$ at each point by adding (see (15))

$$\Psi=\psi'+\delta'+\delta''+\cdots+\delta^{[k-2]}$$
$$+\frac{1-\lambda_1-\lambda_2}{(1-\lambda_1)(1-\lambda_2)}\delta^{[k-1]}+\frac{1}{(1-\lambda_1)(1-\lambda_2)}\delta^{[k]}.\tag{21}$$

Note that while the three last differences of (20) are assumed to obey (16) for the purpose of computing $\lambda_1$ and $\lambda_2$, only the last two differences $\delta^{[k-1]}$ and $\delta^{[k]}$ need obey (16) for the extrapolation (21) to be valid.

### 7. $K=1$, LAPLACE'S EQUATION

In this case we run into no difficulty with negative coefficients under any circumstance. Table I gives the coefficients by which the values at the outside points of Fig. 2 are to be multiplied to obtain the improved value $\psi_0$ at the center point of the block. If these coefficients are used as multipliers on the computing machine, a check of the computation is furnished by the fact that their sum, after all 12 values have been used, is unity. In addition to these values, it is convenient to have those for a block split by the axis as in Fig. 4. For this block the center point

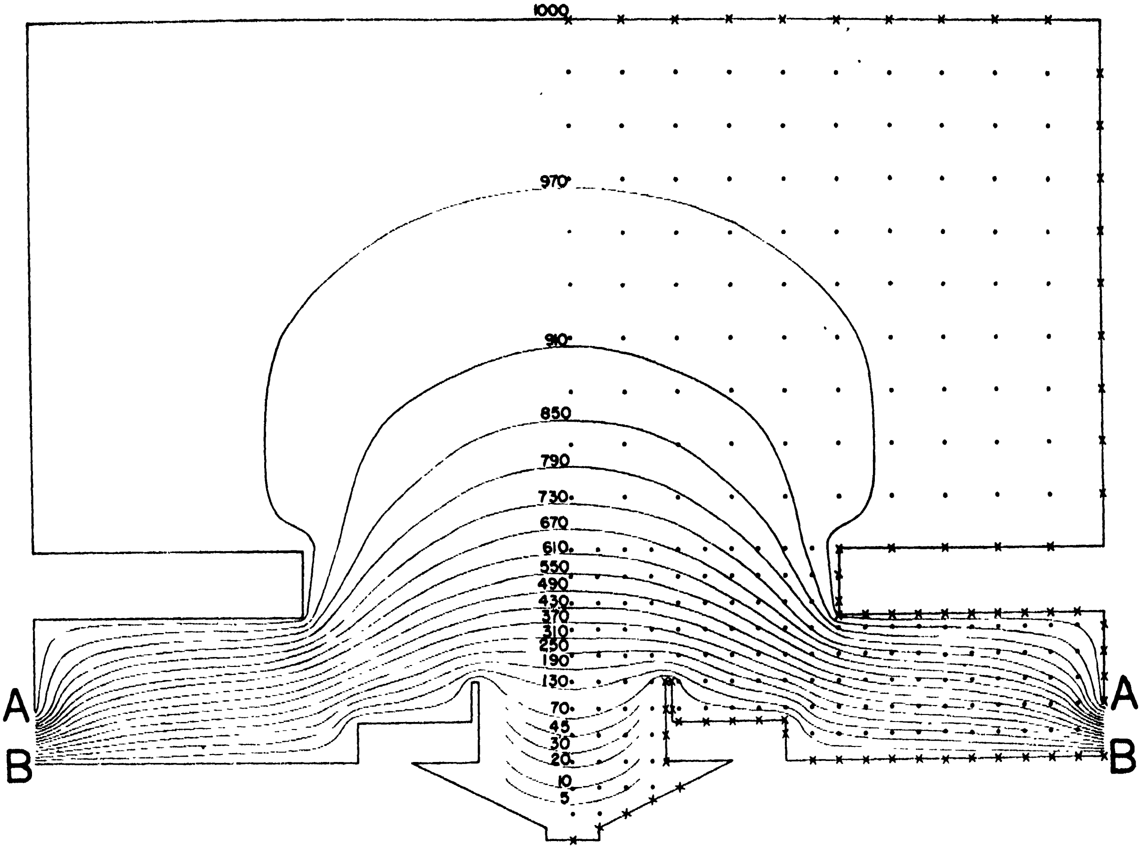

FIG. 5. Equipotential surfaces for an electron lens.

is given by

$$376\psi_0 = 16\psi_m + 40\psi_g + 60\psi_f + 144\psi_e + 60\psi_f + 40\psi_g + 16\psi_m, \qquad (22)$$

where the boundary points are taken in order around the block. These coefficients, divided by 376, are listed for $I=0$ in Table I.

As an example of the application of this numerical method we print Fig. 5, which shows the equipotential surfaces for an electron lens in whose properties we were interested. The axis in this figure is vertical. The potential of the upper electrode $AA$ is taken as 1000 volts, that of the lower electrode $BB$ as zero. The net points and boundary points used in the computation are indicated by circles and crosses, respectively. The equipotential surfaces are accurate for the difference equation on these net points; the departure from the solution of the differential equation is probably about one percent over most of the net. We were particularly interested in the degree of penetration of the field into the almost enclosed spaces in the two electrodes.

## 8. THE TORSION OF AN AXIALLY SYMMETRIC SHAFT

The stresses in a circular shaft of variable diameter subjected to torsion may be expressed[3] in terms of a function $\phi(\rho, z)$ which satisfies the differential equation

$$\frac{\partial^2\phi}{\partial\rho^2} + \frac{\partial^2\phi}{\partial z^2} - \frac{3}{\rho}\frac{\partial\phi}{\partial\rho} = 0. \qquad (23)$$

In terms of this function, the stresses have the values:

Normal stresses: $\sigma_\rho = \sigma_z = \sigma_\varphi = 0.$

---

[3] S. Timoshenko, *Theory of Elasticity* (McGraw-Hill Book Company, Inc., New York, 1934), p. 276 *et seq.*; our definition of $\phi$ differs by a factor $2\pi$ from that of Timoshenko. Physically, $\phi(\rho, z)$ is the torque transmitted across a surface bounded by the circle $\rho = \rho$, $z = z$.

Shears: $\tau_{\rho z}=0,$

$$\tau_{\varphi\rho}=-\frac{1}{2\pi\rho^2}\frac{\partial\phi}{\partial z}, \tag{24}$$

$$\tau_{\varphi z}=\frac{1}{2\pi\rho^2}\frac{\partial\phi}{\partial\rho}$$

Boundary conditions require that $\phi=0$ along the axis or on the inner boundary if the shaft is partially or entirely hollow; $\phi=M$, the torque, on the outer boundary. In a diametral $(\rho, z)$ plane, lines of constant $\phi$ are in the direction of the maximum shear.

For a straight circular shaft of radius $a$, the function $\phi$ is $M\rho^4/a^4$. The only component of stress is $\tau_{\varphi z}=2M\rho/\pi a^4$.

Since $\tau_{\varphi z}$ must vanish at $\rho=0$, we see from (24) that for any shaft $\phi$ must vary like $\rho^4$ near the axis. A function varying this rapidly is inconvenient to handle by numerical methods; it is simpler to work with the function

$$\Psi=\phi/\rho^4 \tag{25}$$

which will start like $A+B\rho^2+\cdots$ (where $A$ and $B$ are functions of $z$) near the axis.

The function $\Psi$ will satisfy the differential equation

$$\frac{\partial^2\Psi}{\partial\rho^2}+\frac{\partial^2\Psi}{\partial z^2}+\frac{5}{\rho}\frac{\partial\Psi}{\partial\rho}=0. \tag{26}$$

Boundary values for $\Psi$ are determined from those of $\phi$ according to (25); along the axis $\Psi$ does not vanish but $\partial\Psi/\partial\rho=0$, and in fact, if $\Psi$ be expanded in a power series, only even powers of $\rho$ may occur.

For a straight circular shaft,

$$\Psi=\text{const.}=M/a^4.$$

For a grooved or filleted shaft with long straight cylindrical end sections, $\Psi$ is constant except in the vicinity of the groove or fillet where the stresses depart from the circular-shaft values. For this reason, we call $\Psi$ the *stress-concentration function.*

To complete this discussion of elastic theory, we note that if $\Theta(\rho, z)$ represents the angle of twist in radians, at any point, this function is related to the stress function $\phi(\rho, z)$ as follows:[8]

$$\frac{\partial\Theta}{\partial\rho}=-\frac{1}{2\pi G\rho^3}\frac{\partial\phi}{\partial z},$$

$$\frac{\partial\Theta}{\partial z}=\frac{1}{2\pi G\rho^3}\frac{\partial\phi}{\partial\rho},$$

where $G$ is the modulus of elasticity in shear. Hence, for a straight circular shaft of radius $a$, $\Theta$ is $2Mz/\pi a^4G$. From the above relations, it follows that in the $\rho$, $z$ plane, lines of constant $\Theta$ are orthogonal to lines of constant $\phi$.

### 9. $K=5$, THE STRESS-CONCENTRATION FUNCTION

We consider next the application of the numerical methods of Sections 2–6 to the solution of Eq. (26).

Coefficients in the simple improvement formulas (4) and (7) become negative at $I=1$ and $I=2$; special formulas for these points are therefore needed.

For $I=2$, formula (4) gives (cf. Fig. 1)

$$16\psi_0=4\psi_1+4\psi_2+9\psi_3-\psi_4. \tag{27}$$

This formula is not adapted to the iteration process because of the negative coefficient. It was derived by passing a quadric function through points (0), (1), (2), (3), and (4) which satisfied the differential equation at (0). An alternative formula (see Appendix 1) is obtained by passing a fourth-order polynomial *solution* of the differential equation through the five points. For such a solution,

$$4\psi_0=10\psi_1+10\psi_2+9\psi_3-25\psi_4. \tag{28}$$

Use of such fourth-order functions is not advisable in numerical work except on extremely fine nets. But the following linear combination of (27) and (28) eliminates the negative coefficient of $\psi_4$, and involves much more of (27) than (28):

$$22\psi_0=5\psi_1+5\psi_2+12\psi_3 \quad (K=5,\ I=2). \tag{29}$$

It is proposed to use this as the ordinary improvement formula at $I=2$. Similar considerations will not give a diagonal formula for $I=2$ which is free from negative coefficients. Hence,

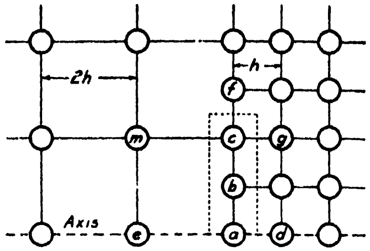

FIG. 6. Change of net spacing near axis.

no diagonal improvement formula is available for $K=5$, $I=2$.

For $I=1$, $K=5$, the simplest and most satisfactory improvement formula is

$$4\psi_0=\psi_3+3\psi_4 \quad (K=5,\ I=1) \tag{30}$$

(cf. Fig. 1, where point (4) is now on the axis). The formula can be obtained by the method used for (29), but more simply, is an approximation to any function that is even in $\rho$. Again, no satisfactory diagonal improvement formula is available for $I=1$.

*Change of net spacing near axis:* For points $b$ and $c$ of Fig. 6, the previous formulas (9) and (5) will involve negative coefficients. For $b$, formula (30)

$$4\psi_b=\psi_c+3\psi_a \tag{31}$$

is available. For $c$, if a cubic *solution* is passed through $b$, $c$, $f$, $g$, $m$, it is found that

$$8\psi_c=5\psi_b+3\psi_f, \tag{32}$$

which is simple and satisfactory. For $a$, (13) gives

$$39\psi_a=36\psi_b+2\psi_d+\psi_e. \tag{33}$$

It is seen that points $a$, $b$, $c$ may be improved simultaneously as a block, thus speeding up the convergence. New values for $a$, $b$, $c$, are obtained from those at $d$, $e$, $f$ by using successively the following three formulas, which are derived from (31)–(33):

$$\begin{aligned} 7\psi_a&=2\psi_d+\psi_e+4\psi_f,\\ 9\psi_b&=8\psi_a+\psi_f,\\ 8\psi_c&=5\psi_b+3\psi_f. \end{aligned} \tag{34}$$

*Nine-blocks:* The regular nine-block procedure sketched in Section 4 can be used only where the center point has $I\geqslant 4$. Table II gives the coefficients used for improvement of the center point. The formulas for the axis nine-block (Fig. 4) may be obtained by use of (30) for points $b$ and $d$. The center point is given by

$$23\psi_0=15\psi_e+3\psi_f+3\psi_f+\psi_m+\psi_m.$$

The other points are then obtained successively from

$$5\psi_c=3\psi_f+\psi_0+\psi_m,$$
$$4\psi_b=\psi_e+3\psi_0, \quad 4\psi_d=\psi_f+3\psi_c.$$

Blocks centered at $I=2$ or 3 are not available because diagonal formulas are needed for the corner points. Hence it is desirable to arrange blocks along the axis and around $I=4$, 7, etc. (cf. Fig. 7). This leaves the row at $I=2$ to be computed from (29). Since the points at $I=1$ do not enter (29), the values at $I=0$ and 1 are frequently absent from the iteration formulas and may be left for computation after all other values have converged.

## 10. STRESS CONCENTRATION IN A GROOVED SHAFT

In order to illustrate these numerical methods and to show how the various quantities of physical interest may be obtained from the stress-concentration function $\Psi$, a complete solution of the torsion problem for the particular grooved shaft shown in Fig. 7 was carried through.

While we are interested in a shaft of this geometrical shape with arbitrary radius $R$, torque $M$, and shear modulus $G$, it is simplest to carry through the numerical computation for the case of unit radius, unit torque, and unit shear modulus, and then to multiply the results by factors which are determined by the physical dimensions of the quantities concerned, i.e., shear values by $M/R^3$ and angles of twist by $M/R^3G$.

*Stress-Concentration Function.* For the shaft of unit radius and unit torque, $\phi=1$ on the boundary and hence the stress-concentration function $\Psi$ equals $1/\rho^4$ on the boundary and approaches 1 on the straight part of the shaft. It is simpler to compute the function $(\Psi-1)$, which satisfies the same differential equation as $\Psi$ and approaches 0 on the straight parts of the shaft. Figure 8 shows contours of this function. The points used in the finest net and the division into blocks are shown in Fig. 7. The values of Fig. 8 are believed

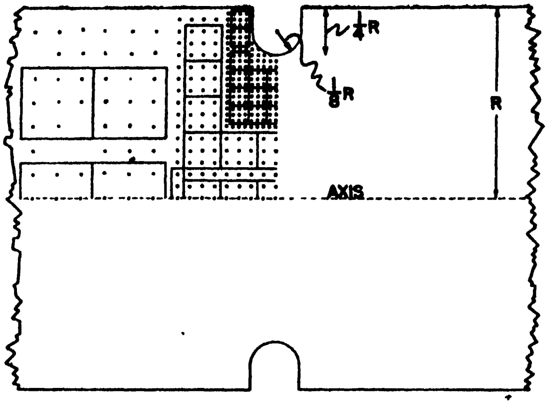

FIG. 7. Grooved shaft showing arrangement of net points and nine-blocks used in numerical stress computation.

to be sufficiently accurate to permit computation of stresses to better than 1 percent accuracy.

*The stress function* $\phi$ for the shaft of unit radius and unit torque is plotted in Fig. 9. Contours are given for $\phi^{\frac{1}{2}}$, which is $\rho\Psi^{\frac{1}{2}}$.

*The twist angle* $\Theta$ is shown in Fig. 10. The values plotted are those of $2\pi\Theta$ for a shaft of unit radius, unit torque, and unit shear modulus. These values were computed from the formula

$$2\pi\Theta(\rho, z) = 2\pi\Theta(\rho, z_0) + \int_{z_0}^{z}\left(4\Psi + \rho\frac{\partial\Psi}{\partial\rho}\right)dz. \quad (35a)$$

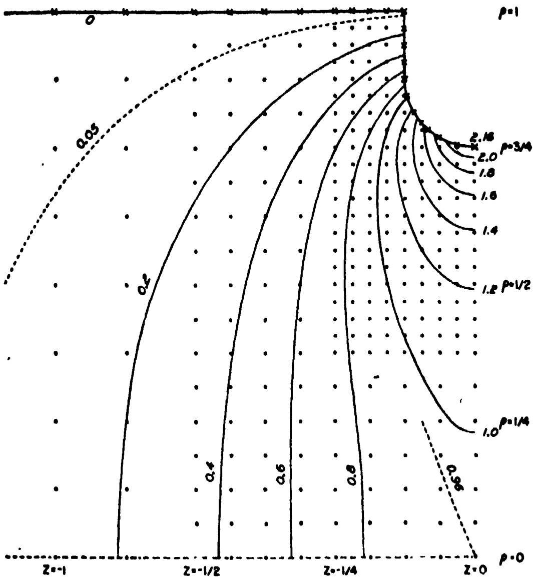

FIG. 8. The stress-concentration function $(\Psi-1)$ for the shaft of unit radius and unit torque.

The value of $\Theta$ was set equal to zero at $z_0 = -1\frac{1}{4}$ (measuring from the plane of symmetry at the groove) where the function $\Psi - 1$ essentially vanishes and the twist is like that of a straight circular shaft. $\partial\Psi/\partial\rho$ was evaluated by the simple parabolic formula

$$\partial\Psi(\rho, z)/\partial\rho = [\Psi(\rho + h, z) - \Psi(\rho - h, z)]/2h$$

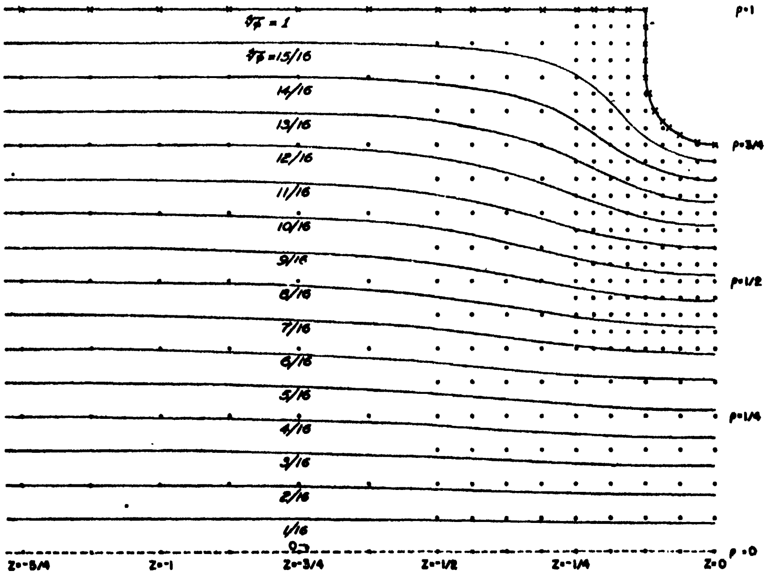

FIG. 9. The stress function $\phi$ for the shaft of unit radius and unit torque. Lines of constant $\phi$ show the directions of the shear vector in the diametral plane.

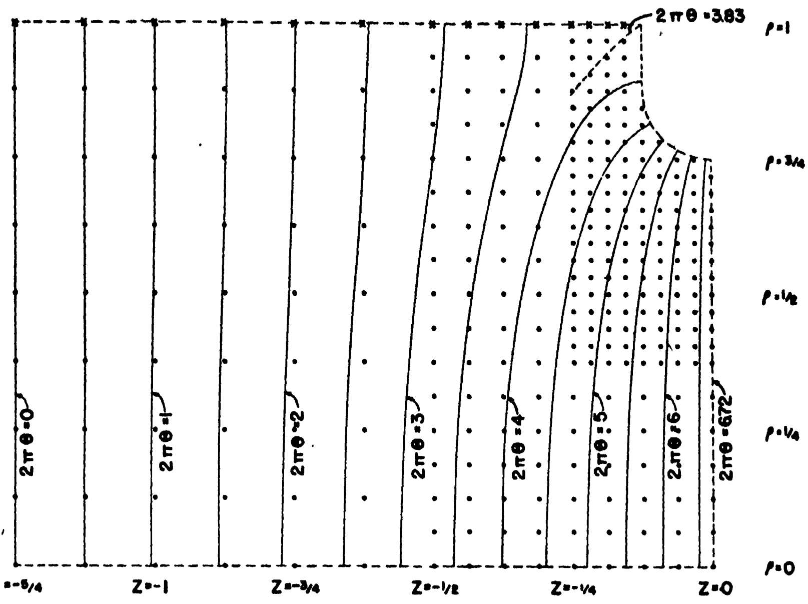

FIG. 10. The twist angle Θ in radians for the shaft of unit radius, unit torque, and unit shear modulus. For the shaft shown in Fig. 7, these values of Θ are to be multiplied by $M/R^3G$. Lines of constant Θ are orthogonal to those of constant $\phi$ shown in Fig. 9, but there is no simple relation between the spacing of the lines on the two plots.

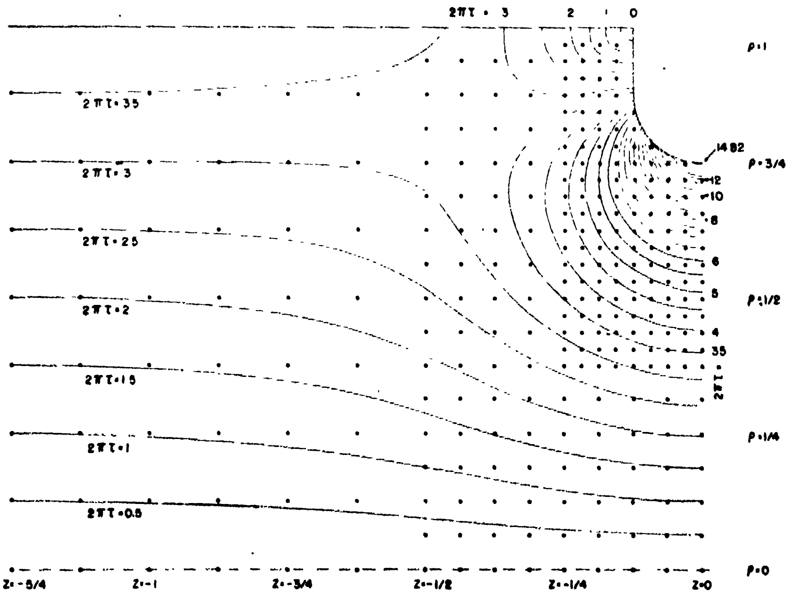

FIG. 11. Magnitude, $\tau = (\tau_{\varphi\rho}^2 + \tau_{\varphi z}^2)^{\frac{1}{2}}$, of the shear vector in the axial plane for the shaft of unit radius with unit torque. The curves of Fig. 9 show the direction of this vector. For the shaft shown in Fig. 7, these values of $\tau$ are to be multiplied by $M/R^3$.

and then the integration was carried out by simple parabolic rules. A check was furnished by the constancy of angle of twist at the plane of symmetry at the groove. Intermediate points were filled in and further checks obtained from the formula

$$2\pi\Theta(\rho, z) = 2\pi\Theta(0, z) - \int_0^\rho \rho\frac{\partial\Psi}{\partial z}d\rho. \quad (35b)$$

It is pointed out that much greater numerical accuracy is obtained in both the angle of twist and in the stresses discussed below by computing them from $\Psi$ rather than from $\phi$.

Figure 10 gives contours[4] of constant twist angle. For a straight shaft without a groove, the contours shown would be uniformly spaced at intervals of $\frac{1}{2}$ in $z$, and the twist at $z=0$ would be $5/2\pi$ radians instead of $6.72/2\pi$ radians for the grooved shaft. The extra twist occasioned by the presence of the groove is thus $1.72/2\pi$ in half the shaft length, or $3.44/2\pi = 0.547$ radian in the whole shaft. For a shaft of radius $R$, torque $M$, and shear modulus $G$, the extra twist introduced by this shape of groove is thus

$$\text{Extra twist} = 0.547M/R^3G \text{ radians},$$

which is equivalent to the twist in a length $0.86R$ of a straight circular shaft of radius $R$. Note that the rate of twist in the section of full diameter decreases as the notch is approached and that this deficiency in twist is made up in the notch in addition to the extra twist given above. One cannot, therefore, determine the extra twist by attaching a torsiometer to the edges of the notch; the value measured will be too great.[4] In our shaft this deficiency amounts to $0.67/2\pi$ radian on the full-diameter part of the shaft near each side of the notch.

Finally, *values of the maximum shear,*

$$\tau = (\tau_{\varphi\rho}^2 + \tau_{\varphi z}^2)^{\frac{1}{2}}$$

are given in Fig. 11. Contours are given for constant values of $2\pi\tau$ for the shaft of unit radius and unit torque. Such values of $\tau$ are to be multiplied by $M/R^3$ in the general case. This plot gives the magnitude of the shear vector in the axial plane, while the curves of Fig. 9 show the direction of this vector.

Values of $2\pi\tau$ were obtained by first computing the components from the formulas

$$\begin{aligned} 2\pi\tau_{\varphi\rho} &= -\rho^2\partial\Psi/\partial z, \\ 2\pi\tau_{\varphi z} &= \rho(4\Psi + \rho\partial\Psi/\partial\rho). \end{aligned} \quad (36)$$

It will be noticed that these formulas involve the same functions of $\Psi$ as in the formulas (35) for twist angle.

The high stress-concentration at the root of the groove is at once apparent from Fig. 11. The maximum stress is

$$2\pi\tau_{\max} = 14.82M/R^3.$$

This is 3.70 times the maximum stress

$$(2\pi\tau_{\max} = 4M/R^3)$$

for a straight circular shaft of radius $R$, and is 1.56 times the maximum stress in a straight circular shaft of radius $\frac{3}{4}R$. This last factor, which compares the maximum stress in the grooved shaft to that in a straight shaft of diameter equal to the root diameter is usually called the *stress-concentration factor* $k$, so for this shaft $k=1.56$. This value is believed to be accurate to within 1 percent.

Our value, 1.56, for the stress-concentration factor may be compared with the experimental value 1.45 read from McGivern's curves of Fig. 4; Bulletin No. 62.[4] The agreement is within the experimental accuracy of McGivern's "Plastic-Flow Method." It may also be compared with Neuber's theory[5] for a "deep external notch." Neuber gives the formula

$$k = \tfrac{3}{4}[1+(s+1)^{\frac{1}{2}}]^2/[1+2(s+1)^{\frac{1}{2}}],$$

where $s$ is the ratio of shaft radius at the root of the groove to the radius of curvature of the

---

[4] This point seems not to have been taken into consideration by J. G. McGivern, Eng. Expt. Station of the State College of Washington, Eng. Bull. No. 58 and 62 (1939), who has made detailed experimental measurements of the torsion of grooved and filleted shafts. We gather from these papers that he placed his twist measuring gauges directly at the edges of the fillets and grooves and thus obtained values of extra twist which were too high. However, the extra twist determined from McGivern's Fig. 5, Bulletin 62, for our particular groove seems to be about twice our computed value, which is a considerably greater discrepancy than can be accounted for by the above comment, but is not inconsistent with the scatter of McGivern's experimental data.

[5] H. Neuber, *Kerbspannungslehre* (Verlagsbuchhandlung, Julius Springer, Berlin, 1937); translated as *Theory of Notch Stresses*, David Taylor Model Basin Trans. 74, Washington (1945).

groove at the root. In our case $s=\frac{3}{4}R/\frac{1}{8}R=6$. This formula is exact for a hyperbolic notch in an otherwise infinite shaft, and is an approximation to any shape of notch deep enough so that the resulting stress-concentration extends significantly throughout the diameter of the shaft at the notch. The value $s=6$ in Neuber's formula gives $k=1.58$, in excellent agreement with our value of 1.56.

We take pleasure in thanking Mr. B. M. Shepard of the Naval Ordnance Laboratory for assistance in the preparation of the figures for the grooved-shaft problem.

## APPENDIX 1. IMPROVEMENT FORMULAS

Consider Fig. 1 and the various cuts in Section 3 showing a point (0) surrounded by four or five neighboring points. The improvement formulas (4)–(11) can be considered as derived in the following way: Let the coordinates of (0) be $z=0$, $\rho=\rho_0$. Write the most general quadric function passing through $\psi_0$ in the form

$$\psi=\psi_0+\alpha_1 z+\alpha_2(\rho-\rho_0)+\beta_1 z^2+\beta_2 z(\rho-\rho_0)+\beta_3(\rho-\rho_0)^2.$$

Now choose the coefficients so that this quadric passes through the neighboring four or five function values $\psi_1$ to $\psi_4$ or $\psi_5$; e.g., for the regular point of Fig. 1, the quadric function passing through $\psi_0$, $\psi_1$, $\psi_2$, $\psi_3$, $\psi_4$ is

$$\begin{aligned}\psi=\psi_0+(\psi_1-\psi_2)z/2h+(\psi_3-\psi_4)(\rho-\rho_0)/2h\\ +(\psi_1+\psi_2-2\psi_0)z^2/2h^2\\ +(\psi_3+\psi_4-2\psi_0)(\rho-\rho_0)^2/2h^2+\beta_2 z(\rho-\rho_0)\end{aligned}$$

with $\beta_2$ arbitrary. Finally, substitute this function in the differential equation (1) and then set $z=0$, $\rho=\rho_0$ to obtain a relation between $\psi_0$, $\psi_1$, $\psi_2$, $\psi_3$, $\psi_4$ which is just the improvement formula (4). This procedure for deriving improvement formulas for various arrangements of points can be formally simplified but is stated in this way to show exactly what is done. *A general quadric is passed through the function values and then required to satisfy the differential equation at just the point to be improved.*

An alternative procedure for deriving improvement formulas is to start with a quantic that satisfies the differential equation (1) *everywhere* and then make it pass through the points of interest in the neighborhood of $\psi_0$. If we are to do this for the points of Fig. 1, a fourth-order polynomial (quartic surface) must be used. The most general quartic *solution* of the differential equation (1) is

$$\begin{aligned}\psi=A+Bz-(1+K)Cz^2+C\rho^2-\tfrac{1}{3}(1+K)Dz^3+Dz\rho^2\\ +\tfrac{1}{3}(1+K)(3+K)Ez^4-(6+2K)Ez^2\rho^2+E\rho^4,\end{aligned}$$

for arbitrary $A$, $B$, $C$, $D$, $E$. Note that this function is automatically even in $\rho$. If now we attempt to put this surface through the four values $\psi_1$, $\psi_2$, $\psi_3$, $\psi_4$ of Fig. 1 in order to determine $\psi_0$, it is found that we must have $E\neq 0$—we cannot put a cubic solution through these values but must use a full quartic. The quartic solution through $\psi_1$, $\psi_2$, $\psi_3$, $\psi_4$ of Fig. 1 determines a unique value of $\psi_0$ and gives the improvement formula

$$\begin{aligned}[96I^3-4K^2I-40KI-48I]\psi_0=[24I^3-6I](\psi_1+\psi_2)\\ +[24I^3+12KI^2-2K^2I-20KI-18I+K^2+7K+6]\psi_3\\ +[24I^3-12KI^2-2K^2I-20KI-18I-K^2-7K-6]\psi_4.\end{aligned}$$

This is a rather complex formula which is probably not so well suited for most numerical work as the simple formula based on a quadric function. Unless the net is fine enough and the function smooth enough so that fourth differences are regular, the use of a quartic function for approximation is apt to introduce rather than to smooth out irregularities. In such numerical work as we are describing it is best to retain simple quadric approximating functions unless one has occasion to reach the point of extreme refinement of net and accuracy.

It is noted that Eq. (28) is an example of the above quartic formula.

## APPENDIX 2. COEFFICIENTS FOR IMPROVEMENT OF NINE-BLOCK CENTER POINT

As a matter of record, we give below the complete expressions, for arbitrary $I$ and $K$, for the nine-block coefficients of which Tables I and II are special cases. If the improvement formula for the center point of Fig. 2 is written in the form

$$\begin{aligned}C_0\psi_0=C_e\psi_e+C_E\psi_E+C_f\Sigma\psi_f+C_F\Sigma\psi_F\\ +C_g\Sigma\psi_g+C_G\Sigma\psi_G+C_m\Sigma\psi_m,\end{aligned}$$

where $\Sigma$ indicates summation of the values at the two points having the same label, the general expressions for the $C$'s are

$$\begin{aligned}C_0=2I\{(512I^4+64I^2(K^2-2K-16)\\ +(K^4-4K^3-60K^2+128K+512)\},\\ C_e=128I^5+128I^4K+4I^3(9K^2-18K-64)\\ +4I^2K(K^2-10K-48)+I(K^4-4K^3-32K^2\\ +72K+128)+K(-K^3+36K+64),\\ C_f=16\{4I^5+4I^4K+I^3(K^2-2K-8)+I^2(-K^2-6K)\\ +I(-K^2+2K+4)+(K^2+2K)\},\\ C_g=32\{2I^5+I^4K-4I^3-2I^2K+2I+K\},\\ C_m=4I\{32I^4+I^2(-K^2+2K-64)+(K^2-2K+32)\},\end{aligned}$$

with $C_E$ obtained from $C_e$, $C_F$ from $C_f$, and $C_G$ from $C_g$ by replacing $I$ by $-I$ and then changing the sign of the whole expression, i.e., $C_E(I,K)=-C_e(-I,K)$, etc.

# Note on a Boundary Value Problem of Reissner and Sagoci

IAN N. SNEDDON
*The Department of Natural Philosophy, the University of Glasgow, Scotland*

(Received June 18, 1946)

## 1. INTRODUCTION

IN their investigation of the torsional oscillations produced in a semi-infinite, homogeneous, isotropic medium by a periodic shear stress applied in an axially symmetrical manner to a circular area of the surface of the medium, Reissner and Sagoci[1] begin by considering a boundary value problem in the theory of elastic equilibrium. The distribution of stress in the interior of a semi-infinite elastic medium is determined when a load is applied to the surface by means of a rigid disk; the torsional displacement is prescribed immediately under the disk, and it is assumed that that part of the boundary which lies beyond the edge of the disk is free from stress. The solution of this mixed boundary value problem is obtained by the introduction of a certain system of oblate spheroidal coordinates.

In the introduction to their paper Reissner and Sagoci point out that the use of Fourier-Bessel methods only reduces the problem to a problem in integral equations which is then reduced to the solution of an infinite number of linear algebraic equations in an infinite number of unknowns. The object of this note is in part to recall that the problem may be reduced to the solution of a pair of dual integral equations.[2] In the static case these dual integral equations reduce to a type which arises in a number of mixed boundary value problems in the mathematical theory of elasticity,[3] and their solution is known. In the present note the dual integral equations are set up by the use of the Hankel transform theorem. It is then shown that the solution for the static case can be derived in this way; though the dynamic problem is not solved a possible approach to it is sketched in Section 3.

## 2. FORMULATION OF THE PROBLEM

We wish to determine the components of stress and of the displacement vector in the interior of the semi-infinite, homogeneous, isotropic, elastic solid $z \geqslant 0$ when a circular area ($r \leqslant r_0$) of the surface is forced to rotate through an angle $\Phi$ about an axis which is normal to the undeformed surface of the medium. It is assumed that the region of the surface lying out with the circle $r \leqslant r_0$ is free from stress. It has been shown by Reissner[2] that, in this case, only the circumferential component $v$ of the displacement vector is different from zero, and that all the components of stress vanish identically except $\tau_{z\theta}$ and $\tau_{r\theta}$ which are given by the relations

$$\tau_{z\theta} = \mu \frac{\partial v}{\partial z}, \quad \tau_{r\theta} = \mu \left( \frac{\partial v}{\partial r} - \frac{v}{r} \right), \tag{1}$$

where, in the absence of internal damping, $v$ satisfies the partial differential equation

$$\frac{\partial^2 v}{\partial r^2} + \frac{1}{r}\frac{\partial v}{\partial r} - \frac{v}{r^2} + \frac{\partial^2 v}{\partial z^2} = \frac{1}{c^2}\frac{\partial^2 v}{\partial t^2}, \tag{2}$$

where $c = (\mu/\rho)^{\frac{1}{2}}$. The boundary conditions of the problem are

$$z = 0, \quad v = f(r, t), \quad r \leqslant r_0, \tag{3}$$

$$z = 0, \quad \tau_{z\theta} = 0, \quad r \geqslant r_0. \tag{4}$$

In the case considered by Reissner and Sagoci

$$f(r, t) = \Phi(t) \cdot r. \tag{5}$$

## 3. REDUCTION OF THE PARTIAL DIFFERENTIAL EQUATION BY MEANS OF THE HANKEL TRANSFORM

To solve the partial differential Eq. (2) we introduce the Hankel transform

$$\bar{v} = \int_0^\infty r v J_1(\xi r) dr,$$

of the circumferential component $v$ of the displacement vector. Hence if we multiply both

---

[1] E. Reissner and H. F. Sagoci, J. App. Phys. 15, 652 (1944); H. F. Sagoci, J. App. Phys. 15, 655 (1944).

[2] Such a reduction was first given by E. Reissner in a paper which appeared in Ing. Archiv 8, 229–45 (1937).

[3] See, for example: J. W. Harding and I. N. Sneddon, Proc. Camb. Phil. Soc. 41, 12 (1945); I. N. Sneddon, Proc. Roy. Soc. A, to be published; I. N. Sneddon and H. A. Elliott, Quart. App. Math., to be published.

sides of Eq. (2) by $rJ_1(\xi r)$ and integrate with respect to $r$ from 0 to $\infty$ we have the differential equation

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\frac{\partial^2}{\partial z^2}+\xi^2\right)\bar{v}=0 \tag{6}$$

for the determination of the function $\bar{v}(z, t, \xi)$. Once this solution is known we obtain the expression for the displacement $v$ by means of the Hankel inversion theorem[4]

$$v=\int_0^\infty \xi\bar{v}(z, t, \xi)J_1(\xi r)d\xi \tag{7}$$

from which we have for the stress component $\tau_{z\theta}$

$$\tau_{z\theta}=\mu\int_0^\infty \xi\frac{\partial\bar{v}(z, t, \xi)}{\partial z}J_1(\xi r)d\xi. \tag{8}$$

The arbitrary functions introduced in the solution of the partial differential Eq. (7) are determined by the boundary conditions. The solution must be such that the displacement and both components of stress tend to zero as $z\rightarrow\infty$; when $z=0$ the conditions (3) and (4) must be satisfied. Substituting these relations into the expressions (7) and (8) for $v$ and $\bar{v}$ we obtain the dual integral equations

$$\int_0^\infty \xi\bar{v}(0, t, \xi)J_1(\xi r)d\xi=f(r, t), \quad r\leqq r_0, \tag{9}$$

$$\int_0^\infty \xi\frac{\partial\bar{v}(0, t, \xi)}{\partial z}J_1(\xi r)d\xi=0, \quad r\geq r_0 \tag{10}$$

for the determination of the remaining arbitrary part of the function $\bar{v}(z, t, \xi)$. These equations are equivalent to Eqs. (129) and (130) of Reissner's paper.[2]

### 4. SOLUTION FOR THE STATIC CASE

In the static case the function $\Phi(t)$ of Eq. (5) is a constant, or, in the general case, the function $f(r, t)$ of Eq. (3) is a function of $r$ alone—say $f(r)$. We may therefore take $\partial/\partial t$ to be identically zero in Eq. (7) so that it reduces to an ordinary differential equation with solution

$$\bar{v}=A(\xi)e^{-\xi z}+B(\xi)e^{\xi z}. \tag{11}$$

Since $v$, and hence $\bar{v}$, tends to zero as $z\rightarrow\infty$ we must take $B(\xi)$ to be identically zero in Eq. (11). Substituting this value for $v$ into the Eqs. (10) and (9) we obtain the dual integral equations

$$\int_0^\infty \xi A(\xi)J_1(\xi r)d\xi=f(r), \quad r\leqq r_0 \tag{12}$$

$$\int_0^\infty \xi^2 A(\xi)J_1(\xi r)d\xi=0 \quad r\geq r_0 \tag{13}$$

which are Reissner's Eqs. (129) and (130) with $k=0$. Writing $r=\rho r_0$, $\xi=\eta/r_0$, $\eta^2A(\eta)=F(\eta)a^3$, $f(r)=ag(\rho)$, we see that these equations reduce to

$$\int_0^\infty \eta^{-1}F(\eta)J_1(\eta\rho)d\eta=g(\rho), \quad \rho<1,$$

$$\int_0^\infty F(\eta)J_1(\eta\rho)d\eta=0, \quad \rho>1.$$

Dual integral equations of this type have been considered by Titchmarsh[4] and Busbridge.[5] By making use of the theory of Mellin transforms and known theorems in the calculus of residues Titchmarsh obtained the solution of a generalization of this pair of dual integral equations in the form of a contour integral. The reduction to real form was effected by Busbridge and covers the case arising here; the solution turns out to be

$$F(\eta)=\left(\frac{2}{\pi}\right)^{\frac{1}{2}}\eta\left\{\eta^{\frac{1}{2}}J_{\frac{1}{2}}(\eta)\int_0^1 y^2(1-y^2)^{-\frac{1}{2}}g(y)dy\right.$$
$$\left.+\int_0^1 u^2(1-u^2)^{-\frac{1}{2}}du\int_0^1 g(yu)(\eta y)^{\frac{1}{2}}J_{3/2}(\eta y)dy\right\}.$$

In the case considered by Reissner and Sagoci

$$g(\rho)=\Phi\rho,$$

so that

$$F(\eta)=\frac{4\Phi}{\pi}\left(\frac{\sin\eta}{\eta}-\cos\eta\right)$$

giving finally

$$v=\frac{4\Phi a}{\pi}\int_0^\infty\left(\frac{\sin\eta}{\eta^2}-\frac{\cos\eta}{\eta}\right)e^{-\zeta\eta}J_1(\rho\eta)d\eta,$$

---

[4] E. C. Titchmarsh, *An Introduction to the Theory of Fourier Integral* (Oxford, 1937), p. 240.

[5] I. W. Busbridge, Proc. London Math. Soc. [2], **44**, 115 (1938).

where $\zeta = z/r_0$. Now it is easily shown that[6]

$$I_1 = \int_0^\infty \frac{\sin\eta}{\eta^2} e^{-\zeta\eta} J_1(\rho\eta) d\eta = \frac{\lambda R \sin(\theta+\phi) - \lambda^2 \sin 2\theta}{2\rho} + \tfrac{1}{2}\rho \tan^{-1} \frac{R\sin\phi + \lambda\sin\theta}{R\cos\phi + \lambda\cos\theta},$$

$$I_2 = \int_0^\infty \frac{\cos\eta}{\eta} e^{-\zeta\eta} J_1(\rho\eta) d\eta = \frac{1}{\rho}(R\cos\phi - \zeta),$$

$$I_3 = \int_0^\infty \frac{\sin\eta}{\eta} e^{-\zeta\eta} J_1(\rho\eta) d\eta = \frac{1}{\rho}(1 - R\sin\phi),$$

$$I_4 = \int_0^\infty \cos\eta\, e^{-\zeta\eta} J_1(\rho\eta) d\eta = \frac{1}{\partial}\left\{1 - \frac{\lambda}{R}\cos(\theta-\phi)\right\},$$

where the quantities λ, $R$, $\theta$, and $\phi$ are defined by the relations

$$\lambda^2 = 1 + \zeta^2, \qquad \zeta \tan\theta = 1,$$
$$R^4 = (\rho^2 + \zeta^2 - 1)^2 + 4\zeta^2, \quad 2\zeta \cot 2\phi = \rho^2 + \zeta^2 - 1.$$

Hence we have the formulae

$$v = \frac{2\Phi a}{\pi\rho}\left[\lambda R \sin(\theta+\phi) - \lambda^2 \sin 2\theta + \rho^2 \tan^{-1}\frac{R\sin\phi + \lambda\sin\theta}{R\cos\phi + \lambda\cos\theta} - 2R\cos\phi + 2\zeta\right],$$

$$\tau_{z\theta} = \frac{4\Phi\mu R}{\pi\rho}\left[\sin\phi - \frac{\lambda}{R}\cos(\theta-\phi)\right],$$

for the determination of $v$ to $\tau_{z\theta}$ at any point in the interior of the elastic medium; a similar expression may be derived for the other shear stress $\tau_{r\theta}$. When $z=0$ and $\rho>1$,

$$I_1 = \frac{1}{2\rho}\left[(\rho^2-1)^{\frac{1}{2}} + \rho^2\left\{\frac{\pi}{2} - \tan^{-1}(\rho^2-1)^{\frac{1}{2}}\right\}\right],$$

$$I_2 = (\rho^2-1)^{\frac{1}{2}}/\rho,$$

and when $z=0$, $\rho<1$,

$$I_3 = \frac{1}{\rho}[1 - (1-\rho^2)^{\frac{1}{2}}], \quad I_4 \doteq \frac{1}{\rho}[1 - (1-\rho^2)^{-\frac{1}{2}}],$$

giving for $v$ and $\tau_{z\theta}$ when $z=0$,

$$v = \Phi a \rho\left[\left\{1 - \frac{2}{\pi}\tan^{-1}(\rho^2-1)^{\frac{1}{2}}\right\} - \frac{2}{\pi}(1 - 1/\rho^2)^{\frac{1}{2}}\right], \qquad \rho>1,$$

$$\tau_{z\theta} = -\frac{4\Phi\mu}{\pi}(1/\rho^2 - 1)^{-\frac{1}{2}}, \quad \rho<1$$

in agreement with the expressions found by Reissner and Sagoci.[7]

# Physics in 1946

BY PHILIP MORRISON
*Cornell University, Ithaca, New York*

NINETEEN forty-six was the first year of peace. Throughout the world, and especially in the United States, the generally difficult problems of reconversion began in earnest. Reconversion meant much for physics and physicists. The strange symbols of wartime work—the SCR-584 radars, the HVAR rockets, the VT fuzes, the compounds of tuballoy—began to lose their compelling interest and their jealously-guarded secrecy. The great "amateur" wartime laboratories, where academic physicists and their industrial and engineering colleagues had worked so hard and so successfully on war program, began to dwindle. The publication of volumes of reports began. And physicists went back, a little rustily, to the problems of the days before the war. Most of those problems were still there, for not much fundamental progress had been made during the war years. But gone was the reluctance to do big things, gone the sometimes valuable, sometimes hampering isolation of the research worker. Physics, especially nuclear physics and its related frontier fields, had grown up. It was pretty well organized, in the wake of the OSRD and the Manhattan Project.

The work of the year very much reflected the problems of the physicist. Much work was begun, but not very much completed. People had plans, often great and exciting ones, but still only plans. Some wits began to talk of the latest "Physical PREview." Teaching loads were heavy, and the flood of students, good and serious and deserving students, drew many research workers away from problems they had almost begun to remember. New laboratories had sprung up, like Oak Ridge and the Argonne, and in the first postwar year began to make their mark on public research.

Most striking of all was the essential disappearance of the peacetime international community of physics. The United States, tired enough by years of war but still incredibly rich by the standards of Europe and Asia, was pre-eminently the home of physics. Our once good communication with the rest of world had atrophied with the secrecy and the contingencies of wartime. By the end of the year, only a beginning had been made towards a return of the days when physics was truly international. Few physicists hoped more wistfully for anything than for the full restoration of the ways of peace in travel, in publications, and in the spirit of a world-wide science.

The present account is for all these reasons a fragmentary account, mainly of "work in progress," and mainly of work here in America. But it is work of the highest promise for physics, work carried on with the highest hope that in 1947 and the years ahead the best of the old spirit will come to employ the great new tools which are the legacy of war.

## SUPERCONDUCTIVITY

One of the most spectacular results of the year was in the tradition of the world before the war. Professor Richard A. Ogg, working essentially alone in the Chemistry Department of Stanford University, discovered a substance which is electrically superconducting at liquid-air temperatures and even above.[1] This statement has little in common with the dramatic discoveries of new particles, but this work may be as fundamental a step towards the understanding of the strange phenomenon of superconductivity as was the finding of the neutron to nuclear physics.

For decades it has been known that some metals and alloys cooled to very low temperatures lost all electrical resistivity. Resistances of many ohms dropped by twelve or fourteen orders of magnitude when the transition temperature was reached. Strange electrical and thermal experiments could be performed with such extraordinary solids. By moving a ring of the material out of a magnetic field in which it was cooled, a current was induced. This current died away with a time constant given by the inductance and the extremely small resistance of the cold metal. It is told that the Leyden laboratory workers delighted to prepare such persistent currents, and to send the loop, still cold in its Dewar, to a distant place where the lecturer could demonstrate that the current was still flowing, hours or even days after it had been started up! Such conductors demonstrated Lenz's law with a vengeance: their low resistivities meant that the induced currents cancelled the external fields to a T, and magnetic fields thus cannot be set up within superconductors. They are almost perfectly diamagnetic.

The large scale theory of such phenomena is fairly clear, but it is quite unsure what is the electronic and atomic mechanism by which the state of superconductivity is caused. Only one thing seemed essential: extremely low temperatures. No superconductor was known which showed the effect above ten degrees absolute.

Ogg had long been interested in a famous and strange set of substances, the solutions of the alkali metals in liquid ammonia. For twenty years these materials have provided work for physical chemists concerned with the nature of ionization in solution. The example which proved so interesting was the dilute solution of sodium in ammonia, in concentrations of twenty or thirty grams of metal per liter of solvent. That solutions of this kind are sufficiently strange in their other properties was well known. They look like metals, with a quickly-frozen solution having a metallic steely blue luster. At −50°C or so, the homogeneous solution separates in two differently-colored phases, bronze and blue, if slowly cooled. It is not hard to prepare the material. In one method, an annular glass trap is employed, attached to a vacuum line.[2] Water and air must of course be kept out. The sodium metal is placed in the system, and anhydrous ammonia brought into contact with the metal. The system is kept cool, below the boiling point of the ammonia, at −34°C, and the solution forms. To demonstrate the superconductivity it is enough to place the liquid solution in its vessel inside a solenoid coil, and to freeze it in liquid air within a matter of ten seconds or so. When the frozen ring is removed from the liquid air, it is placed near a flip coil, and the magnetic field of the ring detected by a galvanometer deflection. A magnetic field will repel the ring strongly, because of the very large *negative* susceptibility of the substance. Such tests seem to prove the superconducting nature of the substance.

It is not quite so simple as that, as usual. Out of a few score preparations, only a few are successful. Apparently the large volume change on freezing causes the solid to crack seriously, and the resistance is the resistance of the cracks and not of the solid itself. One must be patient to find the effect. Two attempts[3,4] to confirm Ogg's work failed to do so, probably for this reason, but it has been confirmed by at least one other worker.

Why the interest? One more superconductor for the handbooks does not sound exciting. But there is a vast difference. This material is a superconductor not at 5 or 10 degrees absolute temperature, but at more than 90°K. Recall that thermodynamically the gap between these tem-

---

[4] Daunt, Désirant, Mendelssohn, and Birch, Phys. Rev. 70, 219 (1946).

peratures is much greater than the gap between the temperature of liquid air and room temperature. Consider, for instance, the amount of work required to remove a given amount of heat energy, say by the use of a mechanical refrigerator. If the region to be cooled is at liquid-air temperature and the condenser of the refrigerator at room temperature, less than one-third as much work is required as if the heat had to be moved from a region at 10°K to a condenser cooled by liquid air. Thus Professor Ogg's solutions hold the suggestion that a superconductor can perhaps be made at room temperature. One cannot predict such a result, of course, but it would be a foolhardy statement now to deny its possibility. A little speculation on what would happen to laboratory apparatus and indeed to all electrical devices if fairly large current density could be achieved *without appreciable ohmic loss* is worth while. Even if no such near-fantastic result ever ensues, the first superconductor at temperatures so "high" as those of liquid air is sure to prove a challenge and a stimulus to the theory of this strange phenomenon.

Ogg predicted this property of the sodium-ammonia system from his own theory[5] of the structure of this unusual substance. His theory is formally strange and unconventional to most physicists, and is unconvincing to this author at least. It involves the notion of paired electrons which move in cavities in the solvent, after escaping from the valence bonds of the alkali metal. These paired electrons have no resultant spin and satisfy a condition years ago proposed to explain superconductivity as an effect bound to occur with particles which have no spin. The stability of these arrangements and the order-of-magnitude of concentrations and temperatures do not appear evident from Ogg's so far preliminary theory. It is to be hoped that the next year will bring wider interest in this remarkable problem both from the experimental and the theoretical side. There is hardly a laboratory which cannot make a superconductor now! Liquid hydrogen generators and the rest of the special techniques of cryogeny are no longer needed.

### THE PUSH TOWARD HIGH ENERGY

The one most characteristic feature of nuclear physics is the high energy per atom involved in the reactions. Where chemical reactions release a few electron volts for each atom involved, the reactions of nuclear physics release or require millions. The very fact of such high specific energies makes it possible to do experiments in which only individual atoms take part, observability following only from the highly energetic nature of the motions and transformations of the reactants. Nuclear physics—with of course the spectacular and decisive exception of the chain reaction of uranium—does not often work with macroscopic amounts of matter.

But to give even single atoms the millions of electron volts they need often requires large scale apparatus. The engineering which is so typical of such laboratories today began in the first efforts to concentrate a few million volts in ions of hydrogen and heavy hydrogen. Since Rutherford's Cavendish days, this has been done by simply setting up a few million volts potential difference in the laboratory (with a.c., as in a surge transformer set, with electrostatically-generated d.c., as in the familiar Van de Graaff machines) and letting the ions fall through the potential difference in a vacuum tube. Always the demand was for higher energy.

The first energy barrier which it was sought to overcome was the electrostatic barrier, the energy required to bring one positively-charged projectile very near the positively-charged nucleus. One wanted the charges near enough so that the nuclear matter could touch and "stick," to produce new radioactive nuclei and to initiate nuclear reactions. The size of this barrier is easy to compute: the energy of repulsion is $Zze^2/r$, where $ze$ is the charge of the projectile (generally $e$ or $2e$ for protons, deuterons, or alphas), $Ze$ the charge of the target nucleus, ranging to $94e$ for the heaviest known, and the distance $r$ is the nuclear radius, never much larger than $10^{-12}$ cm. The answer turns out to be some ten million electron volts needed to cross the barrier for the most difficult cases. No one has yet established a potential difference above six million or so. But the desire to produce particles with such energies has led to ingenious solutions.

---

[5] R. A. Ogg, Phys. Rev. 69, 668 (1946).

The most famous of these is the cyclotron, in which a modest radiofrequency potential difference of a hundred or two kilovolts is applied again and again to the moving particle which is bent into a spiral path by a large magnetic field. Successive passages across the r-f drop occur uniformly spaced in time and, "resonant" with the r-f frequency, lead to high final energies. The Crocker cyclotron at Berkeley, the largest machine of its kind, is capable of making forty million-volt alpha-particles, which cross any nuclear barrier with energy to spare, and make possible many complicated reactions. Why go further?

The answer is, of course, that there are still more remote objectives. The probing of nuclear matter by bringing the "test charge" which is the rapidly moving projectile closer and closer to the nucleus has given us information about distances of the order of $10^{-12}$ cm or somewhat less; we would like to look at matter even more intimately. The closer the impact, the more energy transferred, the finer the detail of exploration. We learned many years ago that there were particles of very short life, which we cannot find in our laboratories, but which stream in to the earth in the cosmic rays. These objects, known now as mesotrons, because of their mass of 200 electron masses (intermediate between that of electron and proton), are believed on quite general grounds to be associated with those extraordinary attractive forces which make nuclear matter sticky, which bind together the neutrons and protons of the nucleus. The argument for the connection is essentially this: The electromagnetic forces are by now familiar. They are long range forces, falling off as the inverse square of the distance between two interacting particles. Now, these forces, which propagate, of course, with the finite velocity of light can be thought of as caused by the transfer of quanta between the moving charges. This is quite evident for the transverse electromagnetic waves, but it is true at least formally for the static Coulomb field as well. From this point of view electric charges are surrounded by quanta. If there is energy available, these quanta may be set free to go as far as they will. Otherwise they must be emitted, last a very short while, and then be reabsorbed by the particle which emitted them or by another particle nearby. By analogy the same mechanism is used to account for nuclear forces by the exchange of mesons, It turns out that the Compton wave-length, $\lambda = h/mc$, of the particles transferred determines the effective range of the forces. Thus, for quanta, the rest mass is zero, and the "Compton wavelength" infinite, and the range infinite. The force decreases only for geometrical reasons, and is simply inverse-square. But the nuclear forces act only at short range, about $2 \times 10^{-13}$ cm. The rest mass corresponding to such a range is about two hundred electron masses, just that observed for the mesons of cosmic rays. The inference is strong that around nuclear particles there is a transient cloud of mesons, and that if one supplies enough energy by collision or even by energetic "light" quanta, such mesons can be set free. The study of this mechanism would correspond for the nuclear forces to the study of Maxwell's equation, and could lead to the understanding of the nuclear forces in detail. It must be said that since the first suggestion of Yukawa in 1936 that such mesons might exist, reinforced by their discovery in the cosmic rays two years later, the best theorists have worn thin their patience on this theory. No consistent description has yet been given of the properties of nuclear forces. All the more has this challenged experimenters to make mesons in the laboratory and there to study them in the number and the detail which is impossible while their source is still only the cosmic ray.

How much energy does one need? No one knows. There are clues. Certainly at least 100 Mev is needed, just for the rest energy, known to be 200 times the 0.51 Mev which is the electron rest energy. Perhaps they can be made only in positive and negative pairs, as are electrons in the field of a nucleus. Then at least 200 Mev is needed. More will be required to make them in some quantity, for one must do more than merely tickle the threshold of the reaction. So a popular target for the ingenious builders of machines has been 300 Mev. There are some who think that many mesons must be made at once really to study the details of their creation; these pessimists (or optimists) are planning in billions of volts, but still for some years in the future!

The first postwar year saw active construction on large machines and smaller prototypes, all shooting at the 300-Mev target, or thereabouts.[6] Most direct attack was that planned long ago at Berkeley, where a giant cyclotron had been built. This seventeen-foot magnet was built in 1940, and used during the war in the experiments which led to the construction of the great electromagnetic separation plant at Oak Ridge. By simply extending the cyclotron design to real California scale, 200-Mev deuterons were expected, somewhat short of the popular goal, the more because such particles directed at nuclear particles have an effective velocity not much more than half of that in the laboratory system of reference. The transferrable energy is given by the velocity with which the particles are brought together computed in the frame of reference in which their center of gravity is at rest. Even this energy is most difficult to get with a cyclotron. In the cyclotron, the particles must all spiral out in step, at constant phase, returning in each circuit to the region between the *D*'s, where the high r-f voltage is applied. The familiar resonance condition is that $2\pi f = eH/mc = \omega$, where $e$ and $m$ are the charge and relativistic mass of the particle, i.e., $m = \frac{(\text{rest energy} + \text{kinetic energy})}{c^2}$, $H$ the constant magnetic field, $f$ the frequency of the r-f oscillator and $\omega$ the angular velocity of the particle. This implies that the particles at all radii have the same resonant frequency, though some go fast and others slow. This is the key to the success of the machine. But the mass value, hence the resonant frequency, is not, in fact, constant, if the relativistic variation of mass with velocity be considered For 200-Mev deuterons this is not a small effect. The hope was, however, that by running up the highest possible r-f voltage, several million volts, some particles could be gotten out in spite of their having fallen a little out of phase on each step, for the number of times they need circle in the machine is only a hundred. The giant cyclotron has indeed been operating at Berkeley since November 1, producing its deuterons as planned, but the principle of operation is quite changed, and the deuterons make not a hundred circles in their spiral path, but nearer to ten thousand. And the r-f oscillator is not a giant device producing thousands of kilowatts but an oscillator which would be considered small even for an ordinary-sized cyclotron.

The story of this change is also a story of 1946. It began, of course, much earlier. The start was probably the development of the betatron in which the accelerating voltage is not applied by any electrodes, but is simply the induced e.m.f. caused by the changing magnetic flux in the a.c. magnet, acting on the electrons in their vacuum doughnut as if they were the secondary turns of a transformer. The total induced voltage in present design is only some seventy-five volts per turn, but the electrons come out with a hundred million volts in the General Electric betatron. These particles have circled the primary about a million times, traveling something like a thousand miles in the vacuum tube. The key to this machine is evidently the stability of the electron orbits, so that a chance disturbance from stray fields or by collision with a gas molecule does not throw too many electrons against the glass walls of the vacuum tube. This is a good machine for energies up to several hundred million volts. The 100-Mev General Electric model produced the first man-made radiation of such high energy, but, in spite of hopes and even the illusion of success, probably has made no mesons. Professor Kerst is now engaged in constructing a 300-Mev model, of quite advanced design, at the University of Illinois in Urbana.

In 1945 Professor E. M. McMillan, then at Los Alamos, of the University of California, proposed a new type of acceleration. Actually, the same proposal had been published months earlier and completely independently by the Soviet physicist V. Veksler. The McMillan-Veksler idea[7] stems in a way from the demonstration in the betatron that it was not foolhardy to plan for very long paths in the vacuum tube, if the conditions of stability are properly fulfilled by the design of the machine. The fact that one could count on geometrical stability had been proved in the betatron. McMillan began to think of the use of radiofrequency accelerating electrodes, as in the cyclotron, with stability in

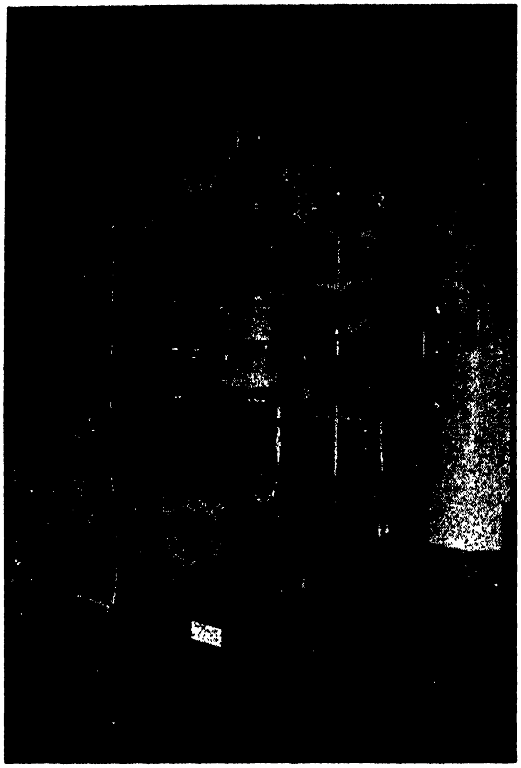

FIG. 1. The first synchrotron to operate in America. This device is installed at the General Electric Research Laboratory at Schenectady, and is under the supervision of Dr. H. C. Pollock. The vacuum tube is visible between the magnet poles.

time, or, as he calls it, phase stability. With such a condition, the resonance condition of the cyclotron might be far from satisfied by all particles, and yet eventually after many turns, the particles might gain a large energy.

For definiteness, think of a particle in the cyclotron at perfect resonance. Each time it reaches the gap between the accelerating electrodes the r-f voltage has reached its maximum. If the particle happened to arrive a little early, the r-f voltage has not yet climbed to its maximum and the particle gets a little less energy than it should have gotten. It will then make the next turn in the field with a somewhat too high angular velocity (the equivalent mass is too small) and arrive still earlier next time. Such a particle lacks phase stability and will gradually fall more and more out of step. It will never gain much energy. Now consider a very different case, that of a particle which arrives when the r-f voltage drop across the gap between electrodes—the accelerating field—has fallen to zero. This particle is just 180 electrical degrees out of phase with the r-f voltage. It will be in resonance, but it will gain no energy in passing the gap. There are two such nodes in the complete cycle. Let us consider the one in which the voltage across the gap is changing from being slightly accelerating through zero to be slightly decelerating. (The other node will not provide stability.) Now suppose the out-of-phase particle arrives just a bit early. It will feel a small amount of an accelerating electric field. It will gain energy, its equivalent mass will increase, its angular velocity go down, it will begin to lag, and next time it will be more nearly 180 degrees out of phase again. If it came a bit late, it would cross a small decelerating potential drop, and be reduced in energy. The mass would go down, the angular velocity go up, and it would come more closely to the 180 degree phase. A particle exactly out-of-

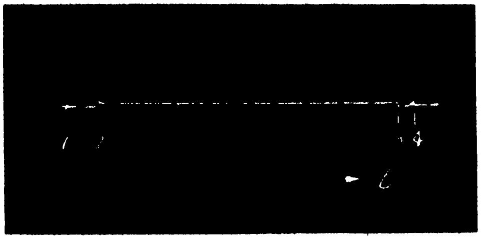

FIG. 2. An oscillogram showing operation of the 75-Mev GE synchrotron. The trace is cut off every 100 microsec. (1) marks the time of electron injection. At this time the machine is operating as a betatron. At (2) the r-f voltage is turned on. The electrons have by now about two-Mev energy. At (3) the r-f is turned off and at (4) is a signal from a photo-multiplier tube placed in the x-ray beam. For this trace the energy was about 20 Mev.

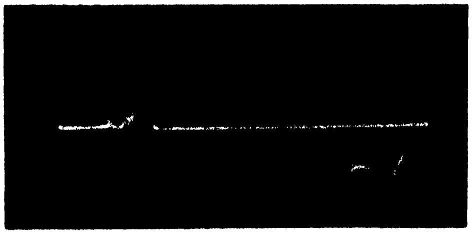

FIG. 3. Another oscillogram of synchrotron operation. The length of the sweep is 1000 microseconds. The trace begins at the time the r-f was turned off, and the electrons soon begin to strike the internal target. The irregular signal shown is taken from the output of a photo-multiplier tube placed in the emergent x-ray beam. Note the complex structure of the beam. This effect is still unclear. The machine is operating between 60 and 70 Mev.

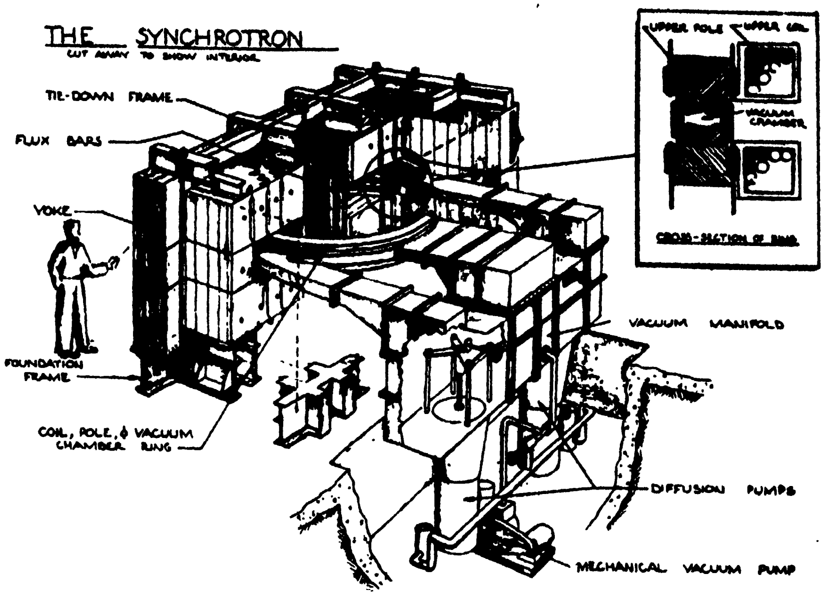

FIG. 4. The synchrotron being built at Berkeley for 300-Mev electrons by the group under Professor E. M. McMillan. The flux bars referred to bars of iron which saturate at a modest field. Until they saturate they strengthen the central field of the machine so that the electrons will accelerate under betatron conditions. When they saturate the electrons are moving at a modest energy, and the synchrotron r-f voltage is turned on.

phase then will have phase stability; it will tend to maintain this condition both at low and at relativistic velocities. Now suppose either the magnetic field or the alternating frequency be slowly increased, changing a little, but only a little, during the time the particle is making its turn in the magnetic field. The stability in phase will act to insure that the particle increases its mass to keep resonant with the increased frequency. The particle will cross the gap just enough before the time when the electric field is zero so that it gains energy sufficient to keep it near resonance. As long as the frequency or magnetic field changes slowly, the particle will oscillate in phase back and forth across the 180 degree time, gaining on the average just enough energy to be resonant under the new conditions. Thus after many turns, picking up a very small amount of the available accelerating energy on each turn, the particle can reach high energy. The frequency may be varied with constant magnetic field, and the particle will spiral out as its energy increases. Or the r-f frequency and orbit radius may stay constant or nearly so and the magnetic field increased. Or combined changes may be made. In all such devices the particles will not be accelerated in a steady stream as in a cyclotron, but in pulses, repeating as rapidly as the frequency is varied or the magnetic field made to increase.

These devices, of which there is clearly a large family, are generically called "synchrotrons." The name is based on the analogy between the motion of the particles and that of the rotor of a synchronous motor. The rotor spins at exactly the synchronous speed with no load. But loading the shaft does not change the speed. The phase slips behind far enough so that the field differences will supply the needed energy to the load. In the same way the particles in the synchrotron slip out of exact phasing, "hunting" in fact for the node, but gaining energy just enough to compensate for the changing frequency or magnetic field.[8]

The first American synchrotron completed is a seventy-five million volt electron machine, Fig. 1. The pulses of fast electrons from this machine are shown in Fig. 2. A synchrotron was made even earlier in Britain[9] by placing a small electrode for the r-f voltage inside a betatron doughnut. The output of the machine went from four millions to more than double that, since the saturation of the central part of the magnet core in the betatron limits the field at the orbit to less than half of practical design saturation values. The stability of orbits in the betatron demands that the central flux change be larger by a

FIG. 5. The vacuum assembly for the Berkeley synchrotron. Note the r-f electrode "dee." It is constructed as a grid instead of as a solid electrode to reduce eddy-current losses and fields which would be set up by the strong a.c. magnetic field. The r-f energy is supplied by a pulsed water-cooled oscillator at about 48 megacycles. The stubs are provided to adjust the position of the nodes on this rather high impedance structure.

definite factor than that at the orbit. Synchrotron stability does not require any such condition, for the voltage gain comes from the r-f field imposed by electrodes, and not from the transformer effect except incidentally. The GE machine actually begins the acceleration of its electrons as a betatron; then, when they have reached an appropriate starting energy, the r-f is turned on.

The giant cyclotron is working now accelerating heavy particles not as a conventional cyclotron, but as a synchrotron, or as it is sometimes called, a synchro-cyclotron. Frequency modulation of the r-f supply accomplished by a rapidly rotating condenser in the plate tank of the r-f oscillator brings out the high energy beam, after thousands of turns, with a modest amount of r-f power. The synchrotron principle maintains resonance acceleration in spite of the relativistic variation of mass.[10] The synchro-cyclotron accelerates deuterons, which are caused so far to strike an internal beryllium target, producing a beam of very fast neutrons. The first operation of the machine was on schedule, November 1, 1946, and experiments with the new fast neutrons are already in progress. No mesons have

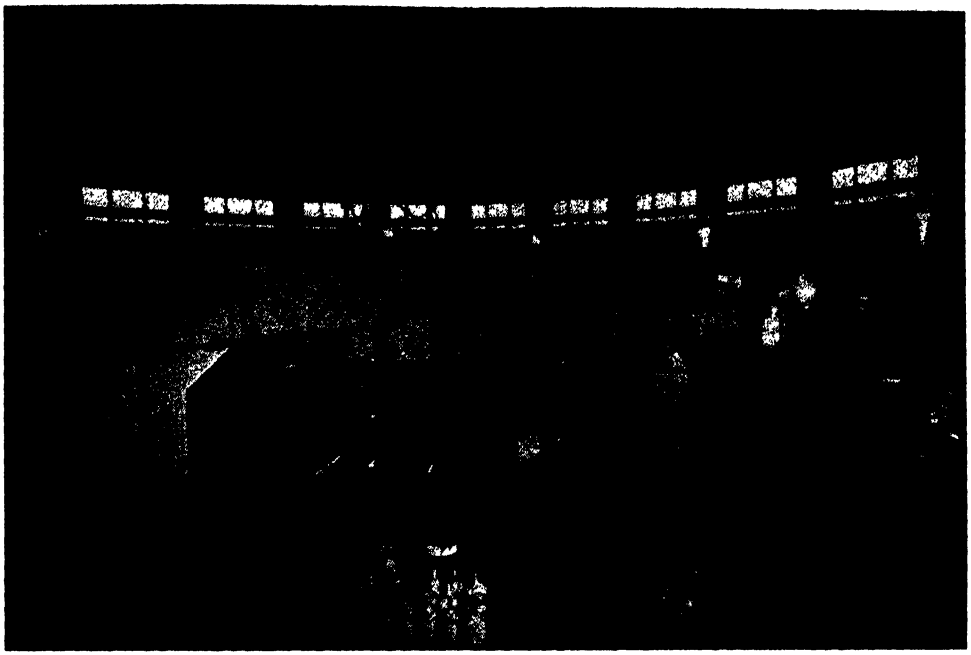

FIG. 8. A general view of the giant Berkeley cyclotron, now operating for 200-Mev deuterons as a synchro-cyclotron. Note the large radial crane of thirty-ton capacity overhead, the magnet with its 184" pole pieces (there is a man visible against the right leg of the magnet yoke), the two 32" oil diffusion pumps used for evacuating the vacuum "can," whose thick iron walls are visible between the pole pieces, and the rails, to the left of the pumps, used for removing the ion source. The temporary concrete block shielding wall and a cloud-chamber set-up are seen at the right. (The photographs of this machine were furnished through the kindness of Professor R. L. Thornton, in charge of the giant cyclotron group at Berkeley.)

yet been seen; but important results on the nature of nuclear forces seem sure already (December 15, 1946). It is planned to bring the deuteron beam itself out of the machine in the near future.

Michigan,[11] Massachusetts Institute of Technology, Cornell, the General Electric Laboratory, Berkeley, and no doubt other laboratories are now engaged in design and construction of synchrotron-type electron accelerators of the 300-Mev size, in a variety of ingenious exemplifications of the same principle. The mechanical and electrical engineering problems involved in such work are not small, and many a design variant may have its own special advantages. General problems like starting the particles in their orbits, removing the particles from the machine after acceleration, detection methods specially suited to these pulsed sources, and many others may be expected to build up a whole science of very high energy physics in the next year or two.

One simple and elegant achievement of the year in this field was the first successful removal of a high energy electron beam from the Urbana betatron, at about 20 Mev.[12] The device which did the work is simply a piece of iron shaped like a U-channel, mounted in the vacuum doughnut in the right position. The electrons enter the U-shaped slot, where the iron walls shield them from most of the magnetic field, and shoot out in the field-free space in a straight line to a target or a thin window outside the machine. The success of this device should make possible many experiments with fast electrons, up till now never available in a well-directed beam.

The idea of bending the fast particles in circular orbits and causing them to retrace their steps is evidently economical. But if the magnet grows

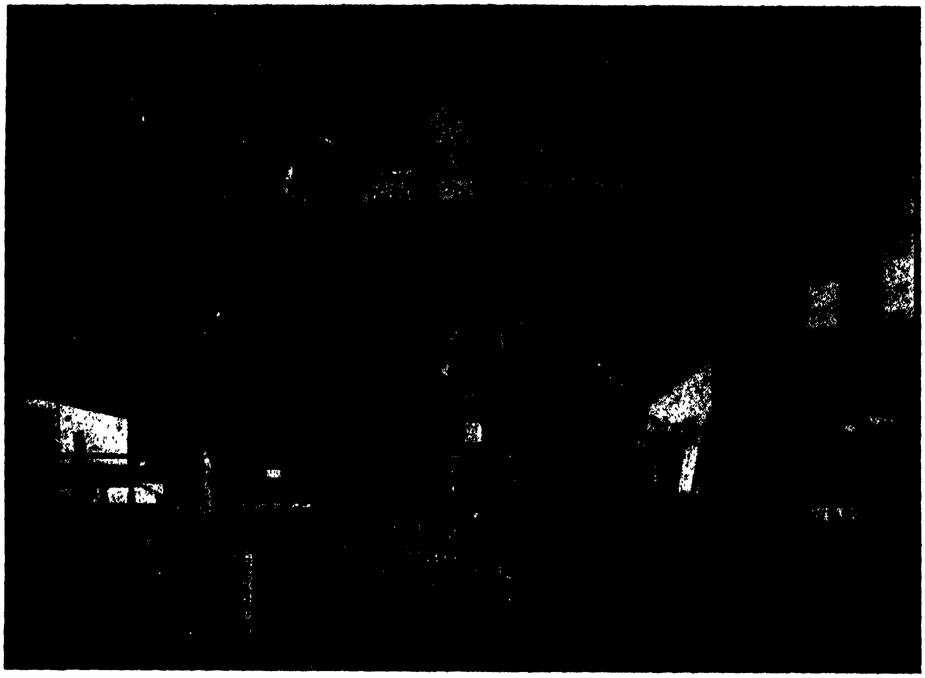

FIG. 9. A view of the big cyclotron from the side opposite to that shown in Fig. 8. In the right foreground, on the truck which moves on rails in the floor, are mounted the round vacuum housing for the rotating condenser, its associated vacuum pump, behind them the oscillator housing. The vacuum chamber is here shown clearly in operating position in the field. To the left may be seen the horizontal rod, which extends into the vacuum chamber holding the internal beryllium probe against which the beam is made to strike. Neutrons were produced at 100 Mev or more on November 1, 1946.

to be very large the economy of the scheme begins to seem less obvious. Perhaps it is better to let the particles fly in a straight line down a long tube. If one can set up a certain electric field strength, the cost of the linear accelerator goes up about as its length (the parts are simply repeatedly placed end-to-end); but if a large magnet needs to be scaled up with the magnetic field kept constant, the volume, weight, and hence the major part of the cost will go up as the cube of the radius. But the energy of particles in their equilibrium orbits goes up only as the radius or, if they are still moving much more slowly than light, as the square of the radius. Thus for sufficiently high energy a linear accelerator will be cheaper than a scaled-up magnetic device. The idea is an old and unsuccessful one; but the familiarity with microwave techniques gained in wartime makes it appear practical once more. Professor Alvarez at Berkeley is now engaged in building a large linear accelerator for protons. Protons enter the machine with a few million volts energy, from a one-step accelerator, in this case a Van de Graaff machine. The vacuum tube down which they fly is one long resonator, made of many resonant cavities placed back-to-back and so driven by individual but phased microwave oscillators at 150 cm that the moving protons enter each cavity in phase with an accelerating electric field. By the time they cross the cavity, one cycle has elapsed, the field behind has dropped to zero, and the next cavity is beginning to acquire an accelerating electric field. There is one difficulty with this simple picture. The protons do not move with uniform velocity, but constantly increase in velocity. If the cavities are driven, as they must be, by an oscillation of one frequency, some trick must be used to keep the protons in step. This is done by adjusting the repeat length of the resonant cavities $l$ so that $l/\sigma = \lambda/c$ where $\lambda$ is the wave-length of the driving oscillator and $\sigma/c$ the velocity of the particle relative to that of light. If the outside cavity diameter is held fixed, the cavities must be modified in shape to keep them resonant, though of different lengths. In transmission line language the line is a loaded line. A short coaxial cylinder is placed inside the outer cavity cylinder, and the protons move down the axis of the whole cavity. Adjusting the diameter of these central tubes keeps resonance. Each cavity will during half the cycle be decelerating: the electric field will point the wrong way. During this time the proton must be inside the central tubes, and shielded from the wrongly-directed field. The tubes are hence called drift tubes, because within them the protons "drift" under no field.[13] To maintain phase stability and geometrical focusing, it is necessary to place conductors athwart the drift tubes, through which the protons must pass. Thin beryllium foils have been developed for this work. In trials more than a million volts per foot has been developed in a cavity. As yet no coupled cavities have been tried for acceleration, but the first forty-foot unit is soon to be tried out. It is expected that it will be delivering protons at more than thirty-two million volts by February, 1947. New high power radar oscillators have been developed for the job, using the pulsed magnetron principle. Here again the output beam will be pulsed at a rather slow audiofrequency, for the sake of magnetron cooling and performance.

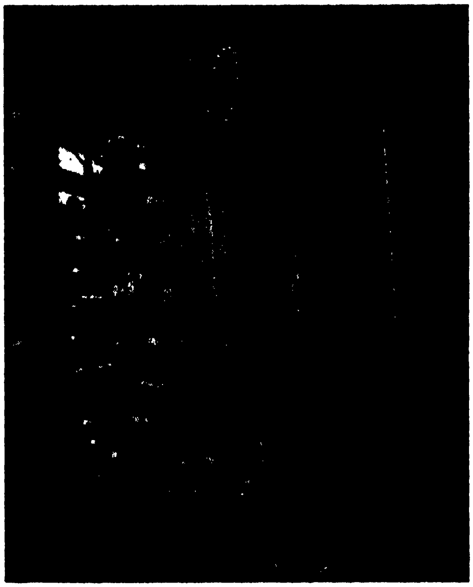

FIG. 10. A close-up of the rotating vacuum condenser whose housing is seen in Fig. 9. The many teeth which produce the varying capacity are plainly visible. The oscillator frequency, which is in the neighborhood of 10 Mc, is varied about 20 percent at a modulation rate of a few hundred times per second by means of this device.

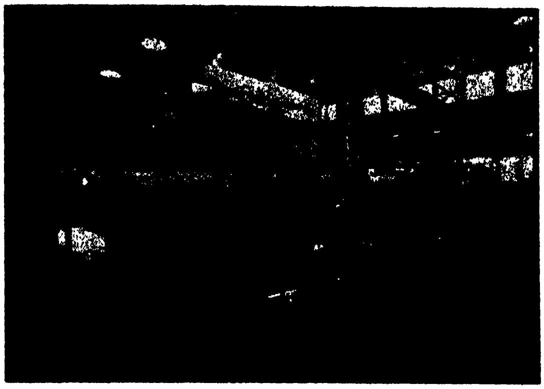

FIG. 11. The forty-foot linear accelerator at Berkeley. Note the large tank of the horizontal pressure Van de Graaff machine at the far right. This is the ion source for the machine. The outer steel tank for the linear accelerator tube itself is conspicuous, flanked by the thirty-odd war surplus 1.5-m radar oscillators on either side. Protons in the thirty-to-forty-million volt range are expected by February, 1947. New high power magnetrons are under construction to replace the many oscillators shown here. Only a few of the new magnetrons would be needed for a forty-foot section. (Photo from Professor L. W. Alvarez, heading the linear accelerator group.)

A similar linear accelerator but without the drift tubes and without phase stability can be built for particles moving near the speed of light.[14] High energy electrons are planned for at M.I.T. and at Purdue by groups working on the design of such a device.

If mesons are not made in 1947, it will not be for want of effort! It is to be hoped that enough leisure will be left to plan the experiments which these machines will make possible.

## THE LEGACY OF THE WAR

The year was marked by the widespread if delayed publication of results of the key war projects in physics, and above all, by the return to their old laboratories of hundreds of war-experienced physicists, brimful of information about what had been done, and confident in their understanding of whole fields of technique which had been vague general possibilities in 1940.

### 1. Radar

To this author one of the most fascinating parts of microwave radar has been the duplication in the radio spectrum of the familiar results of physical optics. The "optics" of microwaves—mirrors, gratings, diffraction at openings—are by now familiar to everyone. Not so familiar is the microwave lens.[15] An optical lens works, of course, because the phase velocity of the electromagnetic wave is reduced by the coherent scattering of the bound electrons in the dielectric. Shaping the lens is a matter of adjusting the delay introduced along each ray path to produce a net wave front with the form desired, usually changing the radius of curvature while leaving a spherical incoming wave still approximately spherical. No one has made bound electrical oscillators on a larger scale for microwave optical glass. But the fact has been used that the propagation of a wave in a wave guide, a region bounded by conducting walls, proceeds with an increased phase velocity, *greater* than that of light in free space. (If the reader is worried about relativity, he should review the distinction between wave and group velocity.) By spacing a set of copper plates, their planes parallel to the direction of propagation of the wave, a half-wave-length apart, a change in the phase velocity of the microwave can be secured. Shaping these plates in forms not unlike those of ordinary optics (but with a refractive index always less than one) microwave lenses can be made which quite successfully act as condensing lens, and even produce a fairly sharp focus. They are of course good only for one wave-length. "Chromatic aberration" is large!

Quite the opposite point of view has been used with good effect in recently-reported experiments using microwave radar technique. These experiments were really experiments in measuring the absorption spectrum of water vapor molecules in the region of wave-lengths from 7 mm to about 1.7 cm. An absorption line was found at 1.34 cm and its shape measured as a function of the pressure. The same line could be predicted roughly from the older work on the rotational fine structure in the infra-red region around 20 microns wave-length. Absorption is of course a quantum phenomenon, and it is satisfying to see that the analysis of the instrument—the "spectroscope"—employed came very naturally if one remembered the quantum nature of microwaves.[16]

The instrument consisted of an eight-foot cubical box of copper, arranged to be filled with moist air. Through the box were strung, at random, the detectors, in this case thermocouples. The box was coupled to a pulsed magnetron oscillator—several were used to get points at several wave-lengths—and the space-and time-averaged energy density measured as proportional to the thermoelectric e.m.f. This energy density for a constant excitation is compared with and without the water vapor. The oscillator pumps a fixed number of quanta into the box each second. These quanta are eventually absorbed, either by the walls of the box, the thermocouples, solder, air, and fingerprints of any actual experiment, or by the molecules of water vapor in the box. Since the thermocouple reading is proportional to the density of quanta built up in the box, all that is required is to compare the rate of loss due to the water vapor with some known absolute rate of loss of quanta, and the absorption of water vapor is known for that particular wave-length. But how to get an absolute loss rate? It is difficult to compute such a quantity for walls of a copper cube, the more because of the actual complex nature of the experimental geometry. But the quantum idea gives a direct method. It is necessary only to make a hole in the side of the box. All the quanta that strike the hole must leave the box. This number can be calculated just as the number of molecules leaving an orifice to form a molecular beam can be calculated. The expression is just the familiar kinetic theory formula: the number of quanta leaving through a hole of area $A$ per second is given by $\frac{1}{4}nc$, where $n$ is the number of quanta per unit volume and $c$, of course, their mean velocity—the velocity of light. The whole method of procedure was checked both by experiment and by the more complicated exact calculations of wave theory.

Randomness had to be guaranteed. No standing wave pattern could be allowed. This was as-

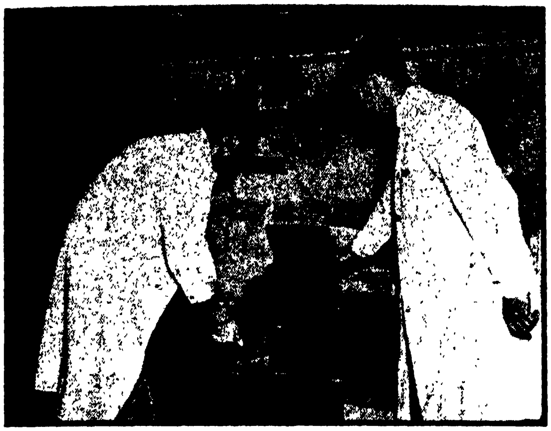

FIG. 12. A face of the shielding wall of the graphite-moderated pile at the Clinton Laboratories at Oak Ridge. The operation shown is that of exposing a sample to a strong neutron flux, for the production of a radio isotope. The sample in an aluminum holder is being inserted into a hole in a graphite block can be pushed back along a slot into the interior of the pile. The slot is then filled with more graphite blocks to complete the structure, and the shield hole is then plugged. Note the many removable "stringers" of graphite for which shield openings are provided.

FIG. 13. A face of the "hot lab" at the Clinton Laboratories. This is a concrete cubicle fitted to permit the remote operation of chemical plant adequate for the inorganic separations needed to produce pure radio isotopes from fission product. The air and steam valves and lines, the thermocouple potentiometer, plainly seen in the right foreground are typical for any chemical operation. The periscopes through which the operators are watching the reaction behind the concrete wall are the evidence of the special problems met in the handling of kilogram equivalents of radium.

sured by the slow rotation of some copper-bladed fans within the enclosure, which changed the geometry and made it sure that a random set of normal modes was excited. Diffraction effects were small, because the hole was made large compared to the wave-length. Apertures up to several hundred square centimeters in area were used. The whole experiment not only gave results and pioneered a method sure to be useful for the study of molecular structure, but formed a beautiful illustration of the unity of our dual picture of radiation.

A number of other gas absorption studies have been made at microwave frequencies, using more conventional techniques, like attenuation in a wave guide, or using the atmospheric propagation itself.[17]

## 2. Atomic Energy

The chain reaction of uranium and its consequences are too well known and too extensive to give any general account here. The slow but steady publication of the results of this project will eventually form a sizeable branch of nuclear physics, as they now do in secrecy. The great continuing laboratories at Chicago, Oak Ridge, Los Alamos, and Berkeley, as well as the new regional laboratory at Brookhaven, Long Island, and the power development laboratory at Schenectady will become an integral part of American physics. Some topics selected out of the many possibilities from the Manhattan project will be sketched here.

### *a. Isotopes*

Some hundreds of separate lots of artificial radioactive isotopes have been sold to research workers already by the Isotope Section, Research Division, Manhattan Engineer District, PO Box E, Oak Ridge, Tennessee. This activity will surely continue and expand under the newly formed Atomic Energy Commission, which took over control of the great project from the Army on January 1, 1947. The long-lived soft beta-emitter, $C^{14}$, made in the high neutron flux of the Clinton graphite pile by the reaction $N^{14}(n,p)C^{14}$ which goes well with thermal neutrons, is the material of greatest interest as a tracer in biological studies. The two-week beta-emitter, $P^{32}$, is also in demand, chiefly for its therapeutic value in some cases of leukemia and related diseases. It is made by neutron capture in the

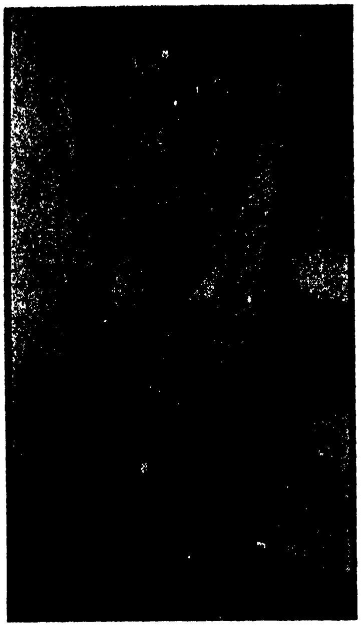

FIG. 14. A microphotograph of the first sample of the new element americium ($Z$-95) ever isolated. The lower part of the photograph shows the eye of an ordinary needle to fix scale. Above it is a small glass capillary, which is the test tube for this sort of chemistry. In the capillary can be seen the curved meniscus of the supernatant solution. At the bottom tip of the *inside* of the glass capillary is the grayish precipitate of americium hydroxide. (Photo furnished by Professor G. T. Seaborg, discoverer of Am.)

normal phosphorus isotope, $P^{31}$. A third popular product is $I^{131}$, which is a fission product, produced in the exposed uranium metal slugs of the pile. These three are only examples, but they indicate the three types of reactions which go with ease in the reacting pile. The technique of separating a particular radioactive isotope out of the complicated mixture which may be formed by bombardment is well shown in Figs. 12 and 13. It always involves remotely controlled chemical operations, with all personnel protected from the radiation emitted by thousands or tens of thousands of curies of activity. The handling of large amounts of radioactive substances is now a well-developed branch of engineering.

### *b. The Transuranic Elements*

The element of highest atomic number and highest atomic weight which is found in nature is of course uranium. But the periodic table now goes well beyond that. In the year 1946 the disclosure and naming of the transuranics had progressed through neptunium, number 93, and plutonium, 94, to americium, 95, and curium, 96.[18] In 1942 plutonium was produced only by cyclotron bombardment beginning with natural uranium. It was obtained in microgram amounts, and the extraordinary techniques developed by the radio chemists to handle such ultra-microchemistry have been admired widely by now. The elements at the top of the table are still made in microgram amounts by cyclotron bombardment. But the starting point may now be the man-made element plutonium, available in kilogram lots! It is interesting that the chemistry of the transuranics, especially of trivalent curium and americium, seems to prove that a new rare earth like series of the periodic table begins with actinium, atomic number 90, and that successive elements essentially are made by adding electrons, not to the outermost $7s$ shell, but to fill the $5f$ shell. This is in close analogy to the rare earths, which may be called the lanthanides, for at lanthanum the $4f$ shell begins to be filled. The transuranics we should call actinides.

It is appropriate here to say that identity and name are now suggested, though not yet officially, for all the elements of the table up to curium, 96.[18] The blanks are to be filled in this way, all by known radioactive isotopes of the element in question: Element 43 will be named by Professor Segrè of Berkeley, probably to be called technesium, from *techne-* art, to indicate that it is artificial only. It has no stable isotopes. The previous identification of a stable 43, called masurium, is certainly in error. Element 61 is now known to be a rare earth fission product. No name has been suggested as yet. Element 85, an unstable halogen, will be called by the beautiful name astasine, from *a-* not, and *stasis-* standing still. Element 87 is known from radioactive work only, not chemically, and on these not quite complete grounds may be named francium, since it was discovered in this sense by a French radio chemist, and is believed to be a homologue of cesium.[19]

### *c. The Pile as an Instrument*

The chain-reacting pile forms an excellent device for the determination of the probability of neutron absorption, especially for thermal neutron absorption, by any material. The substance is placed into the reacting structure at a point where the neutron density is fairly high. At such a place, evidently, the absorption of neutrons will have an important effect on the criticality of the whole structure. Since the time required for the neutron density to double in a barely-critical pile is approximately proportional to the difference between the actual reproduction factor of the structure and unity, careful measurements of pile level changes with and without samples introduced provide a very sensitive way of measuring neutron absorption. Macroscopic samples are used, of course, and the cross section per atom can be measured at least relatively with high accuracy. This method has been applied to many elements—all that could be tried—and even, for engineering purposes, to manufactured materials. By oscillating the sample to and fro, from one point of the pile to another where the neutron density was quite different, sinusoidal change in neutron level of the whole pile is produced.[20] This allows the elimination of slow drifts and the amplification of the effects by the use of resonant galvanometer systems. In the hands of the group at Oak Ridge this has become a method suitable for both precision measurement of absorption cross sections, in favorable cases, and in the detection of very small cross sections. A general review of all the neutron cross sections over the whole periodic table is in preparation based on the extensive project work. The pile work was mainly done at the Argonne Laboratory in Chicago and the Clinton Laboratory at Oak Ridge; very beautiful work in the region of fast neutrons was done mainly at Los Alamos; and neutron spectroscopy, with cyclotron velocity selectors or with crystals (see below) at all these places and by sub-contract at Cornell and Columbia. Much of this work is in the press for release; some has appeared this past year.[21]

### *d. The Pile as a Source of Neutrons*

A well-collimated beam of thermal neutrons defined by cadmium slits only millimeters wide and meters apart was long a dream of neutron physicists. When the intensity in addition leaves little to be desired, real progress has been made. This was made clear in 1946 by the experiments reported from the Manhattan Project—still only fragmentarily—in which the beam of neutrons from a pile was put to work. The Bragg crystal diffraction of neutrons is not a new effect. It has been somewhat obscurely demonstrated in several laboratories. A neutron moving with the energy corresponding to thermal equilibrium in the lattice of the block of graphite in which it has been slowed has a wave-length of a few angstroms. This is just right to give strong low order diffraction maxima from natural crystal gratings. The effect has been put to work in the construction of crystal spectrometers,[22] using not x-ray tubes, sources of the diffracted waves, brass slits, and photographic plates for detectors, but cadmium slits defining a sharp beam of thermal neutrons from the pile, and boron-filed ionization chambers as detectors. The apparatus has had many uses. At Chicago[22] the neutrons have been used to investigate the scattering of neutrons from crystalline compounds. The neutron is scattered with different phase and amplitude by different nuclei. The intensity of scattering

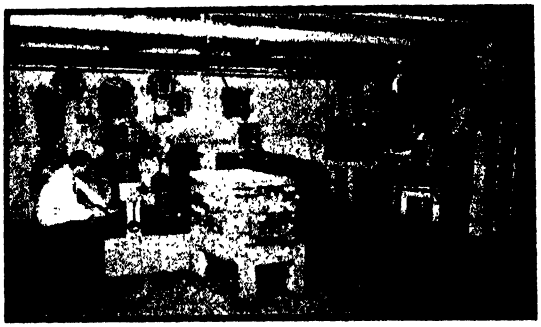

FIG. 15. Another section of the face of the Clinton pile. This suggests at least the kind of geometry applicable to the production of a strong collimated neutron beam. A beam is here emerging from a small hole in the pile face (the opening marked 20) and being caught in the large lead brick housing in the center of the photo.

determines the probability of the process, or the scattering cross section. This has long been investigated. But the interference of the scattered amplitudes from the planes of differing nuclei in crystals, or even in molecules, gives a way to measure the hitherto unmeasured phase shifts in the scattered neutron wave. They show up in the relative intensities of the different orders of diffraction from various crystal planes, for example. This effect has no parallel in x-ray diffraction, where the wave is electromagnetic and its phase shift uniform. When this complication is unravelled, use of the neutron diffraction as a supplement to x-ray crystal analysis is likely to interest the workers in this field. Neutrons feel the effect of hydrogen and especially deuterium atoms much more than do x-rays, which are capable of interaction only with the electron cloud. This may lead to the study of the hydrogen atom location in some compounds with the aid of neutrons. The neutrons which have been thermalized leak out of the pile with a velocity distribution just that of a molecular beam of hydrogen leaking out of a chamber at a little above room temperature. Collimated and directed suitably against a crystal of salt or calcite or what you will, a spectrum of the neutrons will be spread out in angle, according to the well-known Bragg law, $n\lambda = d\sin\theta$. Here $\lambda$ is the deBroglie wave-length, $\lambda = h/mv$, and thus the distribution in angle is a distribution in velocity. Putting absorbers in the diffracted beam at any angle will serve to produce the attenuation for the energy of neutrons present at that angle of deflection. This is a physically monochromatic beam of neutrons, not simply a device for selecting the effects of a particular velocity group, like all the familiar time-modulated schemes. Energy resolution and range of usable energies is about as good as the best time-modulation schemes, and—apart from the pile—very much simpler. This scheme has been responsible already for the mapping of several resonance peaks in neutron absorption, for example those of In, Rh, Sm, Eu, and Gd.

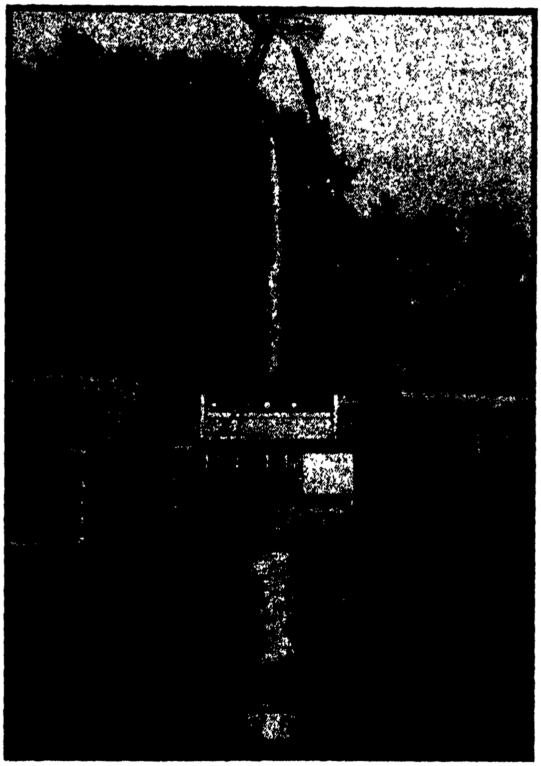

FIG. 17. A war-head of the V-2 fitted with research apparatus, in this case the electronic circuits of a cosmic-ray telescope whose Geiger-Muller tubes "look" through the openings in the war-head. This installation was made by the Applied Physics Laboratory of Johns Hopkins, at Silver Springs, Maryland.

The strong beam has given us one result of decisive importance, a precision re-measurement of the magnetic moment of the neutron.[23] At the Argonne Laboratory, the heavy-water moderated pile, which produces a strong thermal beam, was used as the source for an experiment measuring the magnetic moment of the neutron by polarizing and analyzing the neutrons with ferromagnets through which they passed. The magnetic moment was obtained by observing the resonant frequency at which the polarized beam was partly depolarized by induced transitions in a magnetic field, coming from the Larmor precession of the neutron magnetic moment. (This is the exact experiment of Alvarez and Bloch, an analog to those of Rabi with molecular and atomic beams.) The proton and deuteron moments were measured as calibrating data in the same magnetic field, using the method of nuclear induction in one form (see below). The result was given a conservatively estimated precision of one part in fifteen hundred. To this accuracy the magnetic moment of the deutreron is shown now to be just that of the free neutron plus that of the free proton plus a small calculable contribution arising from the non-spherically symmetric motion of the proton in the deuteron, the known slightly cigar-shaped distribution of charge. No effect of the binding on the nuclear particles themselves is found, to a rather high accuracy. This point is a long debated one in the theory of the lightest nuclei, and sets a necessary condition to be met by any meson theory of the future.

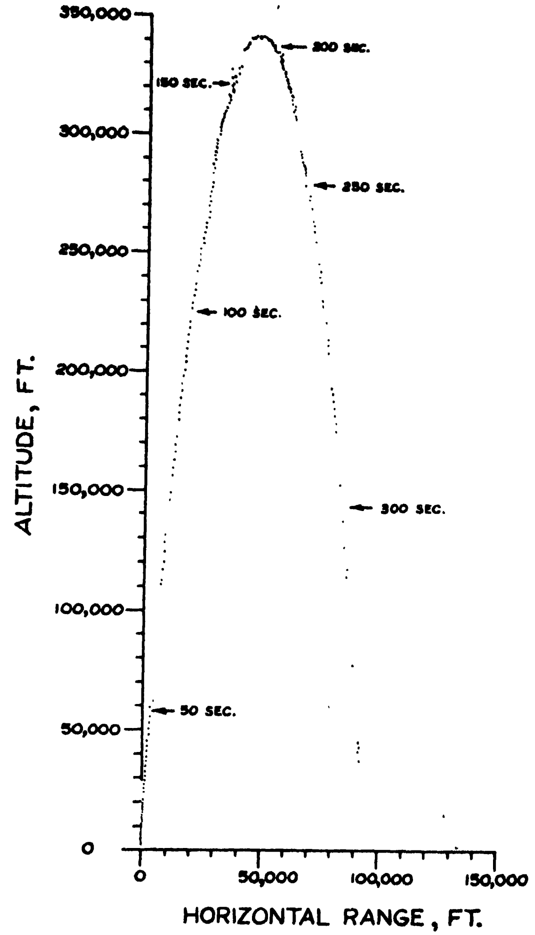

FIG. 18. The graph of the spectacular trajectory of a successful V-2 flight. The high altitude data were obtained by radar tracking. Note that about four minutes is passed in regions beyond the reach of balloons or planes, above 100,000 feet. Not long, but something!

## 3. Rockets

The great technical development of the Axis Powers during the war was certainly the V-2 rocket. For the first time it was possible to launch a projectile of some size into the region beyond the atmosphere. This wartime feat again has meaning for physics. Last year two dozen rockets were launched in New Mexico, most of them reaching altitudes of fifty miles or more. The flight lasts for several minutes, and up to a ton of apparatus can be carried aloft. In cooperation with the ordnance and industrial teams engaged in studying the rockets as weapons, several laboratories have taken advantage of the chance to study the region beyond the atmosphere. Here are the cosmic-ray primary particles, not yet complicated by cloudbursts of secondary particles which they cause on striking the atmosphere. Here may be measured the spectrum of the sun and of the stars, not through the dark glass of the air, but as they come through empty space. Both spectra and cosmic-ray measurements have been made with interesting results.[24] Too little has yet been done to draw any valid conclusions, but it is certain that the exploration

of space beyond the air will have real importance for more than one field of physics.

### THE MASS OF THE MESON

For the years since its discovery, the meson has been examined in the cosmic ray in an effort to measure all its properties. Most fundamental, after its charge, is perhaps its rest mass. If the cosmic-ray meson is that predicted in connection with nuclear force theories, its mass should be somewhere between 150 and 250 times that of the electron. Up until 1946 about twenty-five mesons had been observed with sufficient accuracy to make possible some measurement of their mass. The spread in values was great, and it was by no means sure that the meson had only one definite mass. Perhaps the meson was not a unique particle but a whole family.

An excellent experiment just reported[25] seems to have shown that the ordinary meson which makes up the penetrating component of cosmic rays at sea level has one mass, about 202 ± 5 times the electron rest mass.

This measurement was made by a very careful and successful application of the usual technique. The method of measuring the mass is ordinarily this: The momentum of the meson can be measured by measuring the curvature of its path as made visible in a cloud chamber across which there is applied a known constant magnetic field. This measurement is made difficult by the accidental deflections of the track of droplets caused by the irregular and turbulent motion of air in the cloud chamber. Then the ionization which the particle produces is measured, by counting the droplets left in the chamber gas, or by seeing what thickness of matter it will penetrate before it comes to rest. This gives the rate at which the particle loses energy by interaction with the electrons of matter, and this is known as a function of the velocity of the particle. The scheme then is to measure the curvature of the track and on the same particle to determine what thickness of lead it will penetrate. The experiment here reported divided up these measurements between two cloud chambers. The upper chamber was free of any obstacles, and carefully controlled in temperature. Track curvature could be measured with minimum difficulty from turbulence. A second chamber mounted two feet below the first and in the same plane was expanded simultaneously, and photos were taken of both chambers. The lower chamber was crossed by eight half-inch sheets of lead. By observing in which plate the track appeared to end the range in lead could be gotten to fair accuracy, and the velocity calculated. The particles observed could be assigned a momentum with a spread due to the error in curvature measurement, and a range with the error coming from the finite plate thickness and other sources. The particles then could each be assigned a mass and a definite error. The spread of values was from 142 to 264 electron masses. Statistical analysis of the data gives the result that a unique mass of 202 *m* is quite consistent with the data. The observations agree among themselves just as well as can be expected from their individual estimated errors. These mesons have the single mass 202 *m*.

### NUCLEAR INDUCTION

For some years the magnetic moment which is intrinsic to nuclear particles and to their motion within the nucleus has been an important object of study. This is a very small magnetic moment indeed, roughly two thousand times less than that associated with a single atom. First evidence for and some measurements of these tiny magnetic dipoles were spectroscopic. They interacted with the current respesented by the orbital motion of the electrons around the nucleus in the atom, and the different orientations the nuclear magnetic moment assumed in the magnetic field resulting from the electrons' motion gave rise to atomic energy levels. These levels are very close together: the energy difference is very small, and the difference in frequency and hence wavelength of the emitted spectral lines very small indeed. Lines which originate in this way are said to be lines of the hyperfine structure of spectra. About ten years ago another and more elegant method was devised, which reached its present form in the work of Professor Rabi and his co-workers at Columbia. Here the nuclei are examined as they stream in molecular beams. Such beams are made to pass through strong inhomogeneous magnetic fields. The nuclear mag-

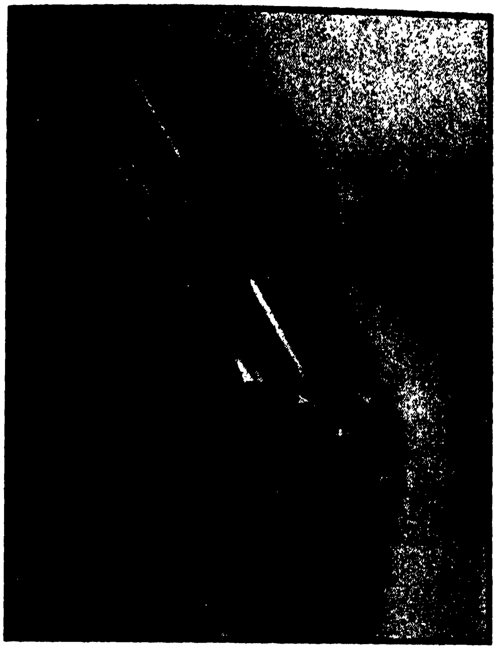

FIG. 19. The receiver-transmitter coils first used to measure the nuclear magnetic moment by nuclear induction. The four heavy turns are the transmitter coil, and the more finely-wound receiver coil is seen within, its axis at right angles to the transmitter coil. Within the receiver coil is placed the sample encased in a half-inch spherical glass bulb. The whole arrangement is shielded heavily. Openings in the shield allow the installation of a rotating copper paddle for adjusting stray fields from without. (Photograph by Professor Felix Bloch of Stanford University, where this work was done.)

netic dipoles feel a force which will depend upon their quantized orientation in space, and the molecular beam will split into several components. These components are each deflected by a different amount, and the deflection may be measured. The deflections one gets with any realizable magnetic fields are small, of the order of hundredths of a millimeter. The method could not by the nature of things be very precise. An elegant adaptation of the molecular beam technique was made by Rabi. He used two equal but oppositely directed inhomogeneous fields. The beam passes through the first and is split into its components. Then the beam is reunited by passage through the second, and strikes a detector. But between the analyzer and the second field there is placed a third region. Here a uniform magnetic field is produced, and also a small radiofrequency magnetic field. The large uniform field has of course no effect on the nuclear

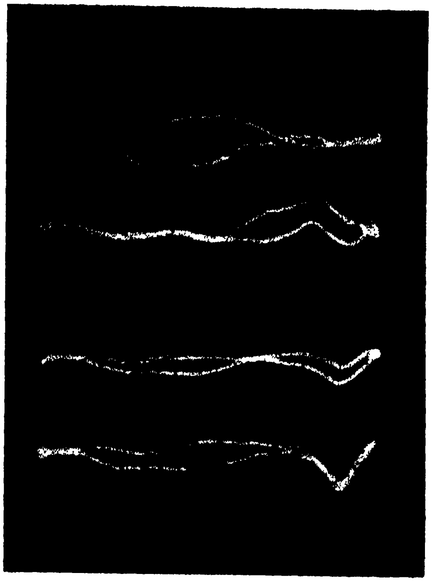

FIG. 20. Oscilloscope traces of the nuclear induction signal. The vertical deflection is proportional to the precessing magnetic moment (or its component in the direction of the axis of the receiver coil), the horizontal deflection to the applied d.c. magnetic field, which has a small, 60-cycle variation in magnitude. The traces shown are those of the proton signal from a water sample. In the top trace the applied field is above the resonance field on the average. The d.c field was lowered in about a second's time to a value below resonance. The proton signal decreased slowly. The next three traces were taken at successive five-second intervals after the reduction of the d.c. field. Note that the signal slowly reverses to a below-resonance condition, though no external change is now going on. This time lag, or "memory," is the consequence of the time it takes for the small nuclear magnets to realign themselves into thermal equilibrium with the new applied field. The time is clearly a few seconds in the case of water. (The double trace is a result of stray 60-cycle pick-up, which separated the forth- and back sweep in the camera exposure.)

dipoles. But the radiofrequency "quanta" may be absorbed whenever their frequency reaches a value such that the quantum energy $h\nu$ equals the energy difference between one orientation of the nuclear magnet in the uniform field and another one. Classically one writes $h\nu = \mu H$, where $H$ is the uniform field strength and $\mu$ the magnetic moment of the nucleus. Fields around a thousand gauss correspond to resonant frequencies of a few megacycles for typical nuclei. Now the nucleus which "absorbs" the quantum is flopped over to a new orientation, cannot be refocused in the second field, and never reaches the detector. By measuring the detector response as frequency or magnetic field are varied, the shapes of the lines corresponding to resonance *with the nuclear magnetic moment can be found.* This leads to precision comparisons of nuclear moments, depending only upon frequency measurements, always easy to do well. No nuclear quantities are known with the precision with which nuclear magnetic moments can be found in this way. But the apparatus is delicate and the *skill and patience required great.* Nor can every substance be gotten into a molecular beam and detected.

It was exciting, then, when not only one but two investigators suggested methods by which the same phenomenon—the flip of the nuclear magnets when they feel an oscillating field of the right frequency—could be detected with no fancy molecular beam techniques. For the first time the macroscopic effect of the nuclear magnets on the magnetic polarization of bulk material was taken into account. Think of a sample of material placed in a magnetic field. The nuclear magnets will line up in the magnetic field to get into the state of minimum potential energy. But of course the thermal agitation of the molecules will act to disorient the magnets. The net result will be given by the usual Curie-Langevin law: the resultant nuclear moment per cc at thermal equilibrium will be approximately $n\mu(\mu H/kT)$, where $n$ is the number of nuclei per cc with magnetic moment $\mu$ per nucleus, $H$ is the applied magnetic field, and $kT$ is Boltzmann's constant times temperature. This is a small contribution to the paramagnetism at best. For protons in water in even pretty high fields it is almost unobservable. What is measured is not the d.c. effect, but a resonant effect at radiofrequency. In one experiment, a resonant cavity was made for about 30 mc.[26] It was filled with paraffin, and was placed in a strong magnetic field, at about 7000 gauss. A weak r-f magnetic field in the cavity was kept perpendicular to the d.c. field. The d.c. field was slowly varied until a sharp resonance absorption was observed. The absorption of r-f energy had changed the $Q$ of the cavity, reduced its output, and affected a detector which had been balanced out off resonance. The same advantages can be claimed for this method as for the molecular beam.

An even simpler technique was applied somewhat later. Here the effect observed is the precession of the resultant nuclear magnetic moment as resonance is approached.[27] The observation is made, not of the reaction upon the driving circuit, but of the e.m.f. induced directly by the precessing nuclear magnets in a pick-up coil in which all e.m f. had been balanced out off resonance. The nuclear-induced precessing field has a component perpendicular both to the constant field and to the r-f field. It is this component which is observed. No more is needed than a radio oscillator, a lecture table magnet, a transmitter-receiver coil arrangement, and appropriate radiofrequency amplifiers and oscillograph circuits. The coils of Fig. 19 are the heart of the apparatus.

It should be noted that the methods of nuclear induction, as they are called, depend upon the nuclear magnets reaching thermal equilibrium, with their moments oriented not at random, but with the equilibrium resultant value. It is just the macroscopic want of cancellation which makes the whole effect. But the mechanism by which the nuclei come to thermal equilibrium is complex and little-known. If it took weeks for equilibrium to arise, the experiment would be very difficult. The time taken will be a function of the chemistry of the compound and of many atomic features. A whole new subject in atomic physics is opened up by this technique, as well as a simple new supplement to the existing study of magnetic moments. The use of the technique for isotope analysis without any destruction of the sample, isotope analysis by radio, so to speak, may prove of great importance in tracer work with stable isotopes. The whole subject is a good example of how new ideas may arise in fields believed already carried to their highest development. The world of physics is surely infinite.

This sketchy review of the first year of peace is full of promise. The promise will be fulfilled only if physicists can share with all men the prospect which carries all our hopes, the prospect of the many years of peace that lie ahead.

I am glad to acknowledge the kind cooperation of all the busy men who answered letters and supplied photographs to make this account possible.

## An Effect of Electron Bombardment upon Carbon Black

JOHN H. L. WATSON
*Plant Research Department, Shawinigan Chemicals Limited, Shawinigan Falls, Quebec*

(Received September 9, 1946)

A significant change is reported in mean particle size and shape characteristics of carbon black due to specimen contamination while under examination in electron microscopes. The effect is described for a number of well-known commercial blacks and examples are given in graphical form to illustrate expected variations in mean particle size with continued bombardment at normal focusing intensities. The effect is observed in other materials but is more pronounced in carbon black. Suggestions are made for minimizing the effect.

A CHANGE in any specimen in an electron microscope resulting from the effect of either vacuum or electron bombardment is of interest to electron microscopists both for itself and for the information which may be gained for interpretation of electron micrographs. Very few effects of vacuum upon electron microscope specimens have been reported, although an evaporation of sulphur crystals has been observed. Some modification of specimens in the electron microscope due to shrinkage or evaporation, is discussed in a recent article by L. Marton *et al.*[1] Artifacts introduced into electron images by electron bombardment of a specimen object are also rare. Dulling of sharp crystal corners and edges by bombardment has been noted and charging effects are common, but permanent deformations are not often seen. One notable exception involves the phenomenon of the deposition of insulating films upon metal surfaces under electron beams.[2]

The particular effect reported here is an increase in the mean size of carbon black with bombardment as measured by the methods of electron microscopy. This was observed first with a filmless[3] preparation where the increase is very pronounced. This increase in mean particle size is important from the point of view of its explanation and from the practical standpoint of its influence upon the problem of carbon black particle size and shape determinations.

A qualitative description of the change in appearance of Shawinigan Acetylene Black under bombardment can be described best from an examination of Fig. 1. This figure shows the appearance of a particular field of a filmless sample as the time of bombardment increases. Bombardment times for each exposure are given in the figure caption and refer to the total elapsed period relative to the first exposure. As the bombardment continues the original crystalline appearance of the particles is lost and almost all become round or oval after a few minutes, where previously they were predominantly crystalline and straight-edged. The particles not only change shape, but they increase in size, and fewer are distinguishable. There is a lessening of contrast over the image, less structure is visible in both chains and particles, and the chains become clumps. The change in mean particle size and in appearance is considerable over even short periods of 15 or 30 seconds, but occurs slowly enough that the eye can distinguish it only after discrete intervals. Over the usual times allowed for examination of a specimen in the electron microscope the changes may be unnoticed qualitatively but will be of sufficient magnitude to materially affect particle size frequency distributions and observations of shape characteristics.

The effect has been checked for many preparations of Shawinigan Acetylene Black and has been observed to some extent in all samples studied.

[3] J. H. L. Watson, J. App. Phys. 17, 121–127 (1946).

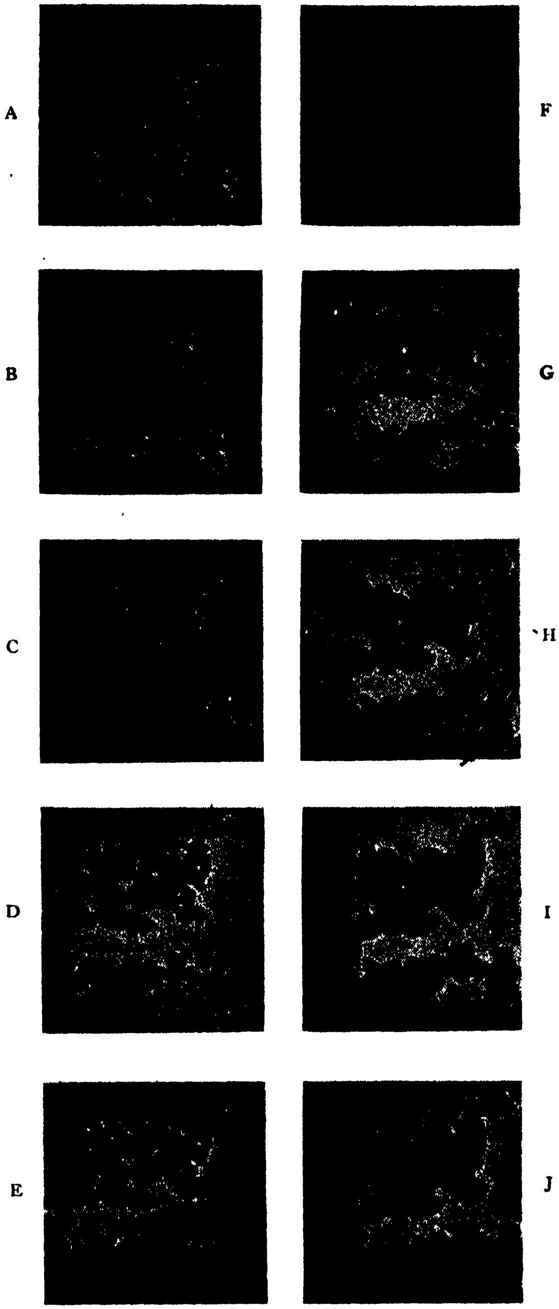

FIG. 1. Shawinigan Acetylene Black under continued bombardment in the electron microscope, filmless preparation ×20,000. Bombardment times are: A, zero; B, 1 min.; C, 2 min.; D, 3 min.; E, 4 min.; F, 5 min.; G, 7 min.; H, 9 min.; I, 11 min.; J, 12 min. relative to the first exposure.

Figure 1 is representative. In general, depending upon intensity, the increase in mean particle size for this black in a filmless preparation is of the

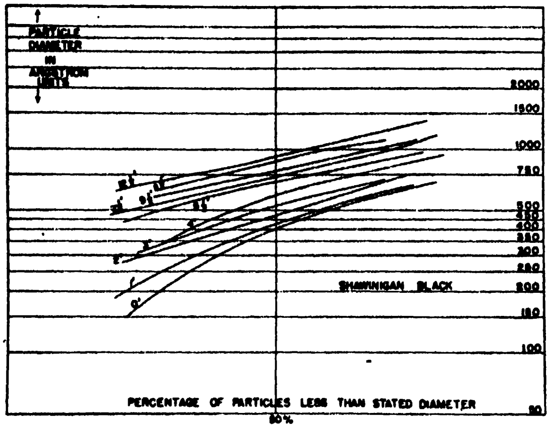

FIG. 2. Particle size frequency distribution curves for each of the exposures in Fig. 1, respectively.

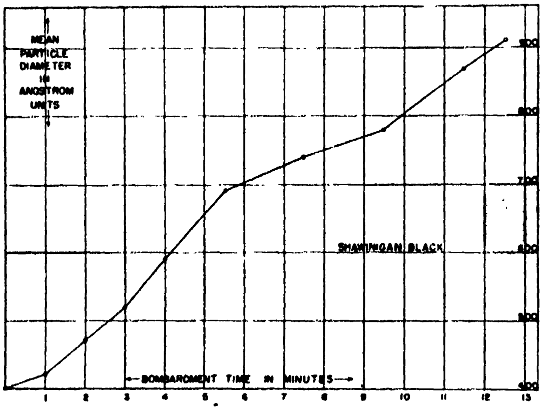

FIG. 3. Mean particle size for each of the exposures in Fig. 1, respectively, plotted against time of bombardment relative to the first exposure Fig. 1A.

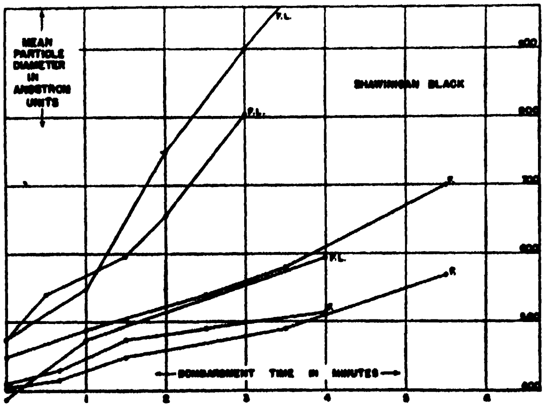

FIG. 4. Other typical increases of mean particle size with bombardment time for filmless and film preparations of Shawinigan Acetylene Black. F., film preparation; F.L., filmless preparation.

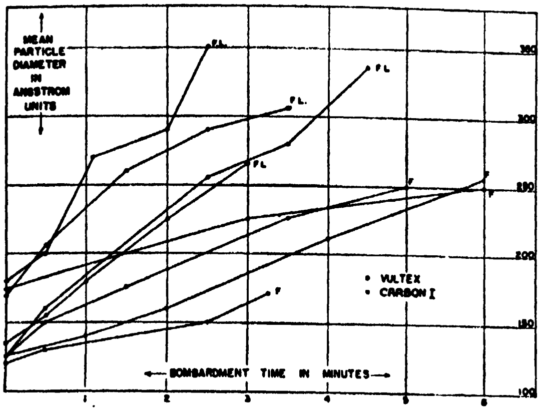

FIG. 5. Typical increases of mean particle size with bombardment time for filmless and film preparations of Voltex and Carbon I. F., film preparation; F.L., filmless preparation.

order of at least 70 percent after 5 minutes bombardment. This is easily a significant value for the type of counting procedure involved. At fairly high, although not focused intensities, the particle size usually will have changed significantly (i.e., say more than 5 percent) in 30 or sometimes in as little as 15 seconds.

In studying a bombardment time series, the same field is photographed after discrete intervals and particle size frequency distributions are obtained from each exposure for comparison. As an example, the frequency distributions, plotted upon logarithmic probability paper[4] (the distributions being negatively skewed), are given in Fig. 2 for each of the exposures in Fig. 1, respectively. In the exposures of this series, too few particles are visible to give good straight lines. The mean particle diameters thus obtained are plotted against time to give the graph in Fig. 3. Other typical increases for acetylene black are shown in Fig. 4. The mean values in the first exposures are within ±10 percent of their arithmetic mean which is fair agreement considering the fact that but one field of the specimen is under study in each case and the number of particles counted is necessarily low. These curves are labeled as being from either filmless or film preparation.* For any particular field, if the intensity is kept constant throughout a run, the relationship between mean particle diameter and bombardment time follows a straight line.

Similar bombardment experiments have been carried out using specimens of such well-known colloidal carbon blacks as Micronex, Voltex, Statex, and P-33. These are structureless carbons as compared with acetylene black which is characterized particularly by its chain structure. Micronex and Voltex are representative of channel blacks of very small diameter. Statex is close to Shawinigan in mean size but is a combustion furnace black, where Shawinigan is formed by a process of thermal decomposition. P-33 is a large diameter black formed by a thermal furnace process. Table I gives (a)—particle sizes for each black represented, (b)—a brief description of the process by which the black is made, and (c) a summary of average values in angstrom units of the increases which can be expected for film and filmless preparations over a 3-minute bombardment period at normal focusing intensity. This table is merely intended to give the reader some idea of expected variation in particle sizes. Other than this it has little significance since the contamination is dependent, as will be discussed later, on several factors which it is difficult to control. Figure 5 gives several curves for mean particle diameter *versus* bombardment time for Carbon I and Voltex. Again, the mean sizes reproduce well from the *first* exposures of the series. Figure 6 shows a typical sequence of Voltex under the electron beam for a film preparation, and

TABLE I. Average increase in mean particle diameter after three minutes of bombardment at normal focusing intensity. The distance of the material from the wire of the grid is unknown.

| Sample | Process of manufacture | Mean* particle diameter | Film mounting | Filmless mounting |
|---|---|---|---|---|
| | | (*A*) | (*A*) | (*A*) |
| Carbon I | Channel Black | 140 | 55 | 155 |
| Voltex | Channel Black | 155 | 110 | 155 |
| Micronex W-6 (EPC) | Channel Black | 295 | 90 | 200 |
| Statex | Furnace Combustion Black | 400 | 115 | 240 |
| Shawinigan | Thermal Decomposition of Acetylene | 430 | 115 | 345 |
| P-33 | Furnace Thermal Black | 1050 | Negligible except at high intensities | |

* The mean particle diameters published here are calculated as an average of the values obtained in these experiments from the particle measurements made on the *first* exposures of the series. The *longest* diameters are taken when measuring a particle. The effect of distortion has been kept as far as possible at a minimum.

---

[4] J. M. Dallavalle, *Micromeritics* (Pitman Publishing Corporation, New York, 1943), p. 47.

* The term "filmless preparation" is described under reference 3. "Film" preparation referred to here involves blowing the dry carbon from a de Vilbuss atomizer toward a Formvar film over a usual electron microscope specimen holder.

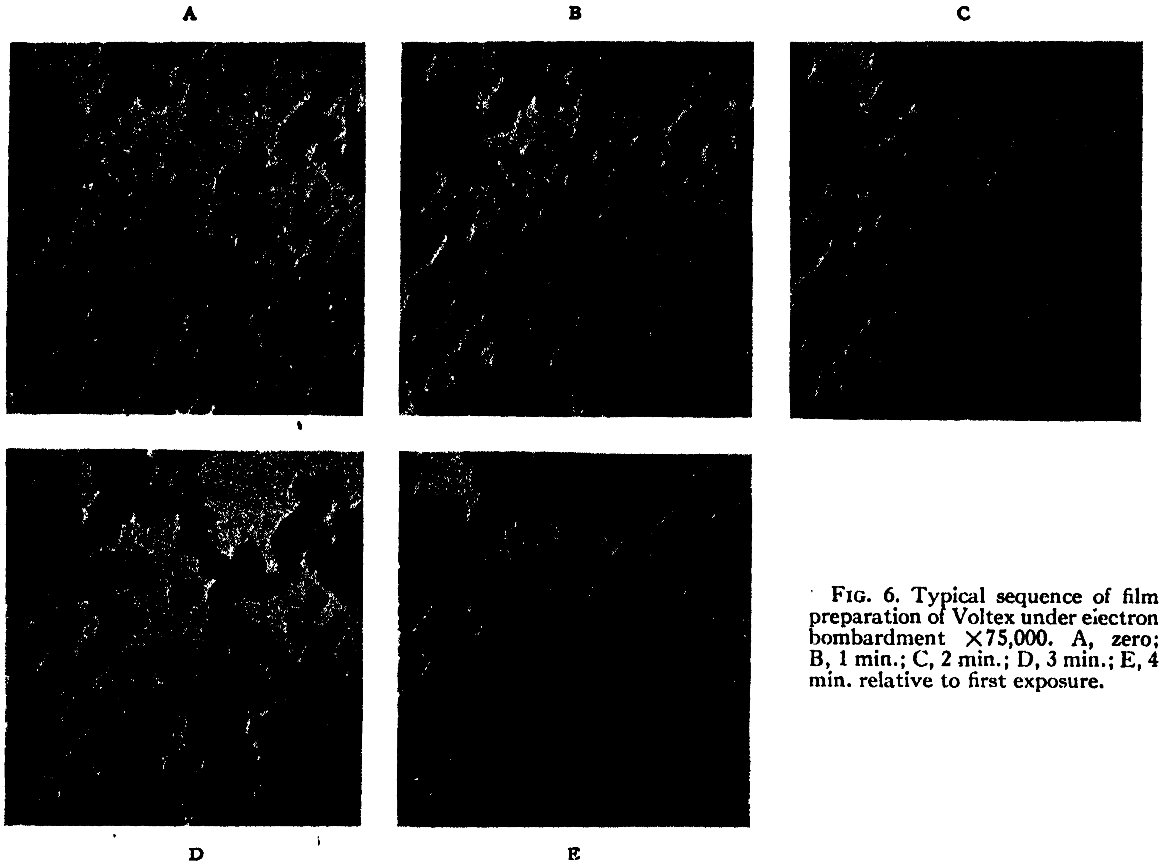

Fig. 6. Typical sequence of film preparation of Voltex under electron bombardment ×75,000. A, zero; B, 1 min.; C, 2 min.; D, 3 min.; E, 4 min. relative to first exposure.

Fig. 7 for a filmless one. Increases of well over 100 percent may be recorded for film specimens of the finest carbons such as Carbon I and Voltex in 3 minutes. From filmless preparations of these two carbons it is difficult to secure particle diameters at all after a few minutes since the clumps seem to coalesce and single particles are no longer visible.

Similar changes are observed with Statex samples and to a marked lesser degree with P-33. However, with very intense bombardment of P-33, large changes are recorded. In general, as would be expected, the percentage increase in mean particle diameter is greatest for blacks of smaller particle size.

Several general observations have been made concerning the relative magnitude of the effect under different conditions of specimen examination. It is more pronounced in a filmless rather than a film mounting. It is zero when the specimen is incorporated into the body of a Formvar film. It is most pronounced at high intensities and may be made negligible if the intensity is lowered sufficiently. With prolonged bombardment of carbon black the effect does not clean up but is permanent, and becomes progressively more pronounced as shown in Fig. 1. The effect is of equal magnitude regardless of whether the sample is on the filament side of the supporting film, or on the reverse side. The carbon "grows" only in that area where the specimen is being bombarded.

That a contaminant surface is deposited, is easily demonstrated by bombardment of a Formvar film which has holes through its surface. The film thickens noticeably and contrast between film and hole space is enhanced by the bombardment, see Fig. 8. Figure 8B was taken after a 3-minute bombardment with all operating conditions and photographic processes, the same as for Fig. 8A. This film thickening will lower resolution and contrast over the specimen but not to a sufficient extent in short times to account for the pronounced increases in mean particle size recorded here. The holes in the Formvar are

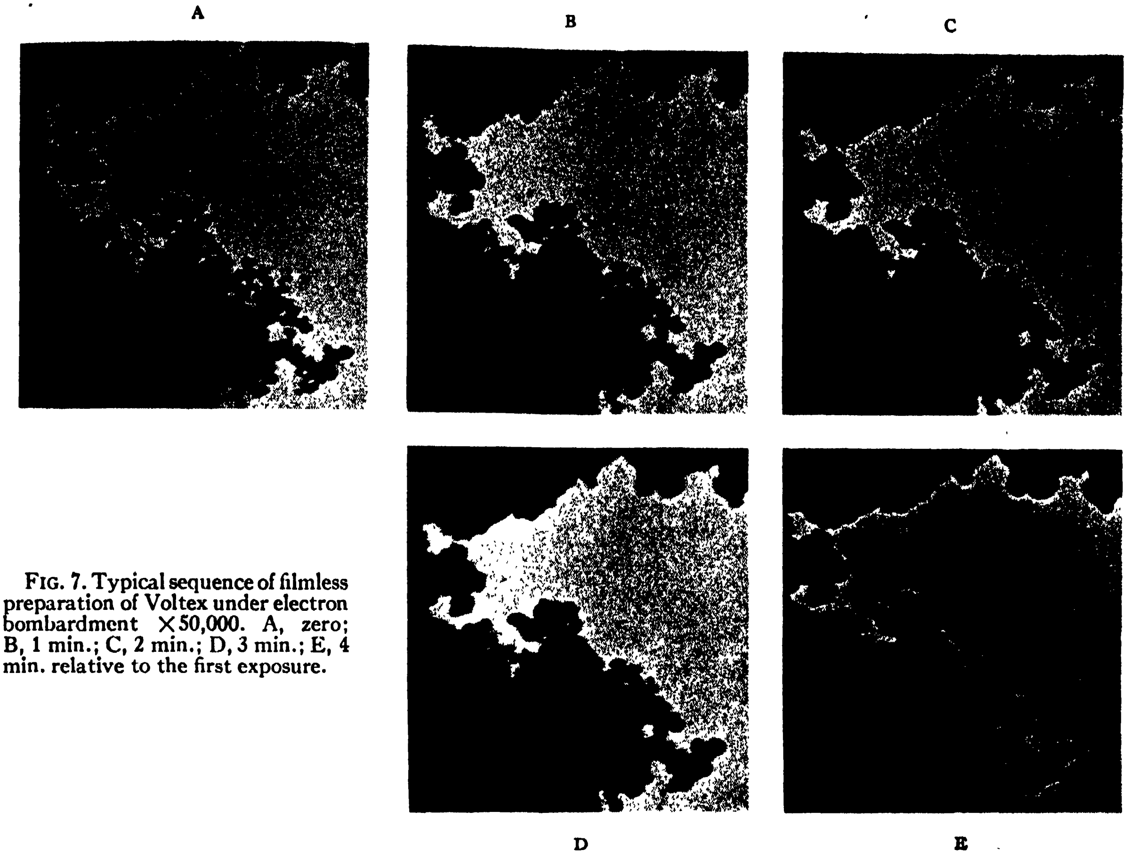

FIG. 7. Typical sequence of filmless preparation of Voltex under electron bombardment ×50,000. A, zero; B, 1 min.; C, 2 min.; D, 3 min.; E, 4 min. relative to the first exposure.

measurably smaller after bombardment; a decrease of about 8 percent occurring in 5 minutes.

It has been pointed out already that a greater contamination effect is observed in filmless than in film preparations. In a filmless one a field is usually chosen which is quite near the metal of the specimen grid. Upon further investigation, it is observed that in either type of specimen preparation, the closer the bombarded area is to the grid wire the greater is the effect of contamination. Figures 9 and 10 are offered to illustrate this. These were taken of the *same* specimen of Shawinigan Black mounted on a filmless holder. Figures 9 A and B were taken of a field in the center of one of the holes, as far from the wire as possible. No change was noted after a bombardment of six minutes. Figures 10 A and B were taken of a field immediately adjacent to the wire. There is an 81 percent change in mean particle size between these two figures after one minute bombardment. The mean particle size changes from 470 to 850 A.

An attempt is being made to relate percentage change in mean particle size with distance from the screen. From preliminary experiments it appears that the very pronounced contamination falls off rapidly and only occurs in a region distant about 8$\mu$ from the wire. This distance will vary with different specimens and electron intensities. In regions further than this from the screen the contaminant builds up more slowly. In order to keep the effect at a minimum, fields for examination should be chosen as far as possible from the metal grid.

The observations cited support an explanation based upon specimen contamination occasioned by the deposition of a hydrocarbon material under electron bombardment after the manner described in reference 2. The mechanism of this hydrocarbon formation in the electron microscope is related to the well-known phenomenon of polymerization and condensation of organic vapors and gases, and certain other gaseous products, under electron or other charged-particle

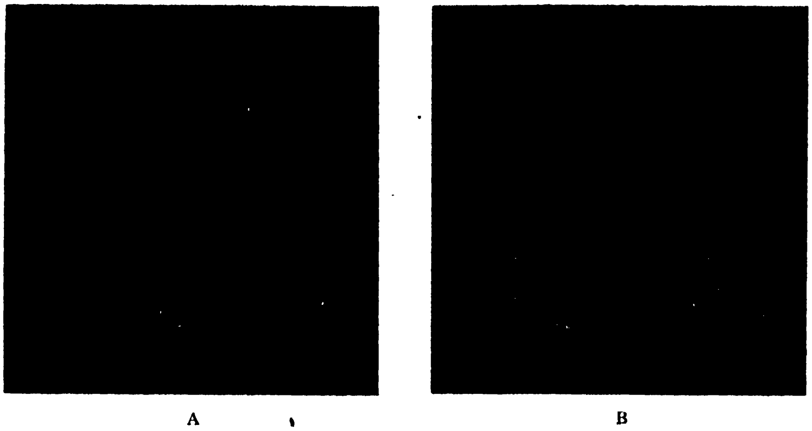

FIG. 8. A, Formvar film before bombardment. B, Same field after three-minutes bombardment ×25,000.

bombardment.[5,6] Theoretically these contaminant surfaces may originate either from organic materials in the metal body of the microscope itself, from grease used to a limited extent on vacuum seals, or from impurities present in the specimen holder and supporting grid. It is con-

ceivable also that organic substances present in the object could be distributed as a vapor under the beam and be redeposited upon the particles; but it is known that the percentage of volatile material in these blacks bears no relation to the magnitude of the change.

If we assume that the explanation for the contamination lies in the above paragraph, a reason for the more pronounced effect near the grid can be advanced. The formation of the polymer can be explained from Lind and Glockler's[7, 8] experiments upon alpha-ray bombardment and consequent polymerization of acetylene and other hydrocarbons. They suggest that when the molecules in gaseous or vapor state are bombarded by charged particles they are ionized and that they then attract neutral molecules to themselves to form a cluster-ion. When this finally is neutralized a large molecule is formed.[9] This neutralization and resulting deposition of the contaminant will occur most easily upon electron microscope specimens at or near the *conducting* grid.

In order to test this explanation a conductive film of chromium metal was deposited over a Formvar film preparation of Voltex Carbon, by use of shadow casting methods. Under these conditions, marked contamination was observed over the specimen regardless of position relative to the grid. Figures 11 A and B are reproduced of a field

approximately in the center of a grid hole. The normal degeneration of contrast over the specimen and increase in mean particle size is observed in Fig. 11 B.

Carbon black, and especially Shawinigan Acetylene Black, is particularly conductive. Heavy contaminant deposits would be expected

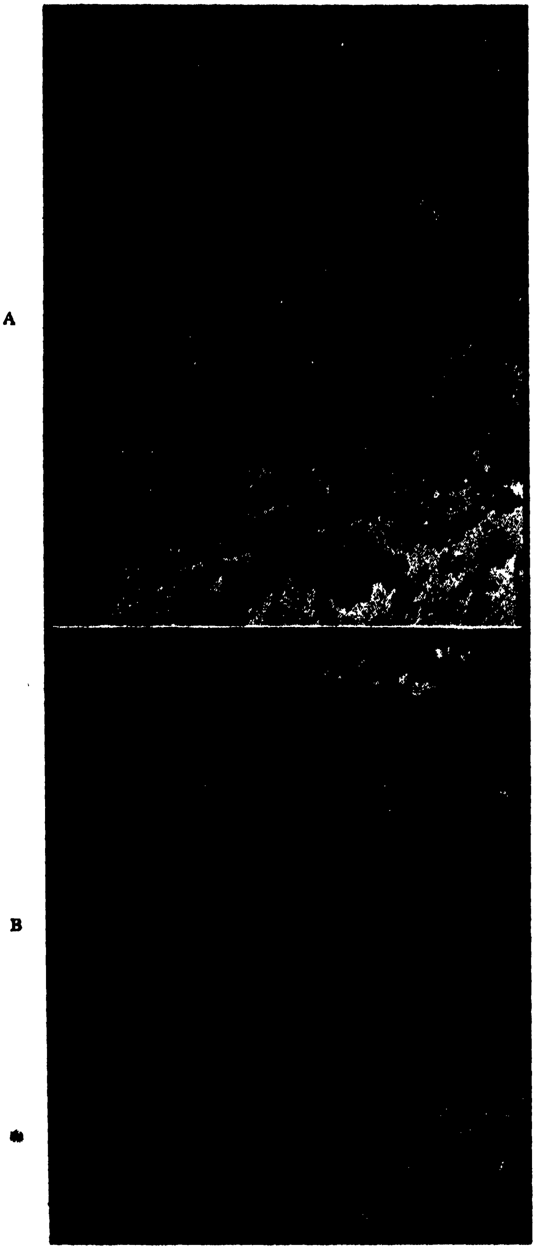

FIG. 11. A chromium shadow cast specimen of Voltex. A, no bombardment. B, after a 4-minute bombardment. The field was chosen far from the grid wire.

therefore to form upon it. Whereas it is always possible with carbon black to demonstrate a rapid increase in size under bombardment, it has not been found possible in this laboratory to do so to the same extent with other materials.

The loss of contrast over the specimen and the lack of detail are explainable on a basis of contamination of both the film and the specimen itself. Likewise masking of the small particles; growth of all the particles; and loss of original shape characteristics could be caused by contamination.

That as large an effect is not noted with other substances as with carbon black may be significant also as an indication that the surface of the black has a certain activity for attracting and holding the contaminant permanently so that it will not clear up under continued bombardment. This would conform with the known activity of carbon surfaces in other regards[10] such as their adsorbent, catalytic, and unsaturated electron properties.

Recognition of the existence of the effect points out at least one way in which values from particle size frequency distribution curves can be secured with greater accuracy and reproducibility. Since increases in particle sizes similar to these but of less magnitude have been found to occur to some extent with other materials under bombardment, precautions for minimizing the effect should be followed in all particle size determinations made with electron microscopes.

The change takes place so rapidly with finer carbons that in any micrograph where there is a possibility that it has occurred the *original shape* of the particles is masked almost certainly. Therefore it may distort not only particle size determinations but it may lead to wrong conclusions concerning particle shape and through these to incorrect calculations of specific surfaces. In Shawinigan Acetylene Black for example, the fine, platelet particles appear as round or oval units after a few minutes. In experiments to date the finest carbons such as Carbon I and Voltex appear to be "feathery" in the original uncontaminated condition but rapidly become small, distinct spheres under bombardment. The feathery appearance may be caused wholly by

---

[10] U. Hofmann and W. Höper, Naturwiss. **32,** 225–226 (1944).

lack of resolution but the possibility exist that some of these extremely fine carbon particles possess crystalline properties and straight-edged shapes in their original condition, much in the manner of Shawinigan Acetylene Black. The shape characteristics however would be within, or near, the limit of resolution, and would not be seen except insofar as they lend the feathery appearance to the image.

The effect may be made zero by incorporating the black samples into the supporting film. However, the sample manipulation required in effecting this type of mounting will tend to change the appearance of the carbon from what it was originally, causing structure breakdown and making interpretation of results more difficult and less reliable. In this laboratory it is desirable to study the black as much in its normal state as possible and therefore dry mounts are essential. It is in these that the change under bombardment is considerable. Therefore it becomes a necessity that conditions in the microscope be kept such that a minimum of change is possible. To do this the following rules of procedure are followed: (1)—the intensity is kept at a minimum, (2)—micrographs are taken as rapidly as is practically possible, (3)—focusing is often carried out using a part of the field which is not to be photographed, and (4)—fields are photographed which are as far as possible from the metal of the specimen grid. If a black is bombarded at fairly high intensity, (focusing intensity) for any length of time longer than 15 seconds a correction downward in particle size should be applied. It is impossible to give a value for this correction here as it will depend upon the time taken for focusing and the intensity used by the individual microscopists.

Many of the observations and much of the information concerning contamination is contradictory and incomplete. Since it is becoming an increasingly important problem in electron microscopy an exchange of information on the subject in publication is needed in order to clarify many aspects of it.

# On Cavity Formation in Water*

E. Newton Harvey, Wm. D. McElroy, and A. H. Whiteley
*Department of Biology, Princeton University*

(Received October 28, 1946)

**Phenomena involving the tensile strength of water have been studied by a kinetic method—high speed motion photography of the rapid movement of a blunt glass rod (5 mm diameter) in a narrow (16 mm inside diameter) glass tube of water. Special precautions have been taken to remove all hydrophobic patches and small gas masses (gas nuclei) but to retain the dissolved gas (air at one atmosphere) in the water. If the rod surface contained gas nuclei, or was hydrophobic and free of gas nuclei, cavitation occurred at the rear end when the velocity was less than 3 meters/sec., but if completely hydrophilic and free of gas nuclei, the velocity could be 37 meters/sec. or 83 miles/hour without cavitation. Addition of a detergent (diactyl sodium succinate) to the water did not prevent cavitation at a low velocity with the hydrophobic rod free of gas nuclei. Movement of a rod in pure corn syrup (viscosity 20.1 poises), free of gas nuclei, left a large cylindrical cavity that collapsed in a matter of hundredths of a second. It is not possible to calculate the tensions developed in these experiments, but it is pointed out that the velocities attained without cavitation are far higher than previously observed for movement of bodies in an aqueous medium, a result believed to be owing to the absence of all gas phases and hydrophobic surfaces.**

## INTRODUCTION

During a study of bubble formation in the blood and tissues of animals—a condition leading to such symptoms of decompression sickness as the "bends"—the conclusion was reached that a decrease in hydrostatic pressure, i.e., a tension in the tissues, was one of the primary factors involved. Favoring this view is the observation that straining movements and muscular exercise at simulated high altitudes greatly increase the incidence of bends in men or of bubbles in animals.[1] This work led to investigation of the tensile strength of pure water containing dissolved air, and it is the purpose of this paper to describe the method and certain observations in connection with the experiments. Calculation of the actual tensions involved has not been attempted, but all relevant data are given.

There is a general belief that water under tension can be easily torn apart; that it is only necessary to reduce the pressure to that of water vapor in order to obtain profuse bubbling and boiling. Actually, the boiling which occurs at the vapor pressure is because of the presence of minute gas pockets adhering to dust particles in the water or on the walls of the container. The gas phase serves as a gas nucleus to start the cavitation. It is a simple matter to show that if gas nuclei are removed, water in non-capillary spaces can be subjected to high vacua or can be heated to over 206°C without boiling,[2] although evaporation from the surface is rapid (Harvey *et al.*[3]).

Many experiments, recently reviewed by Vincent[4] and discussed by Dean[5] indicate that a water column in a well-cleaned container can be subjected to a tension measured in atmospheres without breaking. The maximum values for this tension have been obtained by means of the thermal contraction method. In this method a glass tube, *completely* filled with the liquid at a higher temperature, is slowly cooled. The differential contraction of liquid and container then exerts the tension that finally pulls liquid from the walls with a sudden click. Dixon[6] obtained 150 atmospheres and Vincent[4] 157 atmospheres, using this method.

Both values are far short of the 10,000 atmos-

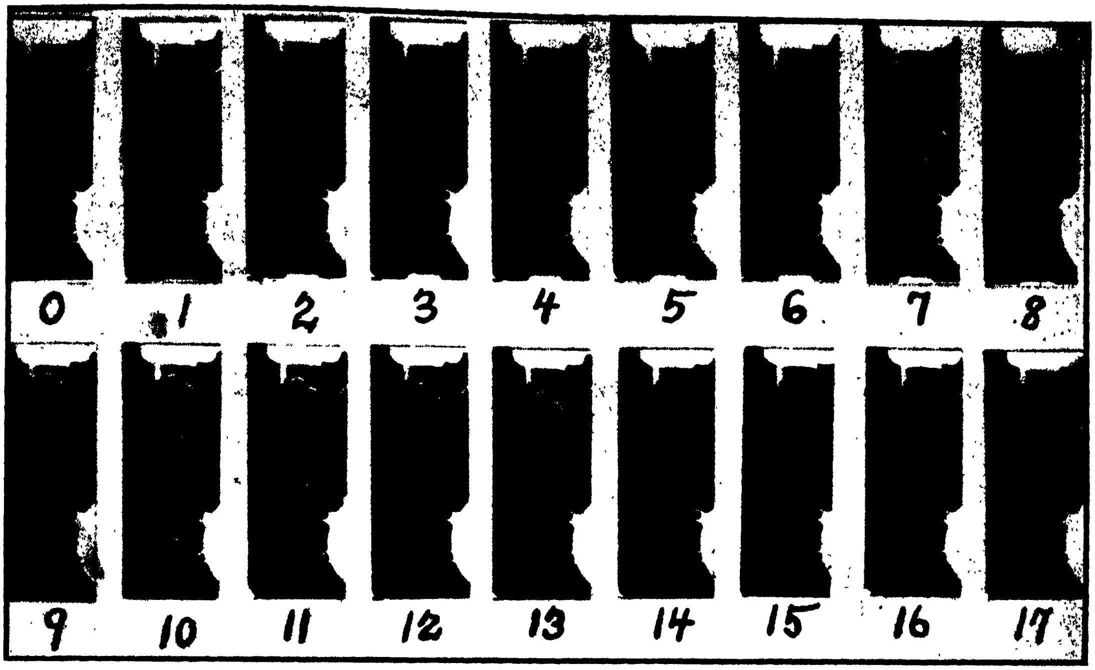

FIG. 1. Moving picture of cavity formation due to a pressure pulse (with negative pressure component) which arises when the bottom of a glass tube containing highly evacuated water (vapor pressure = 19 mm Hg) is struck a blow with a wooden block. The block appears in frame 1 and disappears in frame 10. Note that the cavities, which have enlarged from gas nuclei, first become of maximum size near the bottom of the tube and last longest near the top of the tube. Tube diameter 19.3 mm, 140 frames per second. Exp. 6-9-43.

pheres for the mutual attraction between the water molecules, or the "intrinsic pressure" within the liquid, possibly because breaking is not simultaneous across a unit cross-sectional area. On the other hand, the variation in experimental values from 5 to 157 atmospheres that have been obtained by different workers, may be a reflection of insufficient removal of small gas masses.* In every experimental investigation of the tensile strength of water the container is as important as the water. Not only must there be no gas nuclei on the walls but also no hydrophobic surfaces must be present, since water does not adhere to these surfaces and readily separates from them. Both these conditions indicate that a relatively small amount of water and a minimum surface area of easily cleaned hydrophilic material is essential for experimental work. Glass is unquestionably ideal for the surface since the water-glass contact angle is zero.

In addition to the previously mentioned thermal contraction method of exerting tension on water, kinetic methods are also available. In one of these the bottom of a tall glass tube filled with water, which has been exhausted to the vapor pressure, is struck a sudden blow. The blow moves the glass wall of the tube sufficiently to start a pressure pulse with a negative component. The cavitation and bubble formation under those conditions are well known. In Fig. 1 is reproduced a series of prints from a high speed moving picture which show the resulting cavitation when the bottom of a tube of evacuated water (vapor pressure = 19 mm Hg) is hit with a wooden block. The cavities have started from gas nuclei.

Another method of developing tension is to move a long tube of water rapidly in the direction of its open end and suddenly bring it against a rigid barrier or stop. The momentum of the moving water tends to pull it apart.

Although the above two procedures have readily caused cavitation and bubble formation if gas nuclei were present, after the removal of

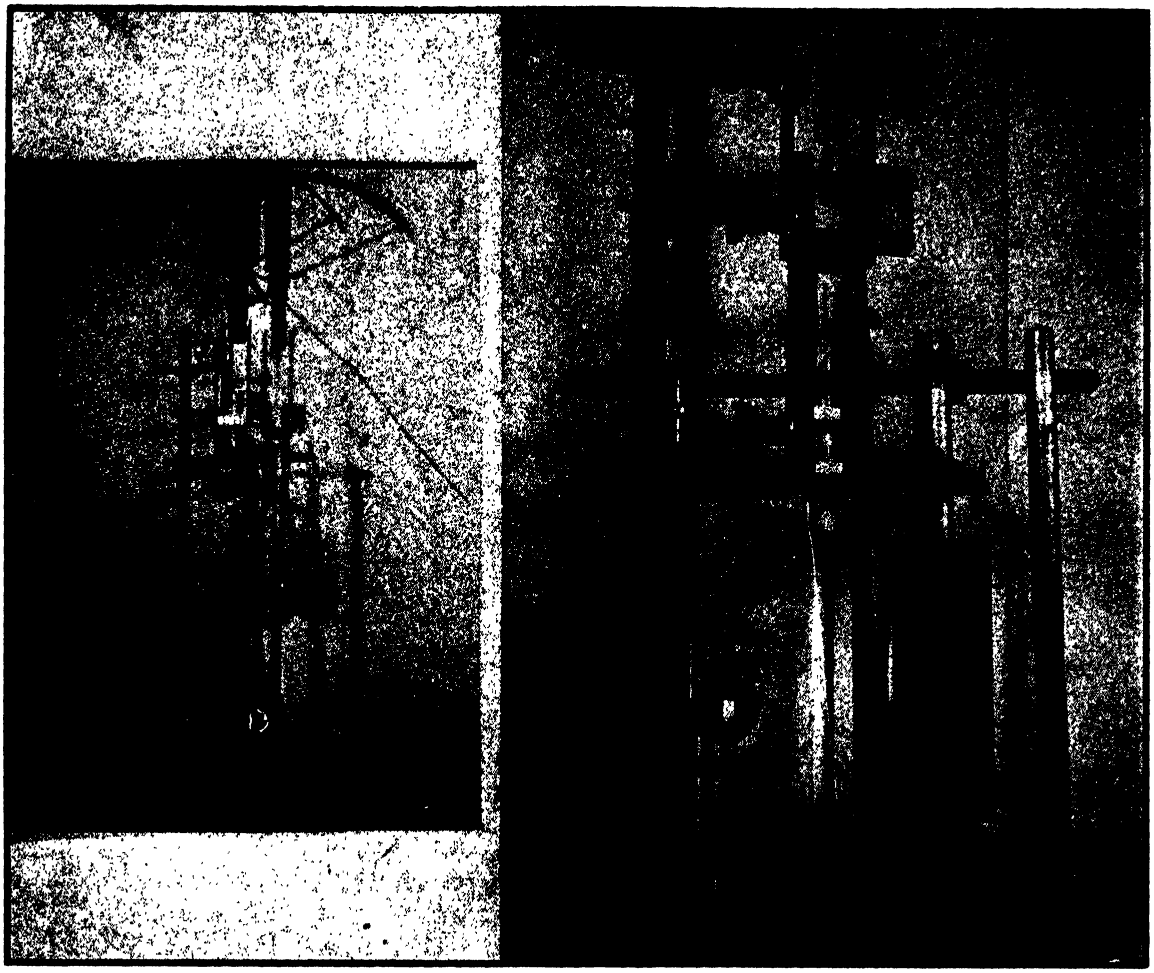

FIG. 2. A far (left) and near (right) view of the apparatus for rapidly moving a glass rod vertically in water. The steel bow appears above and the sodium lamp (with a circular mirror) on right. This lamp flashes 120 times a second and is used for timing the frames. In the near view, the Cellophane covering of the tube to protect against dust and a large mirror to allow a view of the cavitation at right angles to the camera is plainly seen.

the gas nuclei the blow to the tube or the velocity of the movement necessary to cause cavitation were so great as frequently to break the tube. Likewise we have found that cavitation of water, caused by the passage of high frequency sound waves, ceased when gas nuclei were previously removed, although a fairly high intensity of sound was employed (Harvey *et al.*[8]).

Flow methods of reducing pressure, which depend on the principle of Bernouilli (a Venturi or a Reynolds tube, Fig. 6) or the flow past a fixed body in the stream, are not feasible because of the large amount of water necessary and the problem of removing gas nuclei from such a volume. However, by moving a surface rapidly through stationary water similar regions of low pressure develop. The rear end of a moving object, such as a rod, exerts a continuous pull on the surrounding medium, which attempts to follow the rod and close the potential space. This method has been adopted in the experiments described below.

### TECHNIQUE

In order to study the tearing of water from a glass surface moving with high speed, conditions most favorable for the development of tension were selected, namely, a cylindrical glass rod cut squarely across at one end and moved rapidly through a small volume of water in a narrow glass container. The walls of the container were near enough to those of the rod to give the additional suctional effect of a leaky piston. Rod and container cannot be too close, as the contact of one surface with another supplies the conditions for immediate cavity and bubble formation (Harvey *et al.*[7]).

To make certain that no hydrophobic spots remained on the glass surface, cleaning was accomplished by washing with soap and water, followed by hot trisodium phosphate and then hot concentrated sulphuric acid-bichromate mixture. Dust particles were removed by centrifuging (800×g for 30 minutes) the water used in the experiment. Our experiments differ from those of previous workers in that attempts were made to remove completely all gas nuclei, but to leave the dissolved air (at a tension of one atmosphere) in the water.

The method for removing gas masses was that of high hydrostatic pressure treatment (Harvey *et al.*[3]) which forces gas nuclei into solution. The glass tube, 16.0 mm inside diameter and about 41 cm long, with its contained water (distilled) and glass rod in position, with wire attached for pulling the rod, was covered with dialyzing Cellophane tubing tied both to the wire and to the glass tube end to prevent the entrance of dust, as shown in Fig. 2. This assembly was then placed in water in a long steel pressure chamber and subjected to 16,000 lbs./in.$^2$ hydrostatic pressure for from 15 to 120 minutes.

After the cleaning and pressure treatment, the tube, rod, and water were tested by evacuation to the vapor pressure of water to see if bubbles would arise. In no case was bubbling observed. The assembly was then mounted in a frame and the rod connected by its wire either to a coiled wire spring (in earlier experiments) or a bow, fabricated from a steel auto spring leaf, for rapid movement of the rod.

The lower part of the tube and rod were arranged in position before an Eastman 16 mm high speed moving picture camera, the maximum speed of which is 3000 frames per second. Behind the tubes there was a ground glass, illuminated by two No. 2 photo-flood lamps, run on 130 volts in a reflector. This intensity of transmitted light was found to give proper exposure for 2000 frames per second with $f=3.5$ and a camera distance of three feet. In some experiments a mirror was so arranged that a view of the moving rod at right angles, in addition to the direct view, was recorded by the camera. The bow or spring was stretched and locked in position with a trigger release that was activated when about 35 feet of a 50-foot roll of Eastman super XX panchromatic film had passed behind the camera lens. The film was developed in D11 for 5.5 minutes. Just before the motion picture of the moving rod was taken, the Cellophane cover, which protects from dust, was loosened around the edge of the glass tube but left attached to the rod wire, thereby moving upward with the rod. No dust could enter the water until after the rod had moved out of the camera field of view.

Two sizes of Pyrex glass rod have been used, both about 29 cm long, one 5 mm in diameter, and one 10 mm in diameter. The end of the 5-mm rod was fire polished while the end of the 10-mm rod was ground and polished with rouge to make a right angle. The larger rod was introduced to increase the suction and tension on the water. The wall clearance between the 10-mm rod and tube (16-mm internal diameter) is only 3 mm, and the ratio of cross-sectional area of rod (78.5 mm$^2$) to cross-sectional area of tube (201 mm$^2$) is 0.39. It is not feasible to increase this ratio further because scraping of glass on glass causes bubble formation in gas supersaturated solutions or in a liquid under reduced hydrostatic pressure. Such a scraping of glass rod on glass wall has never occurred in our experiments but would undoubtedly result in cavitation.

## EXPERIMENTS

To demonstrate the tearing of water from a hydrophobic surface, dry clean glass rods 5 mm in diameter were covered with a thin film of paraffin or a thin layer of General Electric repellent varnish[8] (two experiments). The special cleaning procedure could not be applied to these surfaces. They were placed in the tube containing

[8] We express our thanks to Dr. F. J. Norton, of the General Electric Co. for a sample of this varnish.

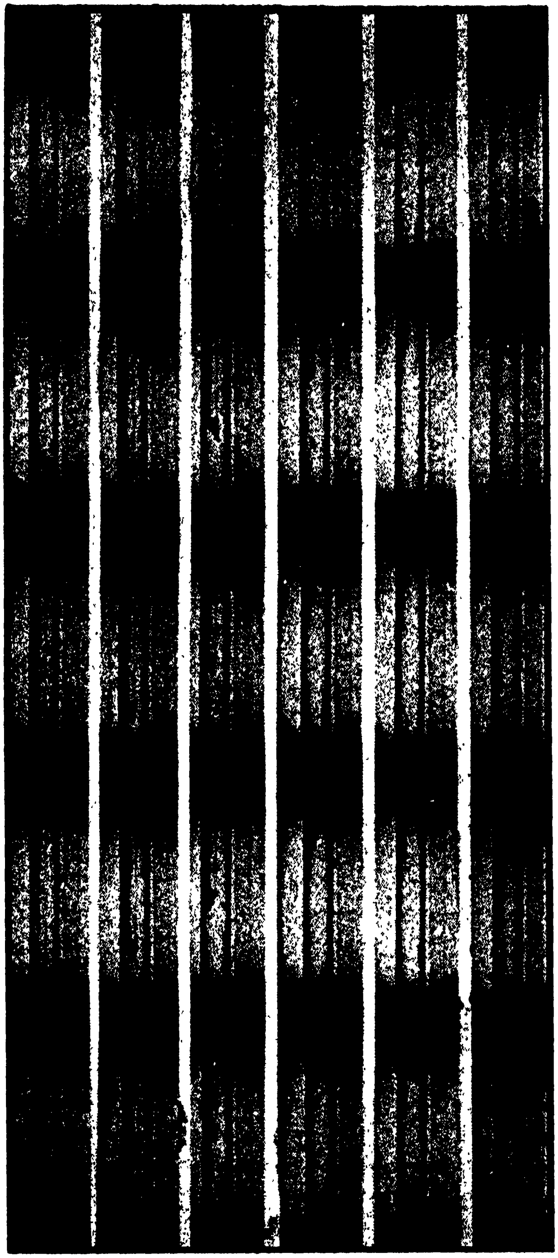

FIG. 3. Moving picture (2280 frames/sec.) of a paraffin tipped rod (5-mm diameter) moved through gas nucleus-free water at a final maximum speed of about 16 meters a second. Note the abundant cavitation, characteristic of hydrophobic surfaces, which appears in the first frame when the velocity was less than 3 meters a second. Cavitation disappears in frame 17, to reappear and again disappears in frame 22, with subsequent periodicity. Scale in centimeters. Exp. 9-7-44.

water and pressurized at 16,000 lbs./in.$^2$ for from 30 to 90 minutes. When tested at the vapor pressure of water (20 mm Hg) no bubbles arose from the glass surfaces or from the water. However, motion pictures of the movement of the hydrophobic rods through water showed cavitation on the first frame when the velocity was less than 3 meters/sec., and a misty trail of fine cavities in succeeding frames, as shown in Fig. 3. The water in the tube after the rod was drawn out was observed to be full of fine bubbles. On the other hand, completely hydrophilic rods, 5 mm in diameter, have been drawn through the water with a velocity of 37 meters/sec. without a sign of cavitation. A plot of rod velocity *vs.* time is shown in Fig. 4 and will illustrate the rapid acceleration attained with our type of bow.

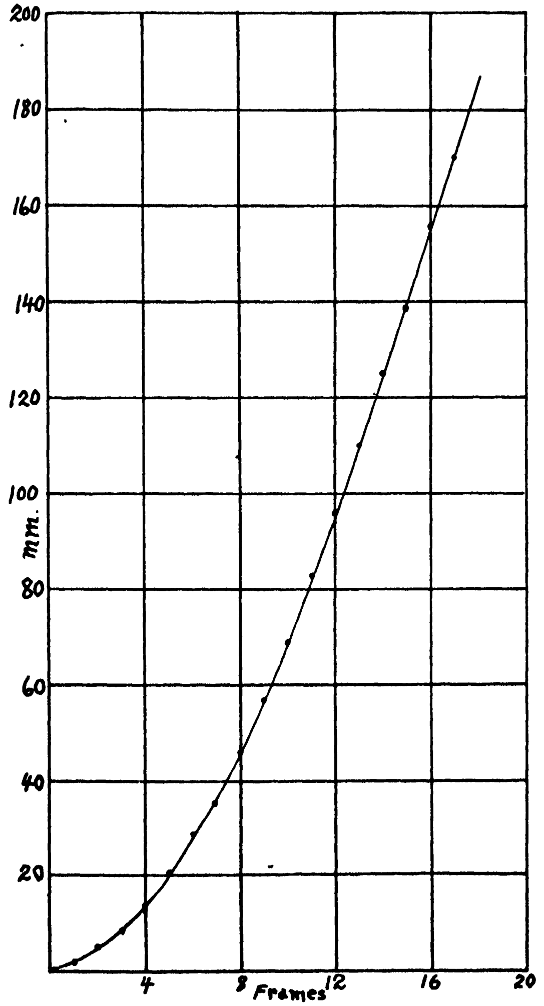

FIG. 4. A plot of the acceleration of a 5-mm glass rod in gas nucleus-free water. Exp. 12-14-44. 2400 frames/sec. The final velocity was 36.7 meters/sec., yet no cavitation appeared at this speed.

The question arises whether the presence of a detergent in the water, that might cover hydrophobic surfaces, leaving an outwardly directed hydrophilic layer of molecules, might not prevent this ready cavitation. Accordingly, one of the water repellent varnish covered rods (5-mm diameter) was moved rapidly in water containing 0.5 percent aerosol OT (dioctyl sodium succinate). Cavitation appeared practically from the start of movement. It is very possible, however, that movement of the rod tears detergent molecules away from the surface, thereby exposing hydrophobic spots.

The bubble formation on the paraffined rod is very similar to that which is observed if the rod and tube have not been subjected to the cleaning and pressure treatment, i.e., if gas nuclei have not been removed. Again the first frame shows a fine mist of cavitation at the end of the rod, when the velocity may be only 3 meters/sec.

In some of the early experiments, where cleaning of glass surfaces involved soaking in cold concentrated sulphuric-bichromate mixtures only, and the tube was not protected from dust particles, cavitation occurred when the 5-mm rod had reached a high velocity. In one case, shown in Fig. 5, two small cavities appeared on the end of the rod at the 9th frame when the velocity was 18 meters per second. These enlarged until the 12th frame, when they disappeared, but reappeared on the 14th, 15th, and 16th frames. This periodic formation and disappearance of cavities is frequently observed during cavitation, and is particularly well seen in a Venturi nozzle. The sound during such Venturi cavitation is caused by periodic formation and collapse of cavities which were photographed by Hunsaker,[9] using the Edgerton high speed technique. In Fig. 6 are reproduced prints from a 2000 frames per second film of cavitation in a small glass Reynolds tube (a glass tube with an abruptly constricted region), taken with our Eastman high speed camera. The burst of cavitation is periodic although the rate of picture taking is not sufficient to follow the complete cycle.

As in the Reynolds tube, the periodic nature of cavitation below the rod is because of the fact that cavity formation relieves the tension in the water, with consequent collapse of the cavity; then further tension develops with cavity formation, followed again by collapse. The process is

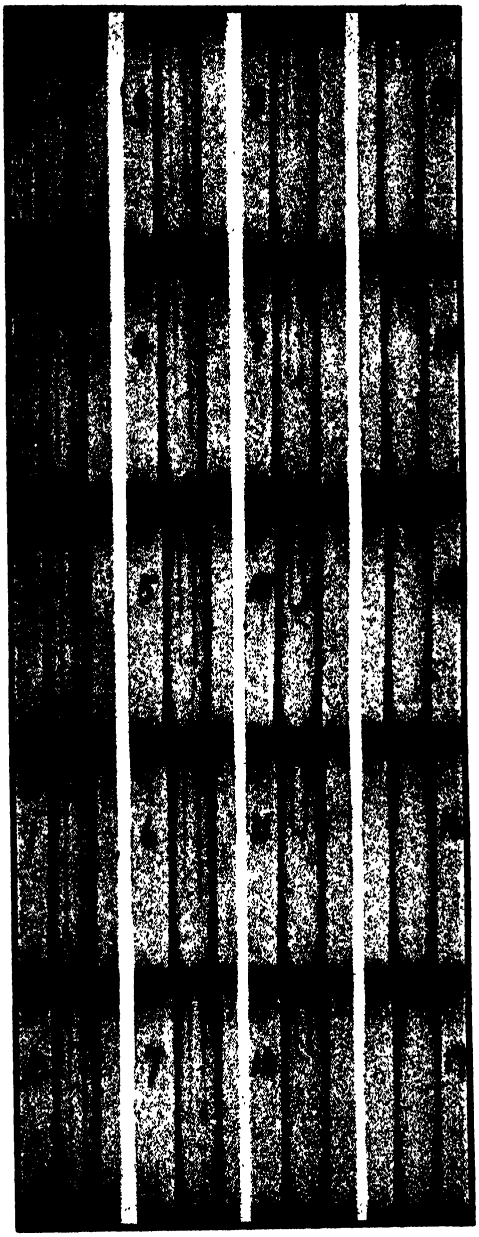

FIG. 5. Moving picture (2280 frames/sec.) of a 5-mm diameter glass rod moved through water in which cavitation first appeared (frame 9) when the velocity was 18 meters/sec. Note disappearance of cavitation in frames 12 and 13, with reappearance in frame 14. External diameter of tube 19.5 mm. Exp. 7-9-44.

[9] J. C. Hunsaker, Mech. Eng. 57, 211 (1935).

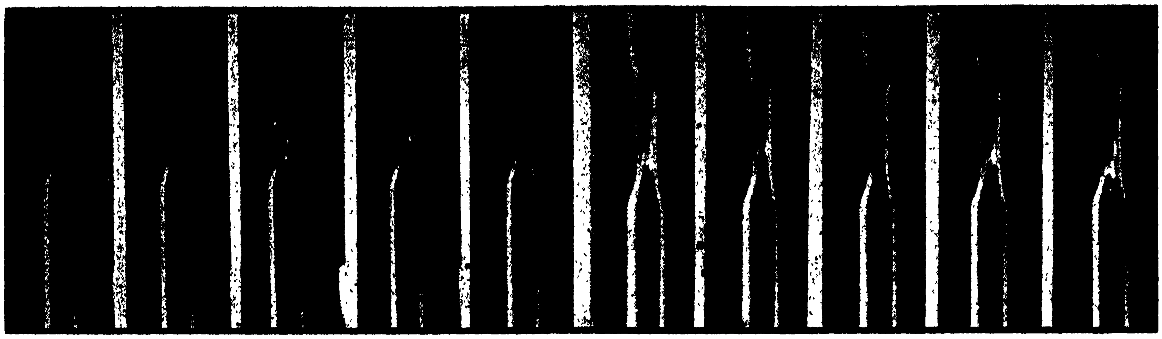

FIG. 6. Negative prints from a moving picture (1680 frames/sec.) showing cavitation in a Reynolds tube (8.3-mm large diameter) from flow (top to bottom) of water through a constriction. Note the periodic cavitation (white in appearance) which always begins at a particular spot on the narrow region of the tube.

repeated as long as the conditions for development of tension persist.

Whenever cavities appear under a rod, they are greatly disturbed by the turbulence and frequently look like a fine mist. If hydrophobic dust particles with air films have fallen into the pressurized water (or are purposely placed there) isolated bubbles may form at a distance from the rod, as shown in Fig. 7. The bubbles may appear almost immediately or after the rod has reached a certain speed. Sometimes they are attached to the wall and sometimes free in the tube. If near the rod, they may enter vortices at the end as the rod passes in the water, and a trail of misty cavitation will follow. Isolated bubbles are also observed to pulsate, appearing for several frames and then disappearing again, reflecting the periodic pressure changes in the tube.

In order to study the effect of viscosity, two 5-mm rods have been drawn from concentrated sugar solutions (Staley's crystal white syrup) at a temperature of 23°C, where the syrup viscosity is 20.1 poises, as compared with a viscosity of 0.00936 poise for water at 23°C. Density of the syrup is 1.383 at 20°C. One rod was of glass and one of aluminum. Since aluminum tends to dissolve in water, this rod might contain films of hydrogen which could not be removed by prepressurization. However, when tested at the vapor pressure of water, the aluminum rod was found to contain no gas nuclei that grew to bubbles. The moving picture film, reproduced in Fig. 8A showed that at the very start of movement (1st frame) several minute cavities appeared at the end and side of the rod and in succeeding frames grew into a long cylindrical cavity the width of which remained approximately that of the rod. Finger-like processes reflecting the initial cavities were present at the lower end where rod movement starts. The cylindrical cavity remained static during the movement of the rod out of the syrup and then started to collapse (Fig. 8B). The collapse occurred along the long axis of the tube from top down, not from side to side, and proceeded at a uniform speed of 940 cm/sec. It was as if the rod had left an impression of itself in the syrup. When the collapse finally occurred, several smaller cavities appeared and oscillated several times before subsiding. The glass rod drawn from the syrup behaved in a similar way, but lacked the several fingers at the tip of the cavity, only one cavity tip appearing.

However, in two experiments, glass rods 5 mm in diameter, moved in 75 percent syrup at temperatures of 25°C and 27°C, failed to cause the development of a cavity, although their velocity reached 18 meters/sec. The viscosity of 75 percent syrup at 25°C is 0.56 poise. There was also no cavitation in citrated cat blood plasma at 18 meters/sec. The viscosity of plasma is only slightly greater than water.

Since the 5-mm rods failed to cavitate in clean pressurized water at the highest velocity (37 meters/sec.) attainable with the steel bow, 10 mm diameter rods were substituted. Both because of the greater cross-sectional surface area at the end of the rod and the greater suction effect in the glass tube, a much greater tension is to be expected for a given speed. In three experiments, 10-mm diameter glass rods, the ends of which had been polished with rouge and cleaned thoroughly by the procedure previously described, were moved through centrifuged water at a maximum speed of 24 meters/sec.[10] In all three cases, cavitation occurred somewhere in the tube. In one experiment cavitation appeared at the end of the rod when the velocity was 16 meters/sec. In another, an isolated bubble formed below and at a distance from the rod in the first frame, followed by additional bubbles when the velocity was 21 meters/sec., as shown in Fig. 9. The first isolated bubble expanded to a large size and later collapsed so suddenly that the glass tube was broken by the water hammer effect. Cavitation may thus appear at the end of the rod despite the presence of a large bubble cavity in the tube. In the third experiment no cavitation formed on the end of the rod, but after the rod had attained its maximum velocity of 24 meters/sec. and disappeared from the camera field of view, bubbles appeared and expanded into a large cavity, the collapse of which again broke the glass tube.

## DISCUSSION

In the three experiments with a 10-mm diameter glass rod, despite rigorous cleaning, high hydrostatic pressure treatment, and every precaution to remove and protect from hydrophobic dust particles, cavitation occurred at some point in the tube before the maximum velocity of 24 meters per second was reached. The suction of the 10-mm rod in the 16-mm glass tube must have been considerable, as evidenced by the large size of cavity, but no figures for the tension can be given until the problem of calculation is solved. It is possible that in the short time intervals involved, negative pressures of the order of 100 atmospheres are developed. The experiments are described in detail, because of the interesting phenomena involved, which could only be detected by the high speed photographic technique.

In most experiments by other workers on cavitation at the surface of moving bodies, the water has not been freed of gas nuclei and cavitation occurs at a relatively low velocity. It is therefore of considerable interest to find that in the case of experiments with the 5-mm diameter rod moving in a 16-mm tube, the velocity reached

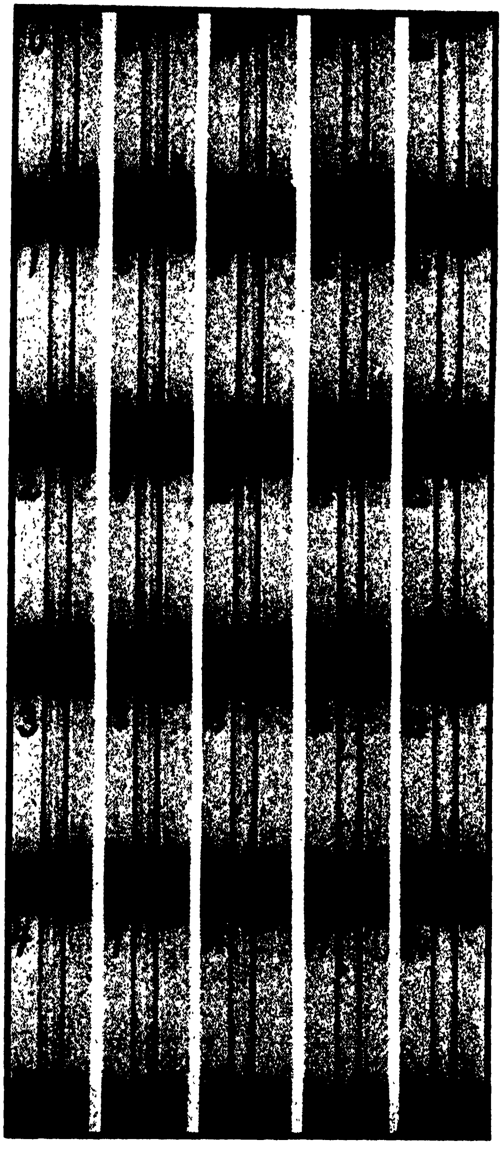

FIG. 7. Moving picture (2160 frames/sec.) of a 5-mm diameter glass rod moving in water at a maximum speed of 16 meters a second. No cavitation appears on the end of the rod until frame 18 but in earlier frames (1, 8, 10) bubbles form away from the rod and grow in size. They probably come from hydrophobic dust particles, as the Cellophane protective covering of the tube was not used in this experiment. Scale in centimeters. Exp. 9-2-44.

---

[10] This rod, which weighed 53.3 grams, when moved with the steel bow in air, attained a maximum speed of 26 meters/sec.

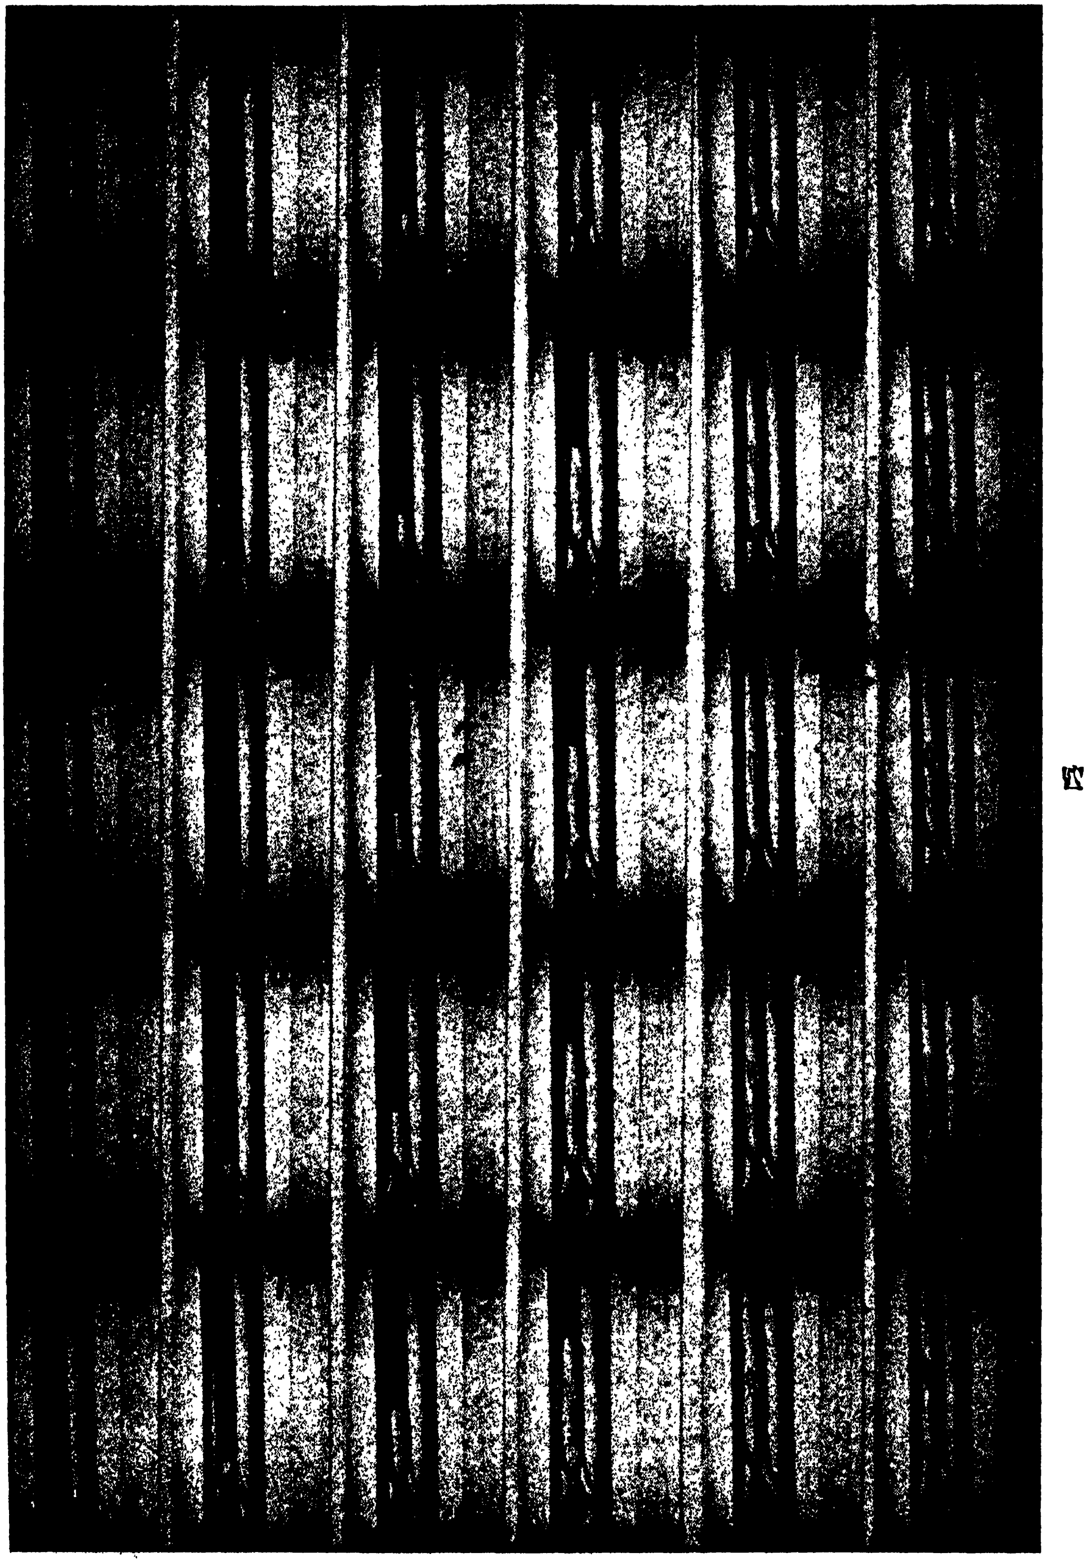

FIG. 8. A and B. Moving pictures of a 5-mm diameter aluminum rod moving in gas nucleus-free corn syrup (viscosity, 20.1 poises; density, 1.383; temperature 23°C) at a maximum speed of 12.2 meters per second. Since the high viscosity of the syrup prevents its filling the space behind the rod, a large

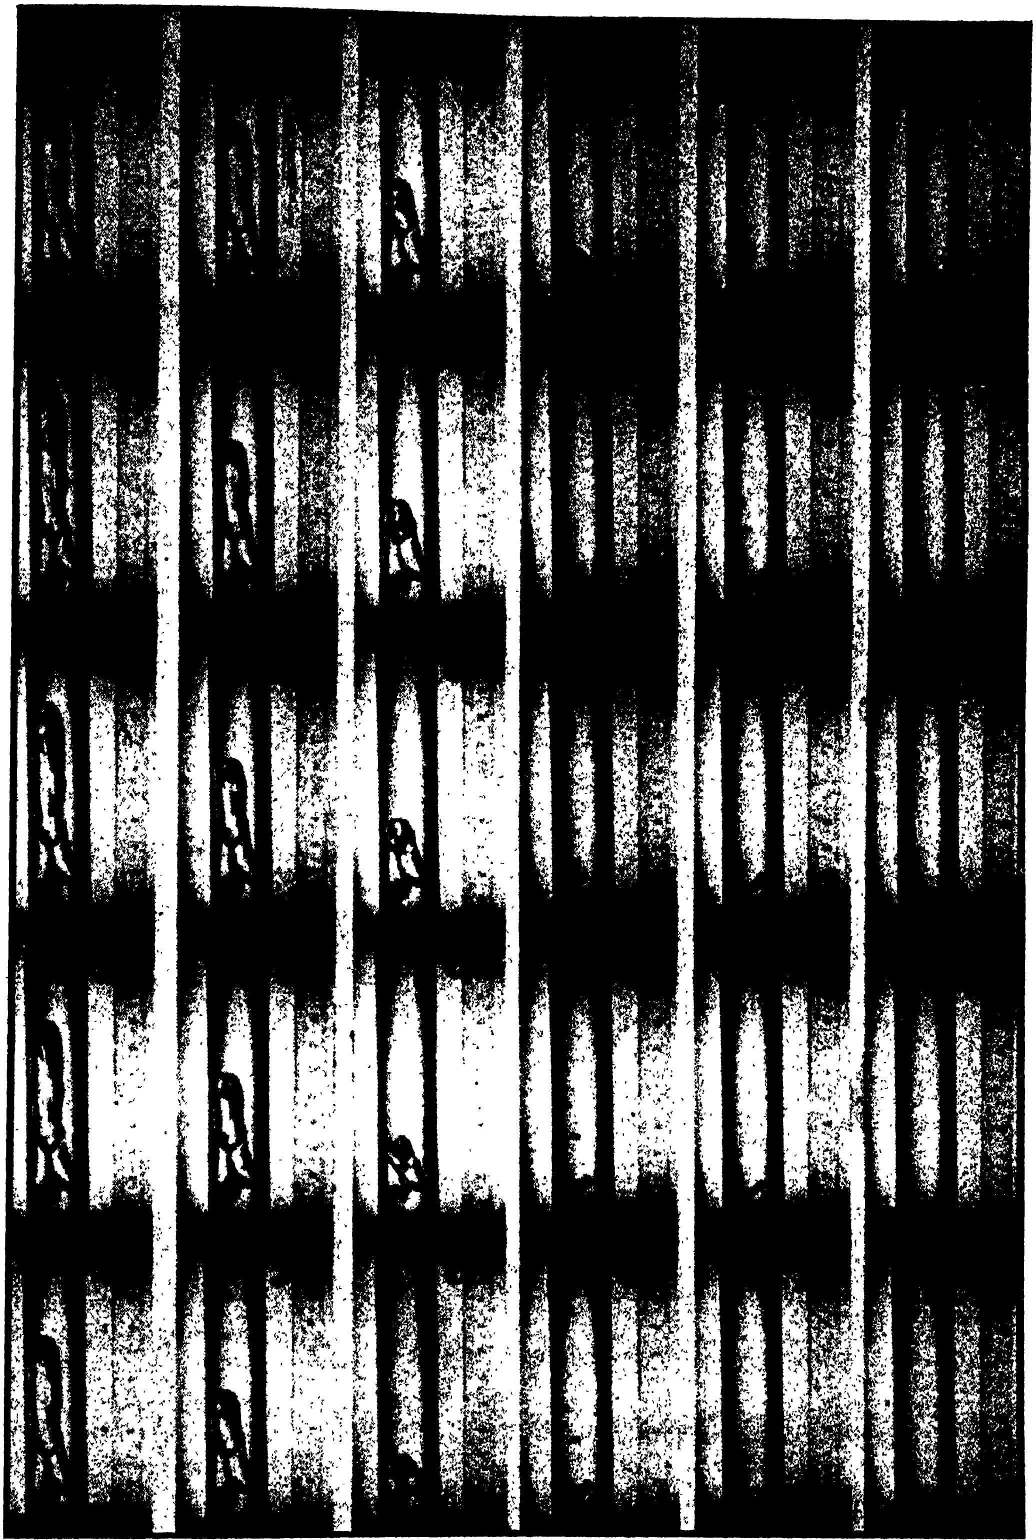

cavity forms from a number of initial points which remain as fingers. In B the collapse of the cavity is shown, beginning with frame 50. Note that collapse is from above downward and that the remnants of the cavity disappear in frame 74 and then reappear again. They oscillate several times before subsiding. Scale in centimeters. Exp. 8-23-44.

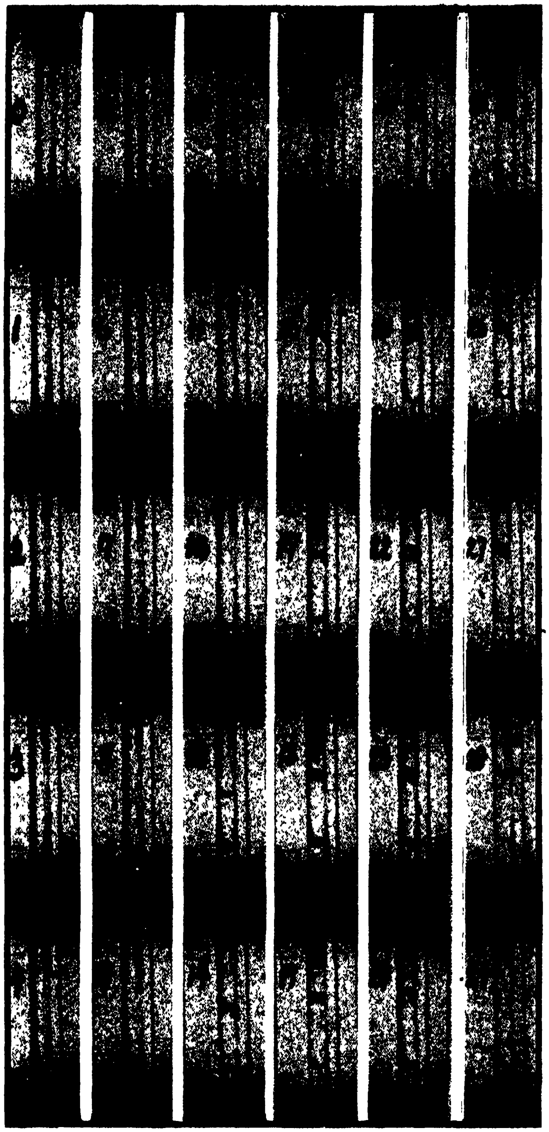

FIG. 9. Moving picture of a 10-mm diameter glass rod, moving in a 16-mm internal diameter tube containing gas nucleus-free water with a maximum speed of 23.2 meters/sec. Note that no cavitation forms on the end of the rod until frame 15 (speed 23.2 meters/sec.) but that a bubble appears below the rod in frame 1 (speed less than 3 meters/sec.) and grows into a large cavity. Bubbles also appear below the rod in frame 13 (speed 21 meters/sec.) and then grow into a mist of cavitation. Collapse of the large cavities broke the glass tube. The two horizontal lines are 10 cm apart. Exp. 12-21-44.

37 meters per second without cavitation appearing anywhere, even at the rear of the rod. This velocity can be better compared with other speeds in water if converted into the English system when it becomes about 83 miles an hour, or 1.38 miles a minute, truly a remarkable figure for cavitationless motion in a liquid medium.

## SUMMARY

Phenomena involving the tensile strength of water have been studied by a kinetic method—high speed motion photography of the rapid movement of a blunt glass rod in a narrow (16-mm inside diameter) glass tube of water.

Special precautions have been taken to remove all hydrophobic patches and small gas masses (gas nuclei) but to retain the dissolved gas (air at one atmosphere) in the water.

If the rod (5-mm diameter) surface contained gas nuclei, or was hydrophobic and free of gas nuclei, cavitation occurred at the rear end when the velocity was less than 3 meters/sec., but if completely hydrophilic and free of gas nuclei, the velocity could be 37 meters/sec. or 83 miles/hour without cavitation.

When improperly cleaned rods (5-mm diameter) were used, isolated cavities formed at intermediate velocities. These cavities appeared and disappeared as the rod movement proceeded, in a manner similar to the periodic cavitation in a Reynolds tube.

Addition of a detergent (diactyl sodium succinate) to the water did not prevent cavitation at a low velocity with the hydrophobic rod (5-mm diameter) free of gas nuclei.

Movement of a rod (5-mm diameter) in pure corn syrup (viscosity 20.1 poises), free of gas nuclei, left a large cylindrical cavity that collapsed in a matter of hundredths of a second. In 75 percent corn syrup (viscosity 0.56 poise) no cavitation occurred.

Large glass rods (10-mm diameter) could not be moved more than 24 meters/sec. within a glass tube (16-mm internal diameter) containing clean gas-nucleus free water without the appearance of cavitation at some place in the liquid, though not necessarily at the end of the rod.

It is not possible to calculate the tensions developed in these "leaky piston" experiments but it may be pointed out that the velocities attained without cavitation are far higher than previously observed for movement of bodies in an aqueous medium, a result believed to be owing to the absence of all gas phases and hydrophobic surfaces.

# A New Magnetic Material of High Permeability

O. L. Boothby and R. M. Bozorth
*Bell Telephone Laboratories, Murray Hill, New Jersey*

(Received November 18, 1946)

This paper describes the preparation, heat treatment, and properties of *supermalloy*, a magnetic alloy of iron, nickel, and molybdenum. In the form of 0.014 in. sheet it has an initial permeability of 50,000 to 150,000, a maximum permeability of 600,000 to 1,200,000, coercive force of 0.002 to 0.005 oersted, and a hysteresis loss of less than 5 ergs/cm$^3$/cycle at $B=5000$. Transformer cores made of insulated 0.001 in. tape, spirally wound, have about the same initial permeability and a maximum permeability of 200,000 to 400,000. The alloy has a Curie point of 400°C and appears to have an order-disorder transformation temperature somewhat above 500°C.

DURING the last few years a magnetic alloy has been made in these laboratories that has an initial permeability several times as high as that of molybdenum permalloy and mumetal, alloys now in general use. The new material has been named "supermalloy" (su-perm′-al-loy). Its preparation, heat treatment, and properties are described briefly in this article. It has already been made in considerable quantities for use in apparatus supplied to the U. S. Navy. When in the form of 0.001 in. insulated tape, used in transformer cores, it has an initial permeability of 50,000 to 120,000; this is to be compared to molybdenum permalloy of the same thickness, having an initial permeability in the range 10,000 to 20,000. The use of supermalloy in communication transformers permits a threefold increase in the range of frequencies transmitted, and a pulse duration three times that heretofore obtained.

Supermalloy constitutes the latest step in the development of the high nickel alloys for use at low inductions. The important previous steps are shown graphically in Fig. 1, where the initial permeability is plotted on a logarithmic scale against the year of discovery.

It is interesting to mention briefly the novelty of each of these steps, regarding them in the light of present day knowledge and theory. The addition of silicon to iron, by Hadfield, neutralized partially the bad effect of the carbon always present as an impurity. The high permeability of the iron-nickel alloys, discovered by Elmen,[1] is attributed primarily to their low magnetostriction, as pointed out by McKeehan.[2] The next improvement, due to rapid cooling or "permalloy treatment," is now believed to be associated with the atomic ordering of iron and nickel atoms in the alloy. The addition[3] of one or more elements such as chromium, molybdenum, and copper, lowered the optimum cooling rate so that it could easily be attained in practice. In Neumann's 1040 alloy[4] the beneficial effect of purification of the material with respect to non-

metallic substances such as carbon and oxygen, as developed by Yensen,[5] Cioffi,[6] and others, was also used to advantage.

Although the physical reasons for the success of the supermalloy process are still not known in detail, the work so far accomplished indicates that there are two main considerations: (1) the presence of certain impurities or combinations of impurities, usually found in commercial alloys, will prevent the attainment of high permeability following the procedure now used; and (2) a definite cooling rate must be used below the temperature at which atomic ordering begins, or the specimen must be held for a definite time at a temperature between about 400 and 500°C. The hypothesis is made that, when a critical amount of ordering is present, the magnetostriction and the magnetic crystal anisotropy both tend to disappear at the same time in the alloy of proper composition and that high permeability then occurs in the polycrystalline material. These properties are now under investigation.

## PREPARATION AND HEAT TREATMENT

The composition of supermalloy is about 79 percent nickel, 5 percent molybdenum, 15 percent iron, and 0.5 percent manganese. Impurities such as silicon, carbon, sulfur, etc., are lower than in most commercial alloys. Materials are melted in vacuum in an induction furnace of about 30 lbs. capacity, and poured in helium or nitrogen at atmospheric pressure.

Ingots are hot and cold rolled by commercial methods to any thickness down to 0.00025 in. The tape is wound spirally to form toroidal specimens. When insulation is desired a thin film of magnesia is applied in carbon tetrachloride suspension so that a film about 0.00005 in. in thickness is left on each side of the tape. Trans-

former cores are made in this manner. Heat treatment consists of maintaining at 1300°C in pure dry hydrogen, and cooling through the temperature range 600° to 300°C at a critical rate appropriate to the composition.

## PROPERTIES

Magnetic properties are given for (a) 0.014 in. uninsulated and (b) 0.001 in. insulated material. Magnetization curves of the former are compared, in Figs. 2 and 3, with curves of molybdenum permalloy and iron. The ratio of permeabilities of supermalloy and molybdenum permalloy varies with induction from about 5 at $B=20$ to about 10 at $B=3000$ (maximum permeability). At inductions of 7000 to 8000 the permeability of supermalloy has decreased markedly and is less than that of molybdenum permalloy or iron; saturation is at $B_s=7900$. Figure 4 shows typical permeability *vs.* induction curves for supermalloy, molybdenum permalloy, and iron.

The permeability in very low fields is shown in Fig. 5 for a representative specimen of supermalloy, and for materials previously known. Finally, hysteresis loops for supermalloy and molybdenum permalloy are shown in Fig. 6.

When thin tape is *insulated* before heat treatment, the permeability in low fields is affected but slightly. However, the curves of Fig. 7 indicate that the maximum permeability of 0.001 in. insulated tape is considerably lower than that of thicker tape. Insulated 0.004 in. tape has a maximum permeability about twice as large as that of insulated 0.001 in. tape; its permeability is therefore intermediate between the 0.001 in.

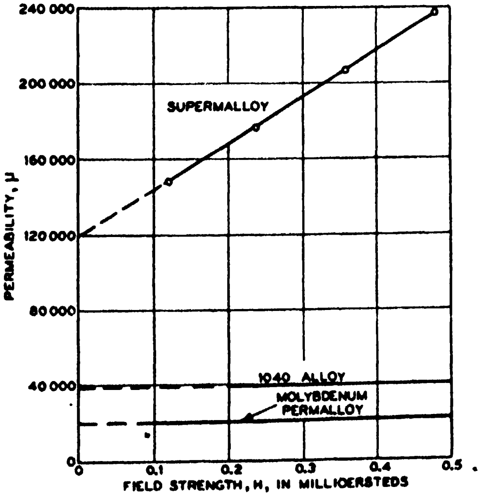

FIG. 5. Permeability *vs.* field strength curves for low fields, for representative specimens of 0.014 in. sheet of three materials of high permeability.

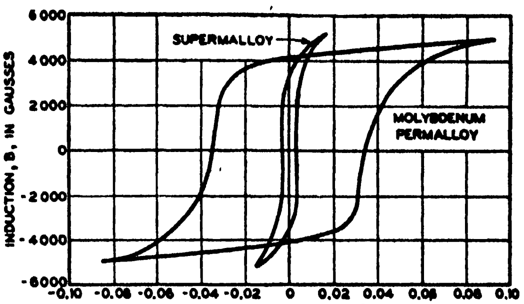

FIG. 6. Hysteresis loops of supermalloy (5 ergs/cm$^3$/cycle) and molybdenum permalloy (50 ergs/cm$^3$/cycle) for $B_m=5000$, in 0.014 in. sheet.

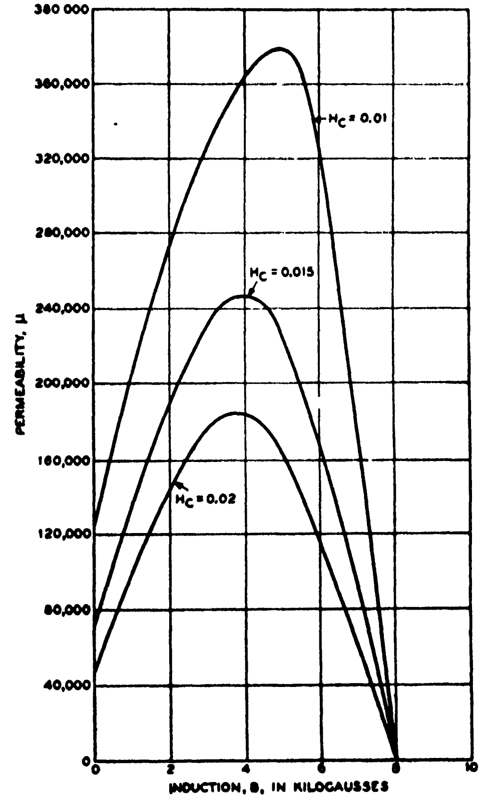

FIG. 7. Representative permeability curves for good, average, and marginal specimens of supermalloy made from insulated 0.001 in. tape.

insulated and the 0.014 in. uninsulated tape. The middle curve of Fig. 7 is near to the average of a lot of several thousand cores of 0.001 in. tape, made in the early stages of development of the material.

The resistivity of supermalloy is about 65 microhm-cm.

The high permeability of supermalloy opens the way toward further improvements in transformers operating at frequencies common in communication engineering, in much the same way that the various permalloys led to the improvements described a decade ago.[7]

We are indebted for cooperation and assistance to many members of the Laboratories and the Western Electric Company. Messrs. D. H. W. Wenny and H. C. Theuerer should be specially mentioned for helping to solve many of the metallurgical problems connected with the development of the material.

# Apparatus and Techniques for Practical Chemical Identification by X-Ray Diffraction

CHARLES S. SMITH, *Department of Physics, Case School of Applied Science*

AND

RICHARD L. BARRETT,* *Department of Mineralogy and Geology, Case School of Applied Science, Cleveland, Ohio*

(Received August 30, 1946)

The method of chemical identification by means of x-ray diffraction is reviewed from the point of view of apparatus and techniques recently made commonly available, with particular emphasis on the use of long wave-length x-radiation. Experience in using the A.S.T.M. card index file of x-ray diffraction data is reported. The discussion is designed especially for the person who wishes to make use of this important analysis tool but who is not an expert in x-ray diffraction.

## I. INTRODUCTION

WHEN Hull in 1919 described the powder method of x-ray diffraction, he observed that the method should be a potent tool for the identification of crystalline substances. Hull pointed out, "That every crystalline substance gives a pattern; that the same substance always gives the same pattern; and that in a mixture of substances, each produces its pattern independently of the other, so that the photograph obtained with a mixture is the superimposed sum of photographs that would be obtained by exposing each of the components separately for the same length of time."[1] The new method immediately began to be used by mineralogists and chemists but at first its usefulness was limited by the fact that standard patterns of known substances were needed for comparison. In 1938 Hanawalt[2] and some of his co-workers at the Dow Chemical Company published tables giving the diffraction patterns of 1000 substances and showed that the data could be indexed in such a way that the identity of any listed substance could usually be found by reference to the three strongest lines in its diffraction pattern. The availability of this table of standard patterns, including as it did most of the more important inorganic compounds, made x-ray diffraction a practical means of quick identification of an unknown substance. Following Hanawalt's publication the American Society for Testing Materials made available a card index comprising the substances he had listed plus additional ones obtained from other sources and arranged essentially according to the indexing system suggested in his paper. More recently the A.S.T.M. has issued a supplementary set of cards greatly amplifying the scope of the index so that it now includes some 3000 substances. This card index, which makes available in useful form the patterns of the commoner inorganic salts, most of the important minerals, and even many organic substances, enables the x-ray diffraction method to take its place along with the spectroscope and the polarizing microscope among the potent physical tools for chemical research.

In his 1938 paper Hanawalt described in detail the technique used in the Dow Chemical Laboratories and his co-workers and others have amplified the description in subsequent papers.[3-5] The Dow technique employs molybdenum radiation, large radius quadrant cameras, and a multiple diffraction unit which permits the exposure of 24 samples simultaneously. It is perhaps particularly adapted to large industrial laboratories where considerable numbers of samples are being run on a day to day basis. However exposures of some six hours are required and the particular apparatus used is no longer being manufactured.

In the last several years the writers have had occasion to examine a considerable number of

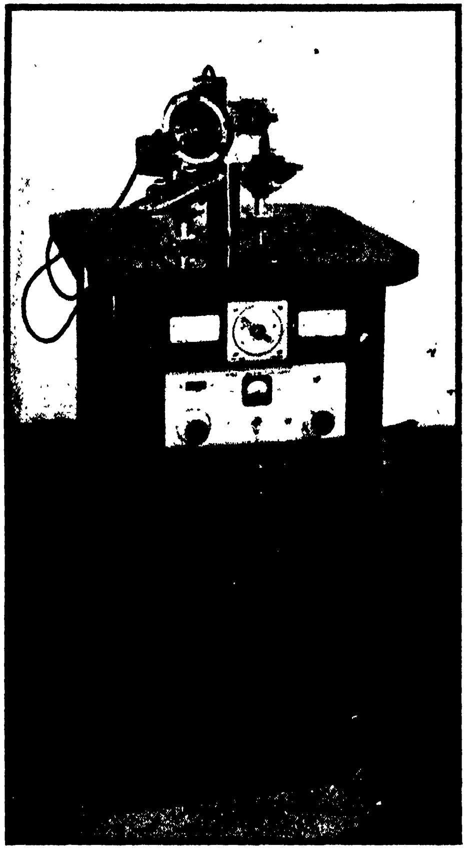

FIG. 1. An example of a modern self-contained x-ray diffraction outfit (Courtesy of the Picker X-Ray Corporation).

industrial samples and, in common with many other workers in x-ray diffraction, have come to prefer a somewhat different technique employing a smaller radius camera of the full circle type, and copper, iron, cobalt, or chromium radiation which makes possible satisfactory resolution of lines with the small camera. Although numerous papers have been published describing details of camera design, special methods of sample preparation, improvements in x-ray tubes, etc., the chemist or mineralogist who is not himself an x-ray specialist has remained dependent for a general treatment of the subject upon the papers of Hanawalt and his co-workers. It is the purpose of the present writers to describe for the nonspecialist the practical considerations involved in modern x-ray methods, employing the more modern apparatus now available commercially. While in a general way the technique to be described will be familiar to x-ray crystallographers some details based upon the writers' experience may be new and it is hoped that the present paper may be helpful to chemists and technologists who have not previously employed x-ray diffraction in taking advantage of this extremely useful tool.

In what follows it will be assumed that the reader has a general knowledge of the physics of x-rays and of x-ray diffraction such as may be obtained in a standard text.[6] It is also assumed that the reader is familiar with the general method of x-ray diffraction chemical identification as presented in the 1938 paper of Hanawalt.

## II. APPARATUS

In the past ten years a number of manufacturers have introduced lines of x-ray diffraction equipment built around the recent American development of efficient diffraction tubes, particularly those with long wave-length targets. In general this equipment is excellent and our intention here is to point out only the practical details in choosing equipment for chemical identification work. The writers' own experience has been in a laboratory primarily devoted to instruction and research and they accordingly have had the benefit of a variety of versatile equipment. They have found it best however to do most chemical identification work with the standard forms of commercial apparatus, employing the available research apparatus only on the rare problems of a difficult or special nature. It is certain that the laboratory doing routine problems will do well to standardize on convenient commercial apparatus chosen for the particular field of identification involved.

### Power Supplies

The available commercial power supplies are designed for use with a particular manufacturer's tube, Fig. 1, and are all uniformly good, incorporating the necessary electrical controls, high voltage, and x-ray protection for the operator and water and electrical failure protection for the apparatus. For identification work alone x-ray tubes of all types can be run at 40 kv and hence the high potential controls are strictly unneces-

---

[6] A new book which presents an excellent treatment is C. S. Barrett, *Structure of Metals* (McGraw-Hill Book Company, Inc., New York, 1943).

sary. Full wave rectification is desirable, and half-wave rectification somewhat less so but neither is necessary. The writers have used for some time a homemade power supply which merits description not because of its originality but because it emphasizes how simple and convenient such equipment can be.

The apparatus employs a ray proofed diffraction tube mounted horizontally on a wide, high wood table. Screens are provided for high voltage protection, but these would be unnecessary were the tube also shockproof and equipped with a shockproof cable. The electrical apparatus consists simply of a high voltage transformer and a filament transformer (both the usual secondhand radiographic equipment), a Variac, millimeter, and voltmeter. The high voltage transformer has a 35-kv secondary and is powered directly from the a.c. line through an ordinary toggle switch which is the only high voltage control. The transformer is located under the table and is protected, the high potential being led by a shielded cable to the tube through the millimeter. The tube filament is powered and controlled by the sequence, a.c. line, Variac, filament transformer. The latter is mounted on the table at the screened cathode end of the tube and supports the filament voltmeter and the milliameter. The cooling water for the tube is carried by Saran tubing, and is run off through a small standpipe in which is immersed a one-ampere fuse which carries the primary current for the high voltage transformer. This water fuse has been effective protection against water or memory failure. The whole outfit is obviously inexpensive, it is simple in its controls, two switches and a Variac; and the horizontal mounting of the tube and the large table area has permitted the easy use of a variety of x-ray cameras.

## Tubes

It has already been mentioned that diffraction apparatus is built around the tube that is used. The diffraction tube is therefore the item on which the choice of apparatus turns and while most features of diffraction tubes, such as a line focus, two or four radiation ports, rated voltage and current, etc., are now standard, there are a few features which vary among tubes and which should be considered in choosing apparatus for chemical identification. Chief among these are window material, effective tube radius, and target material. The first two items determine the x-ray intensity available at the camera, and the choice of the third is influenced by the field of the identification work.

At the present time Lindemann glass and beryllium are used for x-ray tube windows. For Mo target tubes ($\lambda = 0.71$ kX) the difference between these two window materials is not important because the transmission of either is near to one. These window materials were developed for the softer radiation from targets of Cu ($\lambda = 1.54$ kX), Co ($\lambda = 1.79$ kX), Fe ($\lambda = 1.93$ kX) and Cr ($\lambda = 2.29$ kX) where x-ray transmission is inherently low especially with Cr, and here the difference between the two materials is significant, the advantage being with the beryllium.[7]

The effective radius of an x-ray diffraction tube should be as small as possible because one deals always with an inverse square law of radiation intensity. The effective radius is determined by how close one can place the diffraction camera to the center of the tube focal spot. Beryllium window tubes enjoy two advantages here: the camera can be placed in contact with the window if desired, and the window can be placed close to the target, beryllium being a good thermal and electrical conductor.

It has been indicated that the writers have found it advantageous to use characteristic radiations other than the Mo$K\alpha$ recommended by the A.S.T.M. practice.[8] Radiations such as Cr, Fe, Co, and particularly Cu have long been used extensively by crystallographers and metallurgists and now that high intensity tubes with these targets are available in this country, their use in identification problems has become more common. These radiations are all much longer wave-length than Mo, and the choice of the particular one to use will depend strongly on the fluorescence considerations discussed below. Because Cu targets can be safely loaded to higher values than Cr, Fe, and Co targets, Cu-radiation is by far the most commonly used of the group

---

[7] R. R. Machlett, J. App. Phys. 13, 398–401 (1942).

[8] "Tentative Recommended Practice for Identification of Crystalline Materials by Hanawalt X-ray Diffraction Method," A.S.T.M., Philadelphia, Pennsylvania, 1942.

in crystallography and in our own practice. The advantages of long wave-length radiation will therefore be discussed in terms of Cu$K\alpha$; the same remarks will apply to the other radiations with minor changes.

An important advantage of Cu-radiation is the short exposure time required. There are several obvious factors such as necessary camera diameter and film sensitivity which greatly favor Cu-radiation in this respect, but there are also a number of less obvious and equally important factors some of which favor short wave-length radiation. We shall not try to assign a reason therefore but merely state the well known empirical result that for equal dispersion and resolution, a 15-minute Cu exposure is equivalent to one of several hours with Mo-radiation. Such short exposures have made it possible for the writers to supply useful answers to identification problems when the longer exposure would have been prohibitive, and it would seem that workers closer to industrial problems would very frequently find short exposure an advantage.

Since the wave-length of Cu$K\alpha$ is approximately twice that of Mo$K\alpha$ much greater angular dispersion results, the diffraction pattern of most materials being spread through the full 90° range of Bragg angle in contrast to the range of $\theta$ of from 0 to 30° found with Mo$K\alpha$. This fact may be used to help shorten exposures through decreased camera diameter as noted above, or the large dispersion of long wave-length radiation may be used for better observation of those $d$ values lying in the range from 3 to 8 kX. Many materials, especially mineralogical and organic materials, have strong lines, and what is important, discriminating lines, in this region. The writers have found that this $d$ region is indeed a critical one and merits close attention.

In chemical identification work it is seldom necessary to resort to precision determination of $d$ values or lattice parameters. Some specialized problems however are profitably studied by such determinations which are not particularly difficult to make by means of well-known back reflection methods. Back reflection methods necessarily employ long wave-length radiation.

These factors influence us strongly to the use of long wave-length radiation and it is apparent from the availability of the equipment that other workers are so influenced also. There are disadvantages in the use of long wave-length radiation, notably the fluorescence difficulty and the fact that much existing data lists intensities in terms of Mo-radiation. The effect of these difficulties will be discussed, but we are left with a strong preference for long wave-length, and particularly for Cu-radiation, the most generally useful of all.

The fluorescence difficulty may be stated as follows: the characteristic radiation from a given target in the long wave-length group (wave-lengths listed above) is capable of exciting $K$ fluorescence in specimen atoms which have an atomic number less than that of the target by two or more. The resulting $K$ fluorescence radiation ($L$ fluorescence is seldom troublesome) produces a general background on the diffraction pattern which is exceedingly strong if the specimen contains a substantial portion of material located 2, 3, or 4 places below the target material in atomic number. Fluorescence may thus involve an important group of elements, e.g., Co, Fe, and Mn in the case of a Cu target tube, and Mo-radiation possesses the advantage that few important elements are located immediately below Mo in the atomic number.

It is evident then that the choice of the particular long wave-length radiation must be made with the field of the identification work in mind. Thus metallurgists dealing exclusively with ordinary steels use Co- or Fe-radiations; those dealing with high alloy steels would be well advised to use Cr-radiation; chemists concerned only with iron corrosion products should use Co- or Fe-radiation. The person confronted with materials which range the periodic table will find, however, that Cu-radiation is the most generally useful, the number of problems involving Co, Fe, and Mn in such a case being statistically not too numerous, and these problems being susceptible to techniques pointed out below.

The ideal solution in the general case for the fluorescence difficulty is to have available a choice of long wave-length tubes. The writers have fallen back on this expedient upon occasion, but most frequently they actually have found it more convenient to use Cu-radiation and to accept the fluorescence background. The reasons for this procedure may be discussed in terms of Cu-radiation and a specimen known to contain Fe. Four cases arise depending on whether the material is single phase or polyphase, and on whether the phases are simple or complex crystallographically. A single simple phase such as Fe or FeO being high in Fe will produce strong fluorescence when exposed to Cu-radiation, but being simple, it will in general produce a strong diffraction pattern, and we have found such patterns easily identifiable in spite of the background. The same remark applies to a lesser degree to a polyphase mixture of simple materials. Single phase specimens involving crystallographically complex materials will in general give a weak diffraction pattern, but also in general the proportion of Fe and hence the fluorescence will be low. Polyphase and crystallographically complex materials will usually be difficult, and so, of course, would be the detection of any minor phase in the presence of a high Fe major phase. In the Cu-Fe situation and in similar situations the fluorescence background can be reduced by the use of filters discussed below, but this technique is not nearly so effective as when the fluorescence is caused by elements considerably below the target element in atomic number.

Elements five places or more below the target element also produce fluorescence, but in this case the excitation is not nearly so strong, and since the fluorescence wave-length is considerably longer than that of the target radiation, it can be effectively filtered out of the radiation striking the film. Filtration can be effected by placing between the sample and the film sheets of aluminum or better still, sheets of the $K\beta$ filter appropriate to the radiation used. In this manner identifiable patterns of $MnO_2$, and excellent patterns of $TiO_2$ can be made with Cu-radiation. Because fluorescence radiation may be excited by radiation from the tube other than the characteristic radiation which creates the diffraction pattern, the use of the $K\beta$ filter in this fashion is generally desirable and should be standard practice. Since the filter used in this way should not be in contact with the film and because filter materials are difficult to handle, some sort of jig or other holding device is desirable. It would be helpful if camera manufacturers built in such devices in the future.

### Filters

The purpose of the $K\beta$ filter is to reduce to a negligible amount the intensity of the characteristic and monochromatic $K\beta$-radiation relative to the intensity of the $K\alpha$-radiation of the target element. In the case of the long wave-length targets this can be done by inserting in the x-ray beam a filter composed predominantly of the element one lower in atomic number than the target element; for Mo-radiation a proper filter is Zr. Such filters may be the proper pure element and in the case of Ni for Cu-radiation this is convenient[9] but in the case of other $K\beta$ filters the active element is more easily used in the form of a compound. Such filters made with the proper concentration of active elements are now available in any desired size.[10] The filter will serve its designed purpose when a small piece is inserted in the primary x-ray beam, but as indicated above, the $K\beta$ filter will in addition act as a fluorescence filter when introduced in the proper sized sheet between the film and the specimen. Since the $K\beta$ filter does not eliminate the $K\beta$-radiation but merely reduces it relative to the $K\alpha$-radiation, the identification worker will do well to assess its effectiveness by making long exposure trial patterns of a simple substance.

### Camera Design

At the Dow Chemical Laboratories quarter-circle cameras of 8-inch radius are used on an apparatus which permits exposing 24 samples at one time. However the exposure time runs about six hours. Where molybdenum radiation is used, the quarter-circle camera gives all of the pattern that is useful for identification purposes. With longer wave-length radiation, it is profitable to employ a full circle camera which permits recording of back reflection lines and gives a symmetrical pattern which doubles the accuracy of measurement of the angle $\theta$.

Cameras of the full circle type are commerci-

---

[9] Nickel foil of the proper thickness (0.0004 in.) may be obtained from the General Electric X-ray Corporation.

[10] Manufactured by the Patterson Screen Company, Towanda, Pennsylvania, and available through representatives of the leading x-ray apparatus manufacturers.

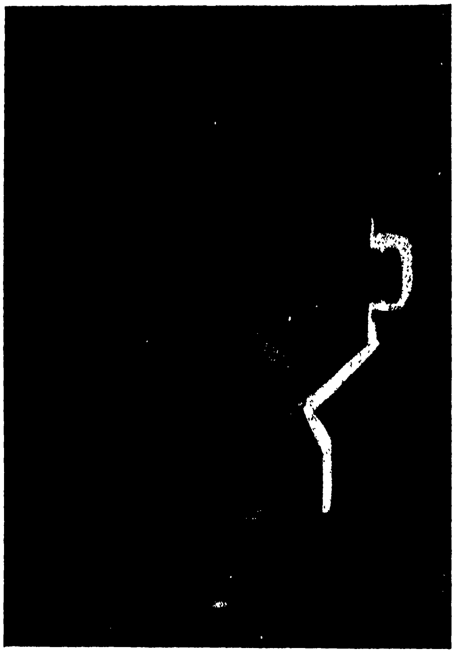

FIG. 2. An example of an x-ray diffraction camera particularly suitable for identification work. The collimating system is entirely within the camera. Two desirable features shown are the specimen centering device and the primary x-ray beam outlet shield (Courtesy of Otto von der Heyde, Newton Highlands, Massachusetts).

ally available from several of the manufacturers of x-ray equipment and also from some of the independent instrument makers. These cameras differ among themselves in a number of details, and the purchaser of new x-ray equipment will do well to investigate a number of makes with a view to getting the most suitable equipment for his purpose. The design of powder cameras for general use has been extensively treated recently in an excellent paper in this journal.[11] We shall mention here points particularly pertinent in chemical identification.

The diameter of the camera should preferably be some integer multiple of 57.26 mm in order that linear measurement on the film will be easily convertible to angular measurement in degrees. This greatly reduces the amount of routine calculation in determining *d* values. The writers have used a camera of 57.26-mm diameter with considerable satisfaction and have found it to give sufficient accuracy for most routine identification work. With copper radiation, exposures run from 10 to 20 minutes. However, we are of the opinion that if only one camera is to be purchased and speed is not too important a consideration, it would be best to select one of 114.52-mm diameter. This camera size used with copper radiation permits somewhat greater accuracy of measurement than the large radius quadrant cameras employed by Hanawalt when used with molybdenum radiation. By using the back reflection lines, lattice parameters for cubic crystals can be calculated with considerable precision. At the same time exposure times are not unduly large. Cameras of still greater size may be useful on occasion, but should not be needed for routine identification work.

Some provision for rotating the sample during exposure is made on practically all modern cameras. The purpose of sample rotation is to increase effectively the randomicity of crystalline orientations in the specimen. In the case of large grained, difficult-to-grind specimens, rotation saves much time and labor. The writers prefer the type of apparatus for rotation with a belt driven pulley attached to the sample holder rather than the built-in motor type. The reason is that the sample can be rotated by hand while the alignment of the x-ray beam is being adjusted, thus checking the centering of the sample. We prefer not to rotate the sample if the sample size is adequate, and the particle size small enough to give a smooth pattern without rotation. It is very important that the sample should be accurately centered in the camera and coaxial with the rotating mechanism. While a number of permanently centered cameras are on the market, the type with centering screws for making this adjustment is to be preferred.

All modern cameras have a fluorescent window in the exit portal for use in aligning the camera in the x-ray beam, and the centering of the sample can be finally checked by watching the shadow of the sample in the window while the sample is rotated by hand. The design of the collimating system is of utmost importance in obtaining clean films with a minimum of background darkening. It is desirable for intensity reasons that the collimating system should be within the camera itself with the final opening as near as possible to the sample. Some cameras have as a highly desirable feature a shield or trap

---

[11] M. J. Buerger, J. App. Phys. 16, 501–510 (1945).

which protects the film from radiation scattered from the collimating system and from the air near the exit portal, Fig. 2.

The camera must be provided with a flexible and convenient mounting arrangement so that it can be easily aligned in the x-ray beam. It should also be possible to remove the camera for loading and unloading films and replace it in accurate alignment without readjustment. A little time saved on these routine operations will mount up if much work is done.

### Film

At the present time x-ray film is available with thick, double emulsions, which film compares favorably in speed with older emulsions used with intensifying screens. Such film sold variously under the names No-Screen, Non-Screen, etc., is best for diffraction work. The writers always use this type of film and in routine work make no attempt to correct for dimensional changes caused by the film processing, finding it readily possible to achieve the accuracy inherent in the A.S.T.M. data without correction. The only precaution taken is to dry the film thoroughly before measurement.

It is proper here to mention the Straumanis technique which has come into common use. The Straumanis technique is essentially a method of eliminating errors owing to camera diameter uncertainty and film dimension changes[12] by an ingenious method of loading the film. Two holes are punched in the film instead of the customary one hole for the exit beam. The two holes are spaced a camera half-circumference apart and the film is loaded so that the beam enters through one hole and leaves through the other. If back reflection lines are present on the pattern, appropriate measurements on the processed film will serve to determine the effective camera diameter. This scheme will fulfill the purpose for which it was designed only when properly used. The technique inherently demands precision positioning of the specimen and, therefore, requires an accurately made camera equipped with specimen centering cross motions. The Straumanis method of loading the film is to be recommended regardless of whether the diameter determination is carried through. No extra effort is involved, and as has been pointed out[11] a complete record of the diffraction pattern results, which can at any latter time be used for diameter correction and/or back reflection measurements.

### Geiger Counter Method

There has recently appeared an excellent Geiger counter spectrometer[13] which has valuable application in the field of x-ray diffraction chemical identification. Because the instrument yields directly and quickly x-ray intensities, it opens wide the field of quantitative diffraction analysis, and it would appear to be especially valuable in routine control operations. While the instrument possesses ample angular precision for identification purposes, the writers are not convinced by the literature statements that the instrument "is capable of angular measurements and resolutions beyond that attainable by means of photographic cameras."[14] The published intensity curves and comparable microphotometer records do not support the part about angular measurements, and it is well known that microphotometer traces are an exceedingly poor way of exhibiting photographic resolution and the detectability of a diffraction line. The instrument will have many applications but we feel that these will be complementary to photographic methods in the general identification laboratory.

## III. TECHNIQUE

### Preparation of the Sample

Probably there are almost as many ways of preparing the diffraction sample as there are x-ray workers. The ideal sample would consist wholly of the substance to be identified without either a container or a binder. The specimen should be small enough for good resolution and to avoid absorption effects and yet large enough for reasonable exposures and for practicable handling. Finally the specimen must contain enough crystals to give a smooth line pattern. These ideals can seldom all be attained simultaneously in practice except in the case of metals which can be drawn into wires.

[14] H. Friedman, Electronics (April 1945).

The size of the specimen to be exposed to the x-ray beam is a matter of compromise primarily between x-ray line resolution and practicable handling. Consensus of opinion among x-ray workers seems to favor a sample diameter of 0.4 mm. For the small 57.3-mm diameter camera, this is certainly an upper limit for good resolution, and the writers have found it necessary to employ smaller sample diameters in many cases.

Specimens which are the proper size but which absorb x-rays highly will produce systematic small errors in $d$ value and large errors in intensity. The cure is reduction in specimen size, error correction, or dilution. Most sample preparation techniques involve a binder which allows qualitative dilution to be made. The writers have never found it practical to follow a schedule of dilution, although this is possible.

Samples should be ground to 200-mesh or finer to help insure that the sample contains enough crystals to produce a smooth line diffraction pattern. Many identification samples have small enough crystal size naturally but must be ground to insure homogeneity and for effective mixing with the binder. Small "sillimanite" mortars are very convenient for grinding and mixing the identification specimen which is often itself quite tiny. Such mortars are so inexpensive that a number can be kept at hand to avoid the necessity of repeated washing, and even to store the specimen for other tests.

Frequently 200-mesh specimens do not produce smooth diffraction lines. In this case the specimen must be rotated, and in some cases should be scanned along its length in order to increase the effective number of crystals. Buerger[11] has discussed the design of rotation devices and of an ingenious scanning device. The latter, unfortunately, is not available commercially to our knowledge. The point to be kept in mind about rotation is that it demands accurate specimen centering; scanning imposes such alignment demands as to be of questionable practicability in routine identification work. The writers prefer not to rotate if it can be avoided by further grinding. An interesting sidelight to rotation is that occasionally in identification work the lines of two phases may be separated by their differing spottiness.

In the Dow Chemical Laboratories, samples are loaded in thin Pyrex capillary tubes having an internal diameter of 0.40 mm. Where molybdenum radiation is employed, glass capillaries are not greatly objectionable, but even very thin glass is quite absorptive of x-rays and most workers who use softer radiations, such as copper or iron, must avoid it. Plastic capillaries have been used by some workers but they are not readily available at the present time. It is quite possible to prepare suitable tubes of Cellophane by rolling it around a mandrel of proper size.[15] The tubes are made as short as the sample holder will permit and the ends are closed with wax after filling. Other workers prefer to mix the sample with collodion diluted with amyl acetate and ether and coat it on a thin thread obtained by untwisting a piece of sewing thread. Another method is to place the sample in a drop of collodion on a glass slide and when the collodion is nearly dry to roll it into the shape of a thin rod incorporating the sample.[16] If only a little sample is available, all of it can be quite conveniently concentrated in one end of the rod. Rubber cement can be used in the same way. Another technique is to mix the sample with a suitable binder such as library paste, dilute collodion, or glyceryl phthalate and then extrude the mixture through a simple die.[17] The die itself with the attached extrusion can be made to fit directly in the sample holder. Probably the beginner in x-ray work will do well to try several of these methods and then adopt the one that pleases him best. It must be remembered that all tubes or binder materials absorb some x-rays and produce more or less background darkening on film, and many of them produce a diffraction pattern of their own. It is desirable to run a blank film on the container or binder without any sample in order to determine whether any diffraction pattern is produced.

### Measurement of Films

After the exposed film has been developed and dried, it may be conveniently studied on a light box with a sloping opal glass front. Some workers use more or less elaborate film measuring devices, but the writers prefer to measure routine films

---

[15] A. A. Burr, Rev. Sci. Inst. 13, 127 (1942).

[16] G. A. Harcourt, Am. Mineralogist 27, 63 (1942).

[17] J. S. Lukesh, Rev. Sci. Inst. 11, 200 (1940).

made in the 57.26-mm diameter camera by setting a pair of sharp pointed dividers on corresponding lines and reading the distance on a good celluloid scale graduated in half-millimeters. Successive readings seldom differ by more than one or two tenths of a millimeter, and errors as large as this are likely to occur in setting any of the measuring devices in use.

When very weak lines must be found and measured, as is sometimes necessary in polyphase samples, the characteristics of the human eye play an important part.[18] The cross line slider with which some measuring devices are equipped has a definite tendency to cause weak lines to vanish, apparently, as the setting is being made. The simple divider technique avoids this difficulty and the detection of weak lines can be made easier by providing the viewing box with a Variac to lower the level of illumination. It is sometimes an advantage to clip or tape the film to a piece of plain glass which can be placed some distance from the opal illuminator and which can be tilted with respect to it. If a device with a slider is used, we prefer a pointed indicator to the cross line type.

If the camera diameter is some simple multiple of 57.26 mm, interlinear measurements are easily converted into angular measurement in degrees by simply dividing by the appropriate factor. $d$ values are calculated from the Bragg formula $d=\lambda/2\sin\theta$. Repeated performance of this routine calculation is time consuming and can be avoided by the use of a very convenient graphical chart prepared at the suggestion of the writers by O. E. Brown.[19] This chart is intended particularly for identification work and covers a range suitable for use with the A.S.T.M. tables. The chart covers copper, cobalt, iron, chromium, and molybdenum radiations which are the ones most valuable for identification work. To use it, the measured $\theta$ value is found under the appropriate horizontal line and the corresponding $d$ value read off above the line.

The intensity of x-ray diffraction lines is most easily estimated by eye and noted on a scale of 1 to 10. Apparently most workers use such a method as do the writers. The method is recommended in the majority of problems for its speed, but some problems may require a more careful method. Hanawalt's method is to use a comparison strip, which is a film containing lines of graded exposure. The comparison method is certainly accurate enough for all identification work, and once the comparison strip is prepared the use of it is nearly as rapid as simple estimation. It is to be hoped that one of the x-ray manufacturers will make comparison strips available commercially.

## IV. INTERPRETATION

The result of the purely experimental side of x-ray chemical identification is a table of $d$ values and the corresponding relative intensities. The interpretation of these data may follow several courses, depending on the complexity of the problem and the comparison data available. Identification work has long been carried out by simple comparison of the unknown film with films of known substances, and much work can be and is done in this way even yet. Such a method fails in the case of polyphase materials or where only a limited library of standards is available. The great contribution of Hanawalt and the A.S.T.M. has been to place in the literature a volume of identified data arranged in a systematic fashion.

### Examples

A great volume of identification problems deal with questions such as "What manganese compound is present in this sample?," "What oxide of lead is this?," or "This substance is predominately one phase; what is the phase?" Where the problem is a simple one of this type, with auxiliary information available, the data for 1000 common materials published by Hanawalt[2] are the rapid and effective means of making the identification. An example is described below in which this interpretation technique was used, and in which also a modified experimental approach was used.

On one occasion the writers were asked to identify a very thin white coating on the inside of a glass tube. The conditions under which the coating had been formed suggested the probability that it was a copper compound. The

---

[18] It may be pointed out here that the eye is a far more sensitive instrument for such purposes than a microphotometer.

[19] Orley E. Brown, J. App. Phys. 18, 191 (1947).

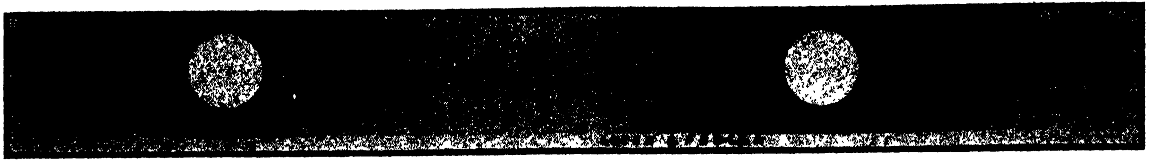

FIG. 3. X-ray diffraction pattern made with Cu$K\alpha$-radiation of an unknown identified as $CaSO_4 \cdot \frac{1}{2}H_2O$ and $CaCO_3$. The line labeled *B* is a superposition of strong lines from each phase. The $K\beta$-filter (a sheet of nickel foil) was placed between the sample and the film. The sharply defined blackening occurs where the filter did not meet and is caused by calcium fluorescence radiation.

thinness of the coating made it infeasible to prepare a sample in the ordinary way. Instead, the tube was broken, and a small piece of the glass was mounted in the center of the camera in such a way that a pencil of x-rays struck the coated surface with a very small glancing angle. A pattern consisting of only four rather weak lines was obtained. The *d* values were computed and the data of Hanawalt[2] were inspected, the search being confined to the simple copper compounds. The data matched perfectly with the principal lines of the pattern for $CuCl_2$. Since the presence of chlorine in the system had not previously been suspected, the information proved highly useful and the determination required less than an hour of elapsed time. Other modifications in technique will be suggested by the ingenuity and experience of the worker. The small 57-mm camera is ideal for problems of this general type, where precision and resolving power are not particularly needed, and where speed may be useful.

The more complex problems involve polyphase samples, or samples consisting of an uncommon single phase. In the former case the interpretation approach described above is often effective with the dominant phase, but the minor phases which may be represented by only a few lines each must be attacked by using a systematic method employing as large a volume of standard data as possible. The A.S.T.M. card index file of x-ray diffraction data provides such a method.

The A.S.T.M. card index file, including the recent supplement, contains data for roughly 3000 substances. A given substance is represented by three cards, one for each of its three strongest lines and their relative intensity, and the card for the strongest line carries, in addition, the data for the entire pattern plus auxiliary information and references. All cards are arranged in order of decreasing *d* value.[20] To use the card file one simply searches the cards in the vicinity of the *d* value of the strongest unknown line, allowing reasonable limits of error. One looks for a card that shows *other* strong lines matching other strong unknown lines, and which corresponds with a substance which is reasonable on the grounds of the other evidence available. When a match of strongest lines is found, the card corresponding with the strongest line of the tentative identification is looked up and all the unknown lines are compared. If all unknown lines match, the identification is complete; if the match is not good, a further search must be made; if the unknown accounts substantially for all the lines of the tentative identification and unknown lines are left over, a second phase must be sought for. The complex situation involving several phases and superposition of lines is best described by example.

Such an example is one which the writers invented for students in an x-ray laboratory class to solve, and the reasoning used by one of the better students is presented below. The sample consisted of equal parts by weight of $CaSO_4 \cdot \frac{1}{2}H_2O$ and precipitated $CaCO_3$, and the students were given no advance information except that of their eyes telling them that the unknown was a white fluffy powder.

The sample was prepared by grinding in a small "sillimanite" mortar, mixing with collodion-ether-amyl acetate and coating on a fine cotton thread. The film was loaded in the Straumanis manner and a filter of nickel foil 0.0004 in. thick was placed in the camera between the sample and the film. In this particular instance a 72-mm camera manufactured by the Picker X-Ray

---

[20] This statement applies to the cards as furnished by the A.S.T.M. Other arrangements within subgroups of cards are possible.

Corporation was used and the exposure was 30 minutes with copper radiation and without rotation of the sample. The resulting pattern, Fig. 3, contained one very strong line, about ten medium lines, and many weak lines. The lines were measured with dividers and scale, the camera diameter was determined from the film, and the $\theta$ values were computed. $d$ values were determined by the use of O. E. Brown's chart.[19] Intensity values were estimated visually. The resulting data are listed in Table I.

Since the line at $d=3.02$ kX is by far the strongest line on the film the student began his attempted identification by searching in the card file from $d=3.00$ to $d=3.04$ kX for cards which also listed a strong line at either $d=5.9\pm0.1$ kX *or* $d=2.80\pm0.02$ kX. When such a card was found, the third listed line was checked against the data for the unknown sample. Those cards on which all three strongest lines did not correspond to lines in the data for the unknown (three cases) were returned to the file. The one case where correspondence occurred for all three lines was the card for $CaSO_4\cdot\frac{1}{2}H_2O$. Accepting this as a tentative identification, all of the lines listed for this substance were compared with the data for the unknown, the cases of correspondence being shown in Table I. It will be seen that the strongest five lines listed for $CaSO_4\cdot\frac{1}{2}H_2O$ as well as some of the weaker lines occur in the data for the unknown. The identification of $CaSO_4\cdot\frac{1}{2}H_2O$ is thus confirmed, but it was clear that an additional phase must be present since so many lines in the unknown were not accounted for. This being the case, the fact that some of the weaker $CaSO_4\cdot\frac{1}{2}H_2O$ lines were missing from the unknown was correctly ascribed to the effects of dilution.

The next step was to identify the as yet unknown phase or phases. At this point the student reasoned that although the line $d=3.02$ is by far the strongest line on the film, it is listed as only the second strongest in the data for $CaSO_4\cdot\frac{1}{2}H_2O$ and consequently there must be a strong line for the unknown phase superimposed upon it. Accordingly he again searched the file in the $d=3.02$ region, this time seeking cards which list a strong line at $d=2.48\pm0.02$ *or* $d=2.28\pm0.02$. This search led to the $CaCO_3$ card which listed as its third strongest line $d=2.28$ and as its second strongest $d=1.92$ which is also found in the data for the unknown. The comparison is completed in Table I which exhibits the fact that all of the experimental $d$ values are accounted for by the identified phases. Conversely the experimental data account for all the strong and medium lines listed in the card file for the two phases except $d=2.13$ for $CaSO_4\cdot\frac{1}{2}H_2O$. Examination of the film revealed that the $d=2.09$ line is in fact broadened toward the high $d$ side suggesting that the $d=2.13$ line was missed because of partial superposition. The intensity agreement is rough but satisfactory. Any doubts on this score are resolved when reference is made to cards which give duplicating data for the two phases from different sources. The experimental data agree with any one card as well as the cards agree with each other.

This example was chosen intentionally to present the student with the difficulty caused by superposition of strong lines from the two phases contained in the sample. Yet the identification was correctly made in a minimum of time. The fact that all the stronger lines for both phases appear on the film would have justified the further inference that both phases are present in major amount. Any further quantitative inferences would not be justified without prepa-

ration of standard films from the two substances for comparison.

### V. AGREEMENT OF DATA

The Hanawalt scheme of chemical identification is based on the empirically demonstrated fact that the *d* values of the three strongest lines of a phase identify that phase nearly uniquely. Completely unique identification implies agreement of all *d* values and in addition substantial agreement of intensities. While *d* value agreement, within allowable limits, must occur intensity agreement often does not occur even in the case of the three strongest lines. Often, too, different sources will disagree on the actual presence of a fairly important line.

Table I lists three sets of data for the same substance, taken from the A.S.T.M. card file, and illustrating these three effects. These data are the work of skilled workers, and there is little likelihood of chemical impurity of the sample examined. It is highly probable that the reader will find as many deviations in his own data as among the ones quoted. The agreement among *d* values is about as good as could be expected considering technical limitations. *d* value results similar to the third set of data quoted *may* occur because of excessive sample size and absorption, poor sample position or possibly film shrinkage, all effects which should be eliminated in standardized technique. The situation with regard to "missing" lines is an interesting one of not infrequent occurrence, the reasons for which are too varied for a general explanation to be attempted here. The very existence of such discrepancies in the card file means that one need not be too disconcerted when it occurs in practice. Of course, a reason and sometimes a significant reason for such effects exists, but if the work has been carefully done the "difficulty" may just as well be in the literature data or literature material.

The discrepancies in intensities of Table II are disturbing at first sight and the writers have made an inspection of published data in an attempt to discover the source of the difficulty. The details of the study need not be given here but the results of the comparison will be of interest to the user of the card file data and are summarized in Figs. 4 and 5.

Duplicate sets of data for 10 simple substances are compared in the figures. Since the chosen substances are simple, reliable calculations of theoretical intensity are readily made by the accepted methods. Figure 4 is a composite plot comparing the relative intensities as measured by Hanawalt by his simple method of visual comparison with prepared standards, against the calculated theoretical intensities. The calculated and measured values agree as well as is usually the case with x-ray diffraction intensities. The comparison is presented here to give added reliance on the measured values and to indicate the degree of intensity agreement to be expected generally.

Figure 5 gives a comparison of intensities as measured by Hanawalt with intensities obtained by the commonly employed method of visual estimation on the basis of an arbitrary scale of one to ten. The data are all from the card file and the number of observers is large enough to eliminate the personal factor. It is clear that the estimated intensities differ rather radically from the measured ones and that the method of estimation tends to exaggerate the relative intensity of the weaker lines. The disagreement is large enough that an identification cannot be expected to show intensity agreement except in a highly qualitative fashion when intensities are estimated. Actually in straight identification work, the disagreements are not as important as they appear. The intensity values themselves are less important than the *order* of intensities and this is quite reliably determined by visual comparison.

Since one of the purposes of the present paper is to recommend the use of long wave-length radiations in identification work, it is pertinent to inquire how the relative intensities on long wave-length patterns compare with the intensities on patterns made with Mo$K\alpha$. Frevel has given an answer for Cu$K\alpha$ on a semi-empirical, semi-theoretical basis,[21] in the form of a table of conversion factors. This table shows that Cu$K\alpha$ intensities should not differ from Mo$K\alpha$ intensities by more than 25 percent, as long as the Cu$K\alpha$ Bragg angle is less than 45°. This difference is certainly not an important one. At Bragg angles greater than 45°, Cu$K\alpha$ relative intensities are very much higher than the relative intensities of lines of the same *d* value on a Mo$K\alpha$ pattern. There may be as much as a factor of 5 at high Bragg angle, arising from the Lorentz polarization factor. Because the most intense lines generally arise from the large *d* values which occur at small Bragg angle, it would seem that the wave-length effect on intensities could as a first approximation be neglected.

The above remarks and conclusion have necessarily been made on the basis of theory and apply to intensity *measurements*. Intensity estimates with Cu$K\alpha$ will of course be as good or as bad as Mo$K\alpha$ estimates. In addition there is the effect of absorption by the sample which can be

[21] Quoted in the "Alphabetical Index of X-ray Diffraction Patterns," A.S.T.M., Philadelphia, Pennsylvania.

important with long wave-lengths. The effect of absorption is to reduce the intensity of high $d$ lines, and because these are generally the strong lines, to raise effectively all relative intensities. That this effect is present to a significant degree is entirely supported by eight cases of duplicate card file data involving both Mo$K\alpha$ and Cu$K\alpha$.

All of the above remarks for Cu$K\alpha$ intensity apply with much more force to the longer wave-lengths such as Fe$K\alpha$ and Cr$K\alpha$. With these radiations the absorption factor is exceedingly important, and further the important lines begin to occur at large Bragg angle where they are enhanced by the Lorentz polarization factor. Three cases have been found in the card file literature where Mo$K\alpha$ intensity measurements are duplicated by estimates on patterns of the same material made with Ni$K\alpha$, Fe$K\alpha$, and Cr$K\alpha$. The long wave-length intensities show only small differences from line to line, while the Mo$K\alpha$ intensities for corresponding lines show radical differences.

## VI. LIMITATIONS AND ADVANTAGES

The x-ray diffraction method of chemical identification is obviously limited to materials listed in the standards library available which ordinarily excludes solid solutions, and, of course, eliminates non-crystalling materials. In addition the method suffers the major limitation that it is not very sensitive to small *concentrations* of a given phase. The minimum concentration that will be detectable will depend upon the substance and also in part, upon the other substances present. Hanawalt states that the minimum may be as low as 1.0 percent or less, or more than 50.0 percent. Perhaps a representative figure would be around 10.0 percent. In general only experiments with known mixtures of the substances to be detected will definitely decide the minimum detectable concentration. However, it is clear that substances giving several lines of high absolute intensities will be detectable in smaller concentration than those yielding only weak lines.

Not uncommonly in industrial work a sample must be studied which contains four or five phases, some of which may be present in such small concentration as to show only one or two of their strongest lines. Clearly in cases of this kind a positive identification cannot be made by x-ray means alone. However, in practical cases some information is usually available to suggest some of the possible substances whose presence the x-ray pattern may confirm. Even in the most difficult cases the diffraction pattern usually yields some information which supplements that obtained from other methods and justifies the effort involved.

The x-ray method also fails to give complete identification in several minor instances. For example, there are numerous oxides of the type $AB_2O_4$ which have the same structure, the spinel type, and of these materials many have lattice parameters that are nearly the same. In addition then to nearly identical $d$ values, the intensities turn out to be similar. Clearly an identification beyond that of the structure type is difficult in such a case. The spinel situation emphasizes that the x-ray method identifies *structures*, from which rigid chemical analyses must not be inferred.

The x-ray diffraction method has unique advantages. Like the petrographic microscope it identifies the phases present and not merely the elements of which they are composed. Dimorphous forms of the same substance are as easily distinguished as different substances, an exceedingly important fact. Unlike the microscope it is not sensitive to very small concentrations of a minor phase but it is particularly successful with opaque materials and very finely divided samples.

Other major advantages of the x-ray method are that only a small sample is needed and the accuracy necessary is easy to achieve. The sample which is used is not destroyed so that it is available for chemical or spectroscopic study later. The x-ray method can upon occasion rival the companion electron diffraction method with respect to its ability to obtain results from a small amount of specimen.

## VII. AUXILIARY PROCEDURES

X-ray diffraction will not displace other means of examination but it does supplement them with information not otherwise obtainable and in some cases it may yield the same information with less effort. In difficult cases it is most helpful to have supplemental information obtained by spectroscopic or conventional chemical analysis. The major cation constitution is particularly useful in interpretation as well as being a time saver if the cations are such as to cause fluorescence. Industrial clients are occasionally reluctant to furnish such analytical and source information as they already possess regarding a sample, with the result that the x-ray worker is greatly handicapped in interpreting his results.

The writers prefer to give each sample a preliminary examination under the petrographic microscope. Sometimes this makes x-ray examination unnecessary. It is frequently possible to tell at a glance whether the sample is homogeneous or not and at times the presence of a minor phase may be revealed which would be overlooked by x-ray examination alone. Where several phases are present it may be desirable to make a preliminary separation by magnetic means, by heavy liquids, by washing or some other physical means and then examine the fractions separately by x-rays.

It has been stated on certain occasions that the x-ray diffraction method permits chemical identification work to be done with untrained personnel. Probably this is true where a certain number of routine determinations of the same type are to be done over and over again. However, it cannot be too strongly stressed that good x-ray diffraction work demands a high degree of experience and judgment, and at least a reasonable background in x-ray theory and crystallography, together with an understanding of the industrial problems to which the work is being applied. It will be completely futile for any laboratory to purchase an expensive x-ray diffraction outfit and expect to "hire a boy" to operate it.

# Charts for Computation of *d*-Values in X-Ray Diffraction Chemical Analysis*

Orley E. Brown
*Department of Mathematics, Case School of Applied Science, Cleveland 6, Ohio*

(Received October 16, 1946)

In chemical identification by x-ray diffraction, Bragg's equation

$$2d = \lambda \csc\theta,$$

in which $d$ represents the crystallographic interplanar spacing, $\lambda$ the x-ray wave-length, and $\theta$ the Bragg angle, must be repeatedly solved to find the $d$-value which corresponds to a known $\lambda$-value and an observed $\theta$-value. Whereas this equation lends itself to conventional treatment graphically, it is not convenient to secure the accuracy required by the ordinary graphical methods.

Since only five different values of $\lambda$, one for each of five different x-ray targets, are commonly used, these five values were assigned and a doubly graduated scale was prepared for each of the five resulting equations. This type of chart has the advantage of being constructable for any desired accuracy and of being immune to damage due to paper shrinkage or distortion in reproduction.

To use one of the charts, locate the $\theta$-value on the lower side of the scale and read off the corresponding $d$-value from the upper side.

The plates used in printing these charts are being retained, and if the demand warrants, arrangements will be made with a commercial concern to supply reprints of the charts in quantity.

# Streamlines for the Subsonic Flow of a Compressible Fluid Past a Sphere

E. R. VAN DRIEST*
*Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received June 28, 1946)

The second approximation to the velocity potential for the irrotational flow of a compressible fluid past a sphere, derived independently by Tamada and Kaplan, is used to calculate the subsonic streamlines for the flow of air at a Mach number of 0.5 past a sphere. Comparison is made between these streamlines and those for the irrotational flow of an incompressible fluid. Velocity and pressure comparisons are also shown.

## INTRODUCTION

THE subsonic irrotational flow of a compressible fluid past a sphere has been studied extensively by Lord Rayleigh,[1] K. Tamada,[2] and C. Kaplan.[3] Designating the flow of an incompressible fluid past a sphere as the zero approximation to a solution expressed in ascending powers of $M^2$ for the flow of a compressible fluid about the same object, the first approximation was obtained by Lord Rayleigh and the second by Tamada and Kaplan. Inasmuch as the work of Tamada and Kaplan included the comparison of velocity and pressure distribution on the surface of the sphere for compressible fluid flow with the corresponding distributions for the incompressible flow, the author thought it would be also worth while to make a comparison of the streamlines for the two cases. The present paper therefore shows the second approximation to the streamlines for the flow of air at a Mach number of 0.5 and the corresponding streamlines when the fluid is considered incompressible.

## THE SECOND APPROXIMATION TO THE POTENTIAL FUNCTION

In the case of the steady adiabatic frictionless flow of a perfect gas, the local velocity of sound is given by

$$c^2=c_0^2\left[1+\frac{\gamma-1}{2}M^2\left(1-\frac{V^2}{U^2}\right)\right], \qquad (1)$$

where $U$ is the velocity of the undisturbed stream, $c_0$ the velocity of sound corresponding to the undisturbed stream, $M$ the Mach number for the undisturbed stream $(=U/c_0)$, $\gamma$ the ratio of the specific heats of the fluid, and $V$ the local velocity of the fluid.

Furthermore, assuming irrotational motion, combination of the equations of motion and continuity takes the form

$$\Delta\phi=\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}+\frac{\partial^2\phi}{\partial z^2}$$
$$=\frac{1}{2c^2}\left(\frac{\partial\phi}{\partial x}\frac{\partial V^2}{\partial x}+\frac{\partial\phi}{\partial y}\frac{\partial V^2}{\partial y}+\frac{\partial\phi}{\partial z}\frac{\partial V^2}{\partial z}\right), \qquad (2)$$

where $\phi$ is the velocity potential. When the motion has axial symmetry as for the flow past a sphere, Eq. (2) becomes in polar coordinates $(r, \theta)$

$$\Delta\phi=\frac{\partial^2\phi}{\partial r^2}+\frac{2}{r}\frac{\partial\phi}{\partial r}+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\phi}{\partial\theta}\right)$$
$$=\frac{1}{2c^2}\left(\frac{\partial\phi}{\partial r}\frac{\partial V^2}{\partial r}+\frac{1}{r^2}\frac{\partial\phi}{\partial\theta}\frac{\partial V^2}{\partial\theta}\right), \qquad (3)$$

in which

$$V^2=\left(\frac{\partial\phi}{\partial r}\right)^2+\frac{1}{r^2}\left(\frac{\partial\phi}{\partial\theta}\right)^2. \qquad (4)$$

By reason of the extreme complexity of Eq. (3), methods for approximate solution have been resorted to. As stated in the introduction, a first approximation was obtained by Lord Rayleigh; he took the well-known solution for incompressible flow as the zero approximation, substituted it into the right-hand side of Eq. (3), placed $c=c_0$, and then obtained a solution of the new equation.

---

* Assistant Professor of Mechanical Engineering.

[1] Lord Rayleigh, "On the flow of compressible fluid past an obstacle," Phil. Mag. 32, No. 187, 1–6 (July, 1916).

[2] K. Tamada, "On the flow of a compressible fluid past a sphere," Proc. Phys.-Math. Soc., Japan 21, 743–752 (1939).

[3] C. Kaplan, "Flow of a compressible fluid past a sphere," N. A. C. A. Tech. Note, No. 762 (May, 1940).

The second approximation to the compressible fluid flow, accomplished by Tamada and Kaplan, was carried out under the assumption that $\phi$ can be expanded as a power series in $M^2$, thus

$$\phi=\phi_0+\phi_1 M^2+\phi_2 M^4+\cdots. \tag{5}$$

Substituting Eq. (5) into Eq. (3) and equating terms of like powers of $M$ on both sides, there results

$$\Delta\phi_0=0, \tag{6}$$

$$\Delta\phi_1=\frac{1}{2U^2}\left(\frac{\partial\phi_0}{\partial r}\frac{\partial V_0^2}{\partial r}+\frac{1}{r^2}\frac{\partial\phi_0}{\partial\theta}\frac{\partial V_0^2}{\partial\theta}\right), \tag{7}$$

$$\begin{aligned}\Delta\phi_2={}&\tfrac{1}{2}(\gamma-1)(V_0^2-1)\Delta\phi_1\\&+\frac{1}{2U^2}\left(\frac{\partial\phi_0}{\partial r}\frac{\partial V_1^2}{\partial r}+\frac{1}{r^2}\frac{\partial\phi_0}{\partial\theta}\frac{\partial V_1^2}{\partial\theta}\right)\\&+\frac{1}{2U^2}\left(\frac{\partial\phi_1}{\partial r}\frac{\partial V_0^2}{\partial r}+\frac{1}{r^2}\frac{\partial\phi_1}{\partial\theta}\frac{\partial V_0^2}{\partial\theta}\right).\end{aligned} \tag{8}$$

It will be noted that the solution of the first equation represents the incompressible fluid case, *viz.*,

$$\phi_0=U\left(r+\frac{a^3}{2r^2}\right)P_1, \tag{9}$$

wherein $a$ is the radius of the sphere and $P_1$ is the Legendre polynomial of the first order (of argument $\cos\theta$). The second equation leads to the first-order correction to the velocity potential as obtained by Lord Rayleigh, i.e.,

$$\begin{aligned}\phi_1=a^3U\Bigg[&\left(\frac{1}{3}\frac{1}{r^2}-\frac{1}{5}\frac{a^3}{r^5}+\frac{1}{24}\frac{a^6}{r^8}\right)P_1\\&+\left(-\frac{3}{10}\frac{1}{r^2}+\frac{27}{55}\frac{a^2}{r^4}-\frac{3}{10}\frac{a^3}{r^5}+\frac{3}{176}\frac{a^6}{r^8}\right)P_3\Bigg].\end{aligned} \tag{10}$$

The third equation yields the second-order correction as given by Tamada and Kaplan:

$$\begin{aligned}\phi_2=a^3U(\gamma-1)\Bigg[&\left(\frac{599}{16800}\frac{1}{r^2}-\frac{3}{70}\frac{a^3}{r^5}+\frac{1}{24}\frac{a^6}{r^8}-\frac{13}{560}\frac{a^9}{r^{11}}+\frac{13}{2800}\frac{a^{12}}{r^{14}}\right)P_1+\left(\frac{83133}{3665200}\frac{a^2}{r^4}-\frac{1}{10}\frac{a^3}{r^5}+\frac{15}{176}\frac{a^6}{r^8}\right.\\&\left.-\frac{57}{1960}\frac{a^9}{r^{11}}+\frac{23}{6800}\frac{a^{12}}{r^{14}}\right)P_3+\left(\frac{1}{7}\frac{a^3}{r^5}-\frac{50517}{276640}\frac{a^4}{r^6}+\frac{3}{52}\frac{a^6}{r^8}-\frac{9}{1120}\frac{a^9}{r^{11}}+\frac{5}{8512}\frac{a^{12}}{r^{14}}\right)P_5\Bigg]\\&+a^3U\left(\frac{1325952}{4065600}\frac{1}{r^2}-\frac{49}{150}\frac{a^3}{r^5}-\frac{243}{1925}\frac{a^5}{r^7}+\frac{1049}{3080}\frac{a^6}{r^8}+\frac{5589}{84700}\frac{a^8}{r^{10}}-\frac{3049}{18480}\frac{a^9}{r^{11}}+\frac{7789}{369600}\frac{a^{12}}{r^{14}}\right)P_1\\&+a^3U\left(-\frac{53}{150}\frac{1}{r^2}+\frac{70620063}{95295200}\frac{a^2}{r^4}-\frac{61}{150}\frac{a^3}{r^5}-\frac{156}{275}\frac{a^5}{r^7}+\frac{28}{55}\frac{a^6}{r^8}+\frac{1137}{7150}\frac{a^8}{r^{10}}-\frac{12631}{64680}\frac{a^9}{r^{11}}+\frac{929}{56100}\frac{a^{12}}{r^{14}}\right)P_3\\&+a^3U\left(\frac{5}{42}\frac{1}{r^2}-\frac{6}{11}\frac{a^2}{r^4}+\frac{2}{3}\frac{a^3}{r^5}+\frac{135921}{640640}\frac{a^4}{r^6}-\frac{60}{77}\frac{a^5}{r^7}+\frac{253}{728}\frac{a^6}{r^8}+\frac{87}{1540}\frac{a^8}{r^{10}}-\frac{997}{18480}\frac{a^9}{r^{11}}+\frac{85}{29568}\frac{a^{12}}{r^{14}}\right)P_5.\end{aligned} \tag{11}$$

## DETERMINATION OF THE STREAMLINES

The potential and stream functions are connected by the relations

$$\frac{1}{r}\frac{\partial\phi}{\partial\theta}=-\frac{1}{\rho r\sin\theta}\frac{\partial\psi}{\partial r}, \tag{12}$$

$$\frac{\partial\phi}{\partial r}=\frac{1}{\rho r^2\sin\theta}\frac{\partial\psi}{\partial\theta}, \tag{13}$$

in which

$$\rho=\rho_0\left[1+\frac{\gamma-1}{2}M^2\left(1-\frac{V^2}{U^2}\right)\right]^{1/(\gamma-1)} \tag{14}$$

where $\rho_0$ is the density of the undisturbed stream.

From Eqs. (12), (14), and (4), there results

$$\rho_0\left\{1+\frac{\gamma-1}{2}M^2\left[1-\frac{1}{U^2}\left(\frac{\partial\phi}{\partial r}\right)^2-\frac{1}{U^2r^2}\left(\frac{\partial\phi}{\partial\theta}\right)^2\right]\right\}^{1/(\gamma-1)}\sin\theta\frac{\partial\phi}{\partial\theta}=-\frac{\partial\psi}{\partial r}, \tag{15}$$

or, absorbing $\rho_0$ in $\psi$,

$$\left\{1+\frac{\gamma-1}{2}M^2\left[1-\frac{1}{U^2}\left(\frac{\partial\phi}{\partial r}\right)^2-\frac{1}{U^2r^2}\left(\frac{\partial\phi}{\partial\theta}\right)^2\right]\right\}^{1/(\gamma-1)}\sin\theta\frac{\partial\phi}{\partial\theta}+=-\frac{\partial\psi}{\partial r}. \quad (16)$$

For the particular case of $M=0.5$ and $\gamma=1.405$ for air, Eq. (16) becomes

$$\left\{1+0.0506\left[1-\frac{1}{U^2}\left(\frac{\partial\phi}{\partial r}\right)^2-\frac{1}{U^2r^2}\left(\frac{\partial\phi}{\partial\theta}\right)^2\right]\right\}^{2.465}\sin\theta\frac{\partial\phi}{\partial\theta}=-\frac{\partial\psi}{\partial r}. \quad (17)$$

Now the simplest way of integrating Eq. (17) is by graphical means, i.e., for certain values of $\theta$, the left-hand side can be computed at various values of $r$, and the area under the curve can be calculated to give corresponding values of $\psi$. The graph relating $\psi$ and $r$ can then be used to determine the radial distance $r$ for certain preassigned values of $\psi$. This process can of course be carried out to any degree of accuracy.

Upon differentiation of Eq. (5) and substitution of $M=0.5$,

$$\frac{\partial\phi}{\partial\theta}=\frac{\partial\phi_0}{\partial\theta}+\frac{1}{4}\frac{\partial\phi_1}{\partial\theta}+\frac{1}{16}\frac{\partial\phi_2}{\partial\theta}. \quad (18)$$

Substitution of Eqs. (9)–(11) into Eq. (18) then yields, when $a=1$,

$$\begin{aligned}\frac{\partial\phi}{\partial\theta}=&-U\sin\theta(r+0.5699r^{-2}+0.0556r^{-4}\\&-0.0995r^{-5}+0.0020r^{-6}-0.0326r^{-7}\\&+0.0525r^{-8}+0.0087r^{-10}-0.0166r^{-11}\\&+0.0019r^{-14})\\&-U\sin3\theta(-0.1760r^{-2}+0.2899r^{-4}\\&-0.1560r^{-5}+0.0071r^{-6}-0.1064r^{-7}\\&+0.0909r^{-8}+0.0215r^{-10}-0.0272r^{-11}\\&+0.0023r^{-14})\\&-U\sin5\theta(0.0183r^{-2}-0.0840r^{-4}\\&+0.1116r^{-5}+0.0212r^{-6}-0.1200r^{-7}\\&+0.0570r^{-8}+0.0087r^{-10}-0.0088r^{-11}\\&+0.0005r^{-14}).\end{aligned} \quad (19)$$

Furthermore,

$$\frac{\partial\phi}{\partial r}=\frac{\partial\phi_0}{\partial r}+\frac{1}{4}\frac{\partial\phi_1}{\partial r}+\frac{1}{16}\frac{\partial\phi_2}{\partial r},$$

so that

$$\begin{aligned}\frac{\partial\phi}{\partial r}=&\,U\cos\theta(1-1.1394r^{-3}-0.2224r^{-5}\\&+0.4975r^{-6}-0.0121r^{-7}+0.2280r^{-8}\\&-0.4201r^{-9}-0.0866r^{-11}+0.1822r^{-12}\\&-0.0266r^{-15})\\&+U\cos3\theta(0.1181r^{-3}-0.3870r^{-5}\\&+0.2595r^{-6}-0.0142r^{-7}+0.2481r^{-8}\\&-0.2416r^{-9}-0.0716r^{-11}+0.0996r^{-12}\\&-0.0106r^{-15})\\&+U\cos5\theta(-0.0073r^{-3}+0.0671r^{-5}\\&-0.1116r^{-6}-0.0255r^{-7}+0.1679r^{-8}\\&-0.0915r^{-9}-0.0174r^{-11}+0.0194r^{-12}\\&-0.0013r^{-15}).\end{aligned} \quad (20)$$

This is all the further that the process can be reduced. The remaining work is pure computation. In this paper, streamlines were located to the nearest one-thousandth of the unit for each of the following nine angles of $\theta$: $\tan^{-1} 1/15$, $\tan^{-1} 1/8$, $\tan^{-1} 1/4$, $\tan^{-1} 4/10$, $\pi/6$, $\pi/4$, $\pi/3$, $\tan^{-1} 11/3$, and $\pi/2$.

Figure 1 shows the streamlines for both the compressible and incompressible fluid flow. Also in this figure are plotted the corresponding velocities in the field at $\theta=\pi/2$ and the corresponding pressures on the surface of the sphere. (Note that in the figure $u_0=U$, and $u=V$ in the field at $\theta=\pi/2$.) The pressure distribution for the compressible fluid case is given by the formula

$$\frac{p-p_0}{\frac{1}{2}\rho_0U^2}=\frac{1}{(\gamma/2)M^2}\times\left\{\left[1+\frac{\gamma-1}{2}M^2\left(1-\frac{V^2}{U^2}\right)\right]^{\gamma/(\gamma-1)}-1\right\}, \quad (21)$$

where $p_0$ is the pressure in the undisturbed

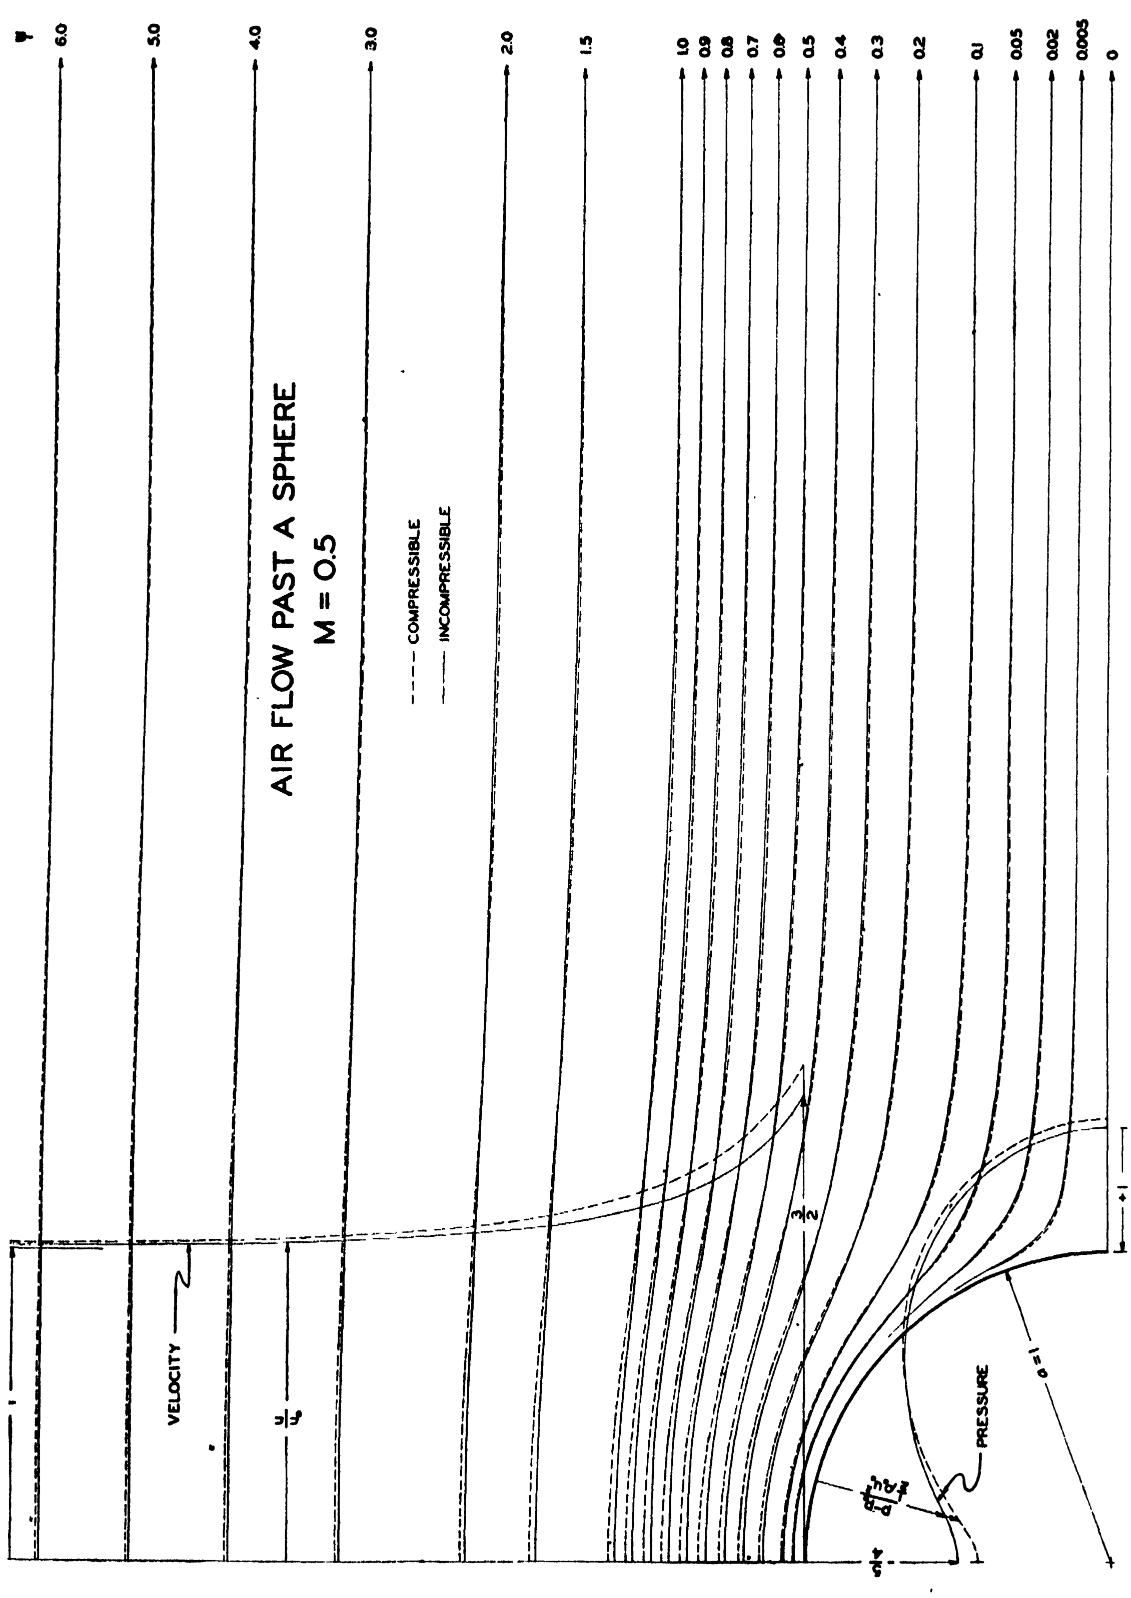

FIG. 1. Streamlines for the flow of both a compressible and an incompressible fluid past a sphere.

| $\tan^{-1} 11/3$ | −1.218 | −1.093 | 1.526 | 1.447 | | | |
| $\pi/2$ | −1.416 | −1.250 | 1.600 | 1.500 | | | |

stream, or

$$\frac{p-p_0}{\frac{1}{2}\rho_0 U^2}=5.695\left\{\left[1+0.0506\left(1-\frac{V^2}{U^2}\right)\right]^{3.465}-1\right\} \quad (22)$$

for the air flow at Mach number 0.5.

Table I gives the velocity and pressure data for the two flows.

It is seen that in the case of the compressible fluid the point on the sphere at which the pressure is equal to the pressure in the undisturbed stream is at a location different from that for the incompressible fluid. For the compressible fluid flow the point is located by placing $-U=(1/r)(\partial\phi/\partial\theta)$, substituting Eq. (19) for $\partial\phi/\partial\theta$, putting $r=1$, and then solving the resulting equation, *viz.*,

$$1.5419\sin\theta-0.0539\sin 3\theta+0.0045\sin 5\theta=1. \quad (23)$$

The solution of Eq. (23) is $\theta=43°\,38'$. For the incompressible fluid case, the point of zero pressure difference is located at $\theta=41°\,49'$.

The local Mach number is greatest at the top of the sphere. This number can be computed using Eq. (1), thus

$$M_l=\frac{V}{c}=\frac{V}{c_0\left[1+\frac{\gamma-1}{2}M^2\left(1-\frac{V^2}{U^2}\right)\right]^{\frac{1}{2}}}, \quad (24)$$

or, since $c_0=U/M$,

$$M_l=\frac{V/U}{\left[\frac{1}{M^2}+\frac{\gamma-1}{2}\left(1-\frac{V^2}{U^2}\right)\right]^{\frac{1}{2}}}. \quad (25)$$

At the top of the sphere where $V/U=1.600$, $M_l=0.833$, and therefore there is no shock in the field of flow. This is to be expected since the critical Mach number of the undisturbed flow for shock establishment is approximately 0.55 as indicated in another paper by Tamada.[4]

# Minimum Sparking Potentials of Barium, Magnesium, and Aluminum in Argon

HAROLD JACOBS AND ARMAND P. LAROCQUE
*Sylvania Electric Products Inc., Kew Gardens, New York, New York**

(Received August 21, 1946)

Minimum sparking potentials of barium, magnesium, and aluminum in argon are found to be 93±½ v, 123±1 v, and 155±1 v, respectively. Utilizing the data in measuring the minimum sparking potentials, the ratios of electrons emitted from the cathode per bombarding positive ion ($\gamma_m$) are determined and found to be .149±.001 for barium, .089±.033 for magnesium, and .045±.002 for aluminum. A relationship is found such that, at a given field per unit pressure, a lower work function indicates a lower sparking potential and a higher $\gamma_m$ indicates a lower sparking potential, for the case of the three metals studied. A graphical method is proposed for predicting the minimum sparking potentials for metals, whose sparking potential values have not been determined, based upon the values of $\gamma_m$ or the work function $\phi$.

WHEN considering the design and manufacture of electron tubes which contain gases at reduced pressure, it has been found that the surface phenomenon plays a major role in successful operations and applications. For instance, the sparking potential of many gas tubes has been found to be a function of the cathode surface as well as the gas in the region of the minimum sparking potential. Similarly, the voltage drop across the gas tube while in operation is a function of the surface as well as the gas.

In spite of the large number of applications of gas tubes, relatively little is known concerning the actual mechanism of operation of these devices. This is probably due to the large number of variables which are possible in gas tubes, and to the fact that techniques of measurement have not been adequately developed. For instance, it has been found that small traces of mercury,[1] oil vapors, and oxygen in the gas or adsorbed by the surfaces in a tube will cause great alterations in the behavior of the tube. Thus, reproduceable results have been difficult to obtain, and, actually, it has only been in recent years that any valid data has been obtained.

One of the problems concerning gas tubes, then, is the effect of surfaces in gases upon sparking potential. In the following experiments, the surfaces of Ba, Mg, and Al were studied in reduced pressures of argon and the minimum sparking potentials obtained. From this data, various interpretations have been made including the deduction of the ratio of emitted electrons released by bombarding positive ions and the importance of this ratio upon the sparking potential.

## EXPERIMENTAL METHOD

Tubes were constructed as sketched in Fig. 1. It should be noted that these tubes consisted of two electrodes and a getter container which held the metal to be studied. Each of the two electrodes were made of nickel and shaped in the

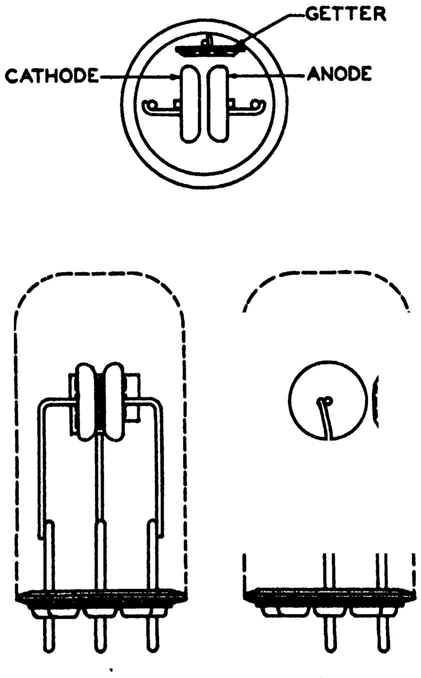

FIG. 1. Experimental tube.

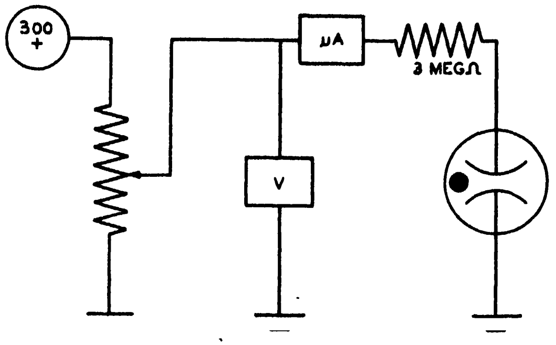

FIG. 2. Circuit for measuring sparking potentials.

manner of "Rogowsky electrodes."[2] That is, the electrodes were shaped such that surfaces facing each other followed equipotential lines. This was done to prevent concentrations of field at the edges and would make quantitative measurements of the field readily accessible. The tube to be studied was placed on exhaust together with a "dummy tube" containing only a barium-aluminum getter. This second tube was used as a reservoir to down any impurities in the argon, i.e., $O_2$, $N_2$, $H_2$ which was to be later admitted.

The nickel electrodes and getter container were then degassed as well as possible and the metal to be studied was evaporated on the nickel surface. In the case of barium, an iron clad barium getter was used and was electrically flashed. Magnesium powder was used for the Mg surface and aluminum powder for the Al surface. These reactions in no way depend upon reducing agents and hence the chance for impurity was greatly reduced. Argon was then admitted to the system from a standard Airco argon bottle (99.9+ percent pure). Liquid air was used at all times between the mercury manometer and the vacuum system. The electrical circuit used was such as sketched in Fig. 2. The criteria for sparking was such that a sudden rise in current would indicate the "breakdown" through the tube. In all cases, tests were conducted for stability of the surface before measurements were made. This was done by allowing 3μa current to pass through the tube. If current and voltage conditions were constant with respect to time, the surface was assumed to be stable. No measurement was made of the thickness of the metal deposited on the nickel cathode.

## DATA

The curves in Fig. 3 indicate the results of measuring sparking potential in relation to pressure times distance. In the case of Ba, Mg, and Al in argon, it was found that the minimum sparking potentials were $93\pm\frac{1}{2}$, $123\pm1$, and $155\pm1$ volts, respectively.

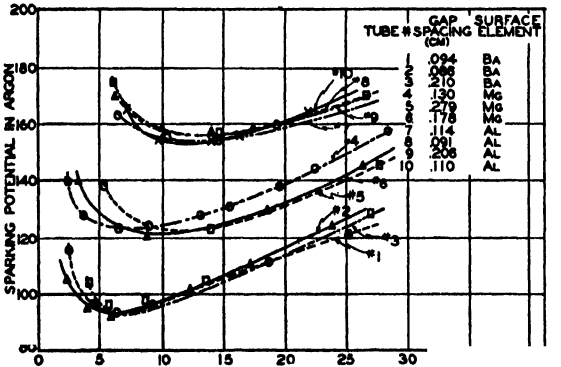
## PREVIOUS DATA CONCERNING COLD CATHODES

Before attempting to interpret the above data, it would be of interest to consider the work of previous experimenters in the field of cold cathodes.

It has been demonstrated,[3] that in tubes such as studied in these experiments, the following relation exists

$$i=i_0\frac{e^{\alpha x}}{1-\gamma(e^{\alpha x}-1)}. \tag{1}$$

$i$ = total current,
$i_0$ = constant,[4]
$x$ = distance between electrodes,
$\alpha$ = ratio of ions formed to electrons in a unit distance,
$\gamma$ = roughly, ratio of secondary emission from the cathode to the ions bombarding the cathode.



| TUBE # | GAP SPACING (CM) | SURFACE ELEMENT |
|---|---|---|
| 1 | .094 | BA |
| 2 | .086 | BA |
| 3 | .210 | BA |
| 4 | .130 | MG |
| 5 | .279 | MG |
| 6 | .178 | MG |
| 7 | .114 | AL |
| 8 | .091 | AL |
| 9 | .206 | AL |
| 10 | .110 | AL |

FIG. 3. Sparking potentials of barium, magnesium, and aluminum in argon *vs.* pressure×distance. The ordinate identifications should read 0, .5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0.

[3] L. B. Loeb, *Fundamental Processes of Electrical Discharge in Gases* (J. Wiley & Sons, Inc., New York, 1939), 378.

[4] The symbol $i_0$ which is the initial photoelectric current leaving the cathode is not truly constant and for very large values of $i$, there is found to be a slight drop in the

Now, this equation has been used by some experimenters as a criteria for determining or predicting sparking potentials. That is, if the denominator goes to zero, the current goes to infinity. Hence, a criteria for sparking may be:

$$1-\gamma(e^{\alpha x}-1)=0,\ \gamma=\frac{1}{e^{\alpha x}-1}. \tag{2}$$

As we shall see later, the higher the value of $\gamma$, the lower is the sparking potential in a given gas. Thus, the constant is extremely important from the point of view of any quantitative work on low pressure cold cathode discharge tubes. The exact interpretation of $\gamma$ has not been well developed, but it should be emphasized that although $\gamma$ is roughly the ratio of emitted electrons per positive ion bombarding the cathode, it also contains the ratio of electrons per quanta of light producing photoelectrons, and possibly several other sources of electrons which have been assumed to be small in comparison with the first ratio. Because of the importance of $\gamma$ in gas discharge work, there has been some research in recent years to determine the nature of $\gamma$ and the mechanism involved.

As late as 1938, Bowls[5] opened many questions concerning the constant $\gamma$. He utilized a mercury free vacuum system, platinum and sodium cathodes, and nitrogen gas. He obtained his values of $\gamma$ not by sparking but by measuring current and computing $\gamma$ from the following equation.

$$i=i_0\frac{(\alpha-\beta)e^{(\alpha-\beta)x}}{\alpha-\beta e^{(\alpha-\beta)x}}, \tag{3}$$

where

$$\beta/\alpha=\gamma.$$

Three very important discoveries were brought to light.

1. There was an "anomalous" peaking of $\gamma$ at low $X/p$ values. This had never been observed by sparking potential measurements.

2. When Hg was introduced to the system, radically different results occurred as to the value of $\gamma$. Thus, it appears that all work done previously without safeguards as to mercury contamination may have been in serious error.

3. In nitrogen, the Na cathode had a lower $\gamma$ than the Pt cathode. This is contrary to what would be expected since the lower work function cathode should have the higher $\gamma$ and hence the lower sparking potential.

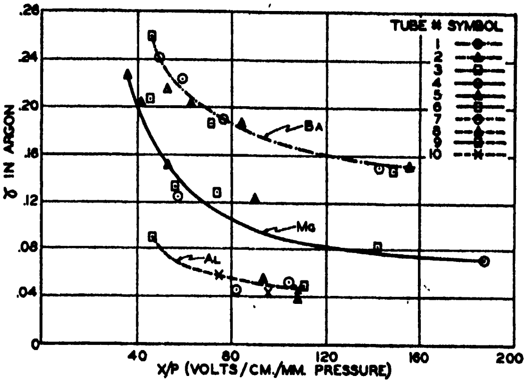

FIG. 4. $\gamma$ of barium, magnesium, and aluminum in argon *vs.* field per unit pressure.

In 1939, Hale[6] continued this work, but this time made measurements in hydrogen instead of nitrogen. His results again indicated:

1. An "anomalous" peaking in $\gamma$ appeared at very low $X/p$ values. (Pt: $X/p=125$; NaH: $X/p=10$.)

2. The presence of Hg could alter the characteristics of the surface completely.

3. Except at very low $X/p$ ratios, the $\gamma$ of the sodium was less than that for platinum.

Now, in this work, it was thought that the anomalous peaking was caused by a photoelectric phenomenon. That mercury vapor could change the surface was well established. The question of work function *versus* $\gamma$ was by no means settled and still remains open to question. In the experiments of Bowls and Hale, it is possible that the nitrogen and hydrogen combined with the Na surface in such a manner as to create a high work function surface. The answers to this question will be revealed by further experiments in inert gases.

In 1939, Huxford[7] studied Cs-Ag-O surfaces in photo-tubes filled with argon. He measured $\gamma$ by two methods, using the sparking criteria method as indicated above and also the method of measuring current prior to discharge and calculating the $\gamma$-values by means of Eq. (1). He obtained very good agreement using both methods.

Another piece of work is described by Loeb[8]

---

sparking potential. However, for very small currents ($<1\ \mu$a) such as used in the experiments above, the effect is small and has not been detected experimentally. For further comment, see L. B. Loeb, reference 3, pp. 420–425.

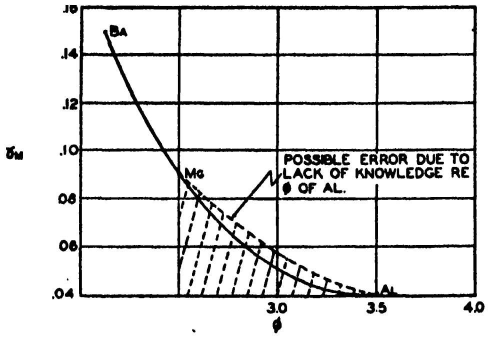

FIG. 5. $\gamma_m$ (ratio of emitted electrons per bombarding positive ion at the minimum sparking potential) *vs.* work function.

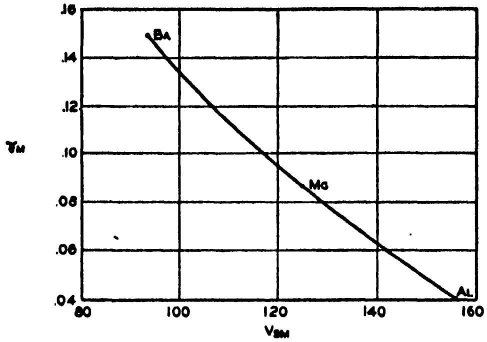

FIG. 6. $\gamma_m$ (ratio of emitted electrons per bombarding positive ion at the minimum sparking potential) as a function of the minimum sparking potential.

concerning some work done by Engstrom[9] on barium cathodes in argon. Here, also, good agreement is obtained between the two methods of measuring $\gamma$ except that the sparking method provides a smoother line. In other words, it is claimed that when measuring by sparking methods, the anomalies are wiped out and a more continuous value of $\gamma$ is obtained as a function of $X/p$.

## INTERPRETATION OF DATA

With the above background in mind, we can now return to the data concerning Ba, Mg, and Al in argon. Utilizing Eq. (2) again:

$$\gamma=\frac{1}{e^{\alpha x}-1},\quad X=\frac{V_s}{x},$$
$$\therefore\quad \gamma=\frac{1}{e^{\alpha}V_s/X-1},\quad \gamma=\frac{1}{e^{(\alpha/p)\cdot(p/X)V_s}-1}. \tag{4}$$

$V_s$ = sparking potential,
$X$ = field (volts/cm),
$x$ = distance (cm),
$p$ = pressure (mm).

The values for $\gamma$ as determined by Eq. (4) are shown in Fig. 4. The $\gamma_m$ values (at the minimum sparking potential) were found to be .149±.001 for barium, .089±.033 for magnesium, and .045±.002 for aluminum.

Having evaluated $\gamma$, we are in a position to draw certain conclusions. The work functions of Ba,[10] Mg,[11] and Al[11] are 2.1 electron volts, 2.42 electron volts, and 3.57(2.5−3.6) electron volts, respectively.

We can therefore conclude from the data in Fig. 4, that, at any of the given values of $X/p$ in the range we have observed, and in the case of the metallic surfaces studied, a lower work function indicates a higher $\gamma$. And, in addition, from the data in Fig. 3, a lower work function will indicate a lower minimum sparking potential.

One may wonder, then, why Bowls obtained a lower $\gamma$ in a large region of $X/p$ for platinum than was obtained for sodium. The answer may well be that the Na was not free on his cathode surface, but was, in fact, combined to form a composite cathode with nitrogen.

We should emphasize that in the case of Ba, Mg, and Al we were dealing with pure metal surfaces. As yet, there are no available data concerning the effects of $\gamma$ and $\phi$ on composite cathodes in gas tubes.

Knowing $\gamma$ and the $\phi$ of the surfaces in argon, it may be possible to predict the $V_{sm}$ (minimum sparking potential) of a cold cathode gas tube. If these predictions are valid, the designer would take a tube with a given sparking requirement and estimate the region of sparking potential by considering the published values of the work functions of the surfaces. Loeb[12] gives the following formula for minimum sparking potentials.

$$V_{sm}=\frac{3B_4}{A_4}\log\frac{1}{\gamma_m}+\frac{B_4}{A_4}\,\frac{1}{\log\left(\frac{1}{\gamma_m}\right)}. \tag{5}$$

[11] J. D. Cobine, reference 2, p. 109.

[12] L. B. Loeb, reference 3, p. 414.

$B_4$ and $A_4$ are constants which could be evaluated. However, at best, this is an empirical formula and does satisfy a requirement which can be fulfilled more rapidly and simply by graphical methods.

In the first graph, we have $\gamma_m$ *versus* $\phi$. (Figure 5.)

Then by either knowing $\gamma_m$ or $\phi$, we may estimate $V_{sm}$ of a surface in argon by Fig. 6.

As an example of the use of these charts, suppose we calculate the $V_{sm}$ of sodium. The $\phi$ of sodium is given as 2.46−1.90 volts.[13] This is roughly a $\gamma_m$ in argon of from .08 to slightly more than .15 using Fig. 5. Now, turning to Fig. 6, this is roughly between 90 volts and 125 volts. According to Loeb,[14] the $V_{sm}$ of a Na surface in argon is 95 volts, or in the expected region.

We realize our range is limited and more samples may be desirable in future work, but the indications are that this may be a fruitful method for utilizing data concerning cold cathodes.

# Fatigue of Ag-Cs$_2$O, Ag-Cs Photoelectric Surfaces

S. Pakswer
*Continental Electric Company, Geneva, Illinois*

(Received August 8, 1946)

Fatigue of Ag-Cs$_2$O, Ag-Cs surfaces has been observed in blue and red light. In blue light the long wave threshold shifts to shorter wave-length and the long wave maximum increases and sometimes shifts to shorter wave-length. Rise of temperature at the cathode counteracts the phenomena. In red light temperature effects are dominating. The observed phenomena are in line with de Boer's theory of the photoelectric effect on such surfaces as the formation of positive ions on the surface causes polarization of the neighboring Cs-atoms and a change in their selective absorption.

SURFACES with *S*1* spectral sensitivity have been commonly manufactured for a number of years and the technique of their production is well known. There is, however, little agreement concerning the mechanism of the photoelectric emission. The spectral sensitivity characteristic of the *S*1 surface shows two main maxima—one at approximately 3500A and the other around 8000A corresponding probably to two different emission processes. It has not yet been definitely established where these electron emission processes take place.

According to the ideas developed by J. H. deBoer,[1,2] the sensitivity maximum at 8000A is caused by cesium atoms adsorbed at so-called "active" spots on the surface of a semi-conductive layer containing Cs$_2$O and interspersed with Cs and Ag metal atoms. The surface layer of the semi-conductor polarizes the atoms of Cs and thus reduces their work function. The emitted electrons are supplied by diffusion through the layer of the semi-conductor.

Timofeev,[3] in a series of experimental investigations, emphasizes the importance of the formation of positive charges on the surface of the semi-conductive layer, and their influence on the photoelectric and secondary electron emission of Ag-Cs cathodes.

Other authors[4-6] believe that the photo-ionization takes place inside the layer of the semi-conductor as an "inner" photoelectric effect and that the electrons have to break through the

---

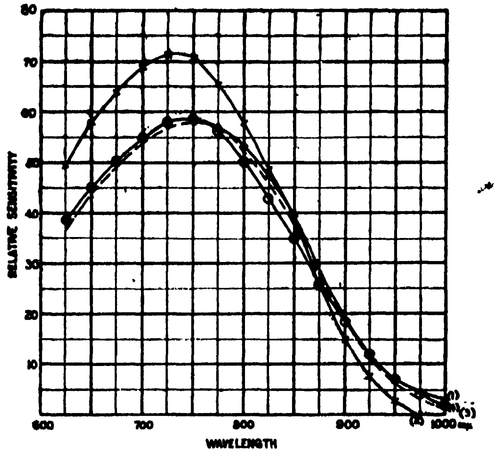

FIG. 2. Tube No. 10 type CE-1 vacuum exposed to blue light (500 w at 12″+filter 554) curve 1 (0): 0 hr., curve 2 ($X$): 1 hr., curve 3 (△): 24 hr. illumination, curve 4 (———): 50 hr. in the dark.

potential barrier at the surface, possibly at "active" spots.[5]

Experiments tend to support the deBoer conception[7] particularly the behavior in polarized light, the high velocity of emitted photoelectrons and the low quantum yield. The semi-conductor theory is supported by experience won on the secondary emission, by the spectral characteristic of the inner photo-effect[4] and by the influence of the thickness of the oxide layer on the sensitivity and the spectral characteristic of $S1$ surfaces.[8] Electron microscopic study of $S1$ surfaces,[9] showing spotty, non-uniform distribution of electrons emitted under illumination by light of 6000A, can be explained by both theories.

An insight into the mechanism of photoelectric emission can be obtained by a study of the fatigue of $S1$ surfaces. DeBoer[10] observed that tubes irradiated with blue light, without voltage applied, dropped in sensitivity to white incandescent light more than tubes irradiated with green light, and that red light and infra-red rays not only did not cause fatigue, but regenerated the original sensitivity of tubes which lost sensitivity. With voltage applied and a white light source, the drop of sensitivity was a function of the applied voltage and the illumination on the cathode. The fatigue phenomena increased at low temperature (−196°C) and decreased at higher temperature. In tubes exposed to white light of .15 lumen, the infra-red threshold was shifted considerably to shorter wave-lengths and the response in the maximum was lower and the maximum itself was shifted slightly to shorter wave-lengths.

To explain these phenomena deBoer assumed that the positive cesium ions recombine with electrons diffusing to them from the conductivity levels of the semi-conductor. The rate of recovery from fatigue is given by the rate of diffusion. Illumination with infra-red rays or rise of temperature increase the thermal agitation of

the lattice, and thus the amount of electrons diffusing toward the surface. If voltage is applied, positive cesium ions migrate toward the cathode into the layer and must be replaced by cesium atoms migrating from the layer to the surface. A decrease of free alkali atoms at the surface has also been observed by Timofeev and Kondorskaya[11] who found that the time variation in fatigue phenomena is a series of exponentials.

It was felt that the data given in literature do not give a complete picture of fatigue phenomena. Following observation of the influence of different parameters on the stability and the fatigue of Ag-Cs photo-tubes, it was, therefore, decided to obtain additional data. As sensitivity measurements in white light give only integrated values, it seemed that a study of spectral distribution would give a better picture of the phenomena.

Measurements of the distribution of spectral sensitivity were made with a Coleman spectrophotometer Model 10S, calibrated against a VanCittert monochromator and a thermopile. The instrument was a Leeds & Northrup galvanometer. The plate voltage was 22.5 v. The color temperature of the lamp in the photometer was 2870°K. All tests were made on tubes of the type CE-1/918, vacuum and gas-filled, with silver-plated copper cathode and also on gas-filled 918 tubes with massive silver cathode.

### TESTS IN "BLUE" LIGHT

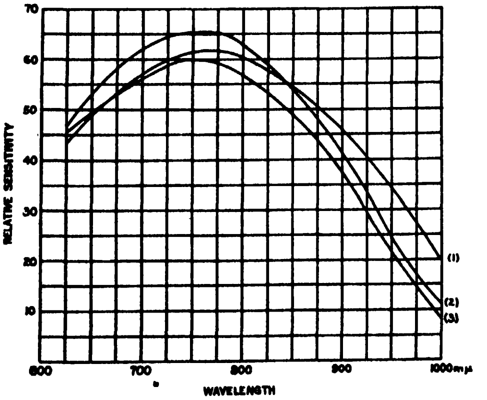

FIG. 4. Tube No. 3a. 918 gas-filled exposed to blue light (200-w lamp at 12″ filter 554) $V_A = 22.5$ v curve 1: 0 hr., curve 2: 3 hr., curve 3: 264 hr. illumination.

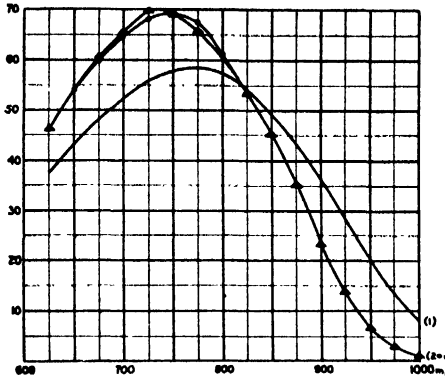

FIG. 5. Tube No. 16 CE-1 vacuum, curve 1: 0 hr., curve 2: exposed 1 hr. to blue light (500-w lamp at 1′+filter 554), curve 3: 2 hr. in dark at −80°C.

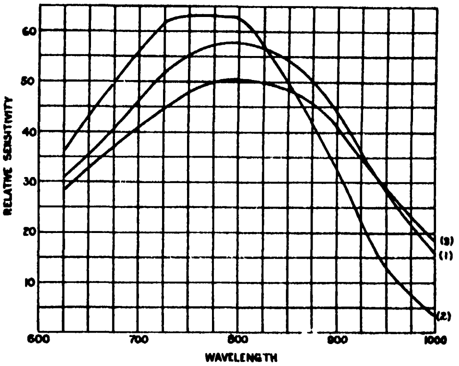

FIG. 6. Tube No. 17 CE-1 vacuum, curve 1:0 hr., curve 2: 1 hr. exposed to blue light (500-w lamp at 1′+filter 554), curve 3: 2 hr. in dark at +90°C.

The tubes were exposed to the light of a 200-w lamp at 12″ distance filtered by a Corning filter 554; only blue and ultraviolet radiation fell on the cathode. In some tests the 200-w lamp was replaced by a 500-w projection lamp. The intensity of the radiation in this case, as measured with a blue-sensitive CE-61 tube was increased three times.

In Figs. 1 and 2 are represented typical distribution curves. In Fig. 1 curve 1 is the original curve. After 1-hour illumination by the 200-w lamp without any plate current on, the sensitivity in the maximum surprisingly increased considerably and the threshold shifted to shorter wave-lengths (curve 2). After a protracted period of time the sensitivity at the maximum decreased slightly (curve 3, after 48 hr.) and the threshold was shifted still further. The tube was now kept in the dark. After 78 hours (curve 4) the increase at the maximum still persisted

---

[11] Timofeev and Kondorskaya, Physik. Zeits. Sovjetunion 9, 683 (1936).

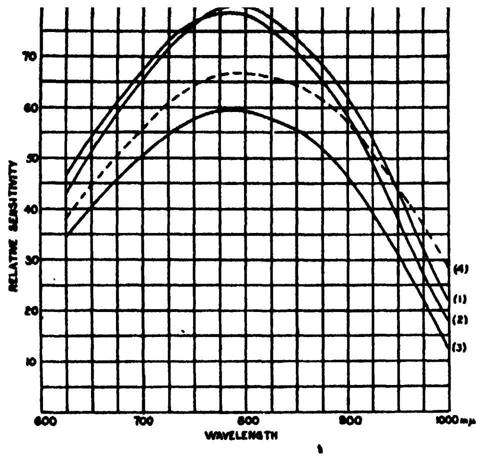

FIG. 7. Tube No. 15 type CE-1 vacuum exposed to red light (500-w lamp at 1′+filter 244) curve 1: 0 hr., curve 2: 1 hr., curve 3: 24 hr., curve 4: 50 hr. in the dark.

but the threshold moved back to longer wave-lengths.

This tube was now subjected to the light of the 500-w lamp (Fig. 2). After 1 hour the maximum had greatly increased (curve 2) but fell down rapidly (curve 3); the tube was heated up to about 50°C. After 50 hours in the dark (curve 4) the maximum and the threshold shifted to longer wave-lengths.

All other tubes investigated, gas-filled and vacuum, silver and silver plated, showed this initial increase in the maximum. Sometimes a shift in the maximum could be observed (Fig. 3). In Fig. 4 is shown the response of a tube with a silver cathode.

It was thought that these tests indicated the influence of three separate processes:

1. A process in blue light leading to a shift and an increase of the maximum and a shift of the threshold.
2. A process due to the rise of temperature which decreases the maximum.
3. A process in the dark which shifts the threshold back to longer wave-lengths.

To investigate further, separately, the influence of light and temperature two tubes were exposed to light of the 500-w lamp for 1 hour (curve 2, Figs. 5 and 6). Then one tube was kept for two hours in a mixture of solid $CO_2$ and acetone ($-80°C$) (curve 3, Fig. 5) and the other at $+90°C$ for the same period of time (curve 3, Fig. 6). In the first tube the initial changes persisted while in the second tube the sensitivity in the maximum decreased considerably and the sensitivity on the long wave side recuperated completely.

### TESTS IN "RED" LIGHT

The same lamps were used in conjunction with Corning filter 244 transmitting red-infra-red radiation. With the 200-w lamp the curves showed a small drop of sensitivity in all wave-lengths. With the 500-w lamp (Fig. 7) where the heat development on the cathode was considerable, the sensitivity in the maximum went down considerably after 24 hours (curve 3). A large amount of sensitivity, especially at long wave-lengths, was recuperated after 50 hours in the dark.

### CONCLUSION

It can be easily understood that changes of spectral sensitivity, combining with the energy distribution of an incandescent lamp, will cause variations of output current which will appear as "instability." Parameters affecting the long wave end of the sensitivity curve will have a relatively greater effect than parameters affecting the maximum. This will explain why "blue" light or high plate voltage cause a higher drop of sensitivity than red light. By proper choice of the color temperature of the lamp, the temperature, the applied voltage, and the intensity of the light, it is possible to balance the different influences out and obtain stable operation.

It is difficult to explain the observed phenomena solely by the recombination of positive ions and electrons. It can be easily shown that fatigue and recovery would follow exponential or hyperbolic laws in case of recombination and depending on its mechanism.

The increase and the shift of the maximum and the shift of the threshold indicate changes in the electrical state of the Cs-atoms on the surface due to the formation of positive charges. This polarization of atoms next to an ion, and the change of selective absorption of light following the Franck-Condon principle, have been described by deBoer in his book,[1] mainly on pages 193, 228, 280, and 333.

Acknowledgment is made to Mr. John A. Loeber, who performed most of the experiments described above.

# The Measurement of Elasticity in Fluids of Low Viscosity

John R. Van Wazer* and Herbert Goldberg**
*Department of Manufacturing Experiments, Eastman Kodak Company, Rochester, New York*

(Received August 19, 1946)

By means of an apparatus applying an alternating shearing motion to a liquid, it was shown that fluids with a viscosity of around one poise have elastic properties. A discussion of the variation of the resonance maxima with the amount of damping is given, and the shear modulus and damping viscosity are calculated for some dilute solutions of high polymeric materials.

## INTRODUCTION

Although all forms of matter exhibit elastic behavior upon the application of hydrostatic force, it is customary to think of only solids and rather thick gels as being elastic on the application of force in shear or extension. This viewpoint is based on the concept that the relaxation time of the structural bonds holding a liquid together is of the order of $10^{-8}$ sec. However, a different state of affairs exists in many fluids. When a close-knit gel of a high polymer is diluted, the interlocking molecular chains to which the elasticity in shear is attributed are gradually separated and broken. It thus appears that the shear modulus of such a gel will decrease upon dilution until there are not enough continuous polymer chains reaching from wall to wall to give a measurable elastic effect. This type of elasticity can be observed experimentally when the time in which inter-polymer bonds make or break is greater than or of the same order of magnitude as that of the experiment—that is to say, when the relaxation time is measurably long.

Kendall[1] has shown that some high polymeric solutions can be diluted to very low concentrations and still exhibit elastic recoil in shear. Although Kendall's method is very sensitive, it suffers from the difficulties of interpretation inherent in transient measurements. In the study reported below, the oscillatory method of Goldberg and Sandvik[2] has been adapted to the measurement of shear elasticity in fluids of low viscosity. This latter method appears to be as sensitive as that of Kendall and is, of course, more easily interpreted.

## EXPERIMENTAL PROCEDURE

The apparatus used in these experiments consisted primarily of a pair of concentric cylinders between which was placed the liquid under study. The outer cylinder was made from a piece of glass tubing selected for regularity of bore. It had a diameter of 1.240 cm. This cylinder was held in the apparatus so that it could be made to oscillate about its axis at a given amplitude and any chosen frequency. The frequency was adjusted by changing the speed of a variable speed motor which drove the oscillating cylinder through a cam and rocker-arm device. Photographic study showed that the rotatory oscillations of the outer cylinder were pure sine waves. The frequency of rotation of the outer cylinder was measured by a strobotac lamp.

The hollow inner cylinder (4.55 cm long with a diameter of 1.174 cm), having a low moment of inertia (4.12 g-cm$^2$) about its major axis, was suspended from a thin fiber. This low moment of inertia was achieved by building the cylinder of thin-walled tubing affixed to a heavy central shaft which served to weight the cylinder so that it would not float. A phonograph needle was used as a bottom bearing for the inner cylinder. Before an experiment was started, the cylinders were aligned by adjusting the support holding the suspension thread; then the inner cylinder was lifted slightly away from its bearing. A mirror was attached to the central rod of the inner cylinder so that a beam of light could be used to amplify its motion. The suspension fiber consisted of a single strand of untwisted silk approximately 15 cm long. Thus, the elasticity of the fiber was so slight that its contributions to the

[2] To be published.

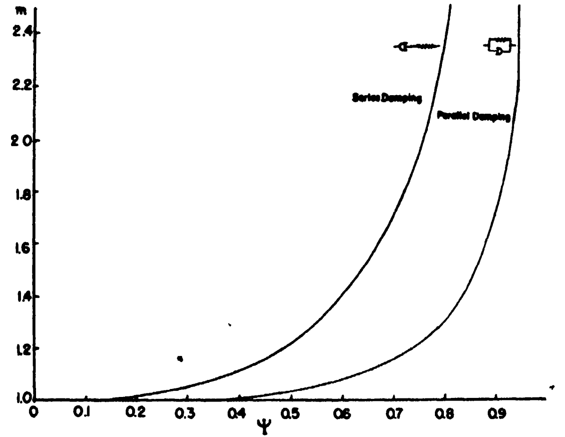

FIG. 1. Calculated variation of $\psi$ with $m$ at resonance for an elastic element with series or parallel damping.

observed elastic effects were negligible. In the studies reported below, end effects were negligible since the layer of liquid at either end of the inner cylinder was approximately 20 times thicker than that in the annular space between the two cylinders.

To make a measurement, the outer cylinder was filled with the solution under study, and then the inner cylinder was carefully inserted so that no air bubbles were entrapped between the two cylinders. After the cylinders were aligned, the outer cylinder was set in oscillation, and the amplitude of rotation of the inner cylinder was measured by the path of a beam of light reflected from its mirror onto a screen which was usually placed several meters from the instrument. Thus, any slight drifting of the inner cylinder with respect to the outer one was greatly amplified with the result that a slow erratic drifting was superimposed upon the oscillatory motion of the light spot. This necessitated "on the fly" measurement of the amplitude of oscillation with a caliper. When a non-elastic liquid was placed between the two cylinders, the inner cylinder had the same amplitude of rotation as that of the outer cylinder at low frequencies; and there was a gradual decrease in amplitude as the frequency was raised until at extremely high frequencies the inner cylinder remained practically motionless. When an elastic liquid was being studied, the amplitude of rotation of the inner cylinder was the same as that of the outer cylinder at very low frequencies and became negligibly small at high frequencies. However, at an intermediate frequency the amplitude of rotation of the inner cylinder was greater than that of the outer cylinder because of the phenomenon of resonance. It should be noted that the existence of mechanical resonance means that there is an elastic restoring force resisting distortion of the liquid. Therefore, the studies reported in this paper cannot be interpreted on the basis of thixotropy, simple non-Newtonian flow, or any other of the multitudinous rheological classifications which are concerned with changes in the internal friction of a substance.

The amplitude of rotation of the outer cylinder could be measured in two ways: first, by extrapolating the plot of amplitude *vs.* frequency of the inner cylinder to zero frequency, and secondly, by rigidly joining the two cylinders together and observing the light beam. The same value for the amplitude was always obtained by both of these methods.

The modulus of rigidity can be calculated from the following easily derived equation:

$$G_0=\frac{2\pi I}{r_1 L}\left(\frac{1}{r_1}-\frac{1}{r_2}\right)f_{\max}{}^2 \qquad (1)$$

where $G_0$ is the modulus of rigidity assuming no damping, $f_{\max}$ the resonance frequency, $L$ the length of the inner cylinder, and $r_1$ and $r_2$ are the radii of the inner and outer cylinders respectively.

The magnification factor, $m$, can be defined as the ratio of the amplitude of oscillation of the inner cylinder to that of the outer cylinder.

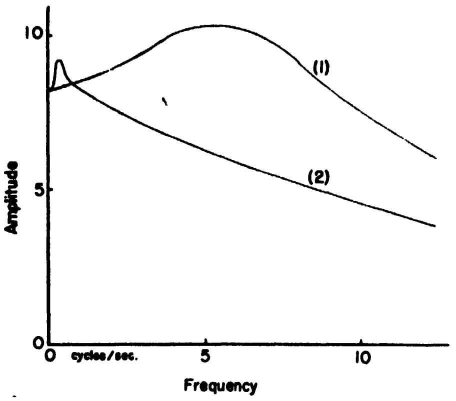

FIG. 2. Resonance curves: (1) methyl methacrylate polymer in dichlorobenzene; (2) rubber cement in benzene.

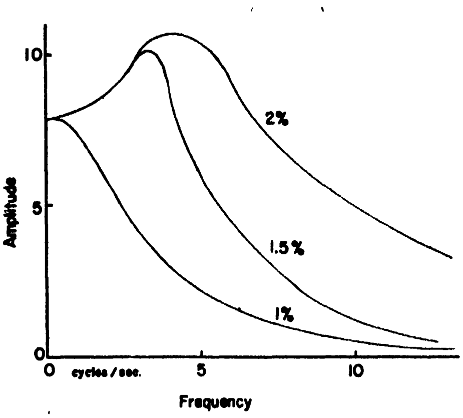

FIG. 3. Resonance curves for various concentrations of napalm in gasoline.

When the magnification factor is smaller than two or three, the modulus of rigidity computed from the previous equation is too small, because the damping causes a pronounced shift in the resonance frequency, and the equation is derived for an undamped system. It is impossible to compute the shift of the resonance maximum due to damping, unless a model for the system is assumed. We have calculated this shift for two models: a spring with parallel damping, and a spring with series damping. The calculations which are based on the direct electrical analog[3] are given in the appendix, and a graph of the ratio of the resonance frequency with damping to the resonance frequency that would be found, if the spring were not damped, *vs.* the magnification factor, is to be found in Fig. 1. From this graph the shear modulus as determined from the above equation can be corrected as follows:

$$G = G_0/\psi^2 \qquad (2)$$

where $G$ is the real shear modulus (assuming that the model is correct); $G_0$ is the shear modulus calculated from Eq. (1); and $\psi$ is the ratio of the frequencies taken from the graph. It is possible to compute the variation of $m$ with $\psi$ for the more complex model of a spring with a series and parallel dashpot, but instead of one $m-\psi$ curve, a family of curves will result depending on the relative values of the damping constants. However, this procedure was not followed because the apparent increase in accuracy of interpretation should not be accepted without fitting the whole frequency-amplitude curve.

The damping viscosity can be computed for the assumed models since the ratio of the damping viscosity to the shear modulus is related to the resonance frequency and magnification factor by means of Eqs. (2), (3), (6), and (9) in the Appendix, for the spring with either series or parallel damping. If the damping viscosity as calculated for series damping is much less than the viscosity determined in a conventional viscosimeter, the predominant damping is in parallel with the elastic element. If the calculated series viscosity is equal to the regular viscosity, the damping is in series with the elastic element. The calculated series viscosity cannot be greater than the regular viscosity. Thus, by comparison of the viscosity as calculated from the models with the regular viscosity, it is possible to find the predominant type of damping and thus the most correct value of the shear modulus as computed for a given fluid. In this discussion of damping, anomalous viscosity has been neglected since most fluids of low viscosity are only slightly non-Newtonian.

## DATA AND DISCUSSION

Several substances studied by Kendall were used with this apparatus to obtain the resonance curves shown in Fig. 2. The rheological constants derived from these measurements are presented in Table I.

An interesting series of measurements was performed on dilute sols of an aluminum soap

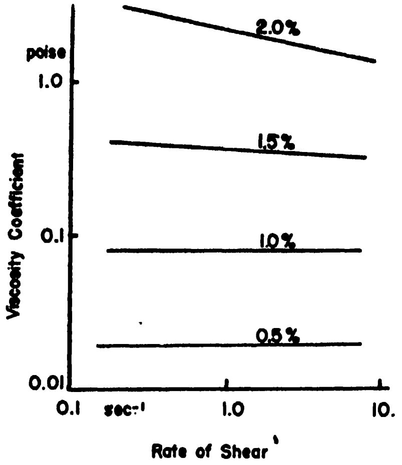

FIG. 4. The viscosity of napalm solutions at various concentrations.

in gasoline. The resonance curves for several concentrations are shown in Fig. 3. The constants calculated from these curves are presented in Table II. The predominant damping at a concentration of 1.5 percent is caused by the series viscosity. Measurements by Goldberg[4] indicate that the damping at concentrations higher than 6 percent is exclusively caused by the parallel viscosity. This means that both the viscosities in series and in parallel with the elastic element grow smaller with decreasing concentration, as might be expected. The transition from parallel to series damping of the elasticity occurs at about 2 percent. It is interesting to note that the concentration at which there is no longer any perceptible change of apparent viscosity coefficient with rate of shear (see Fig. 4) is also the concentration at which the resonance effect disappears.

The variation of shear modulus with molecular weight for a series of fractionated methyl methacrylate polymers is also given in Table II. Although the exact values of the maxima were difficult to determine because of the flatness of the resonance curves, it appears that the shear modulus increases with decreasing molecular weight at concentrations of equal viscosity. This result is in accord with the concept that the elastic properties of such a dilute solution are caused by the stretching of molecules.

TABLE II. Collected elastic data on fluids of low viscosity.

| Fluid studied | | Experimental data | | Calculated constants | | | | | Real constants | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | Shear modulus (dynes/cm²) | | | Damping viscosity (poises) | | | | |

## ACKNOWLEDGMENT

The work reported above was completed in August, 1943 under the sponsorship of N.D.R.C. We wish to thank Dr. E. K. Carver for his helpful advice and suggestions about this problem.

## APPENDIX

## Derivation of the Correction to Shear Modulus Due to Damping

The following discussion is based on the direct electrical analogy, the fundamental definitions of which are listed below:

| *Mechanical Quantity* | *Electrical Analogy* |
|---|---|
| $x$ displacement | $q$ charge |
| $F$ force | $v$ potential |
| $1/G$ reciprocal of shear modulus | $C$ capacitance |
| $n$ viscosity | $R$ resistance |
| $M$ mass | $L$ inductance |
| $v$ velocity | $i$ current |

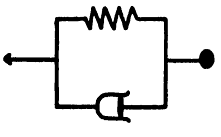
Because of the equivalence of Hooke's law to the capacity equation, the law of Newtonian viscosity to Ohm's law, and Newton's third law of motion to the equation for an inductance, this direct electrical analogy holds true.

Since sine wave oscillations are applied to the apparatus, the displacement $x$ is related to the amplitude $X$ according to the following equation in which $t$ is the time, $\delta$ is a constant to take care of phase difference, and $\omega=2\pi f$ ($f=$frequency):

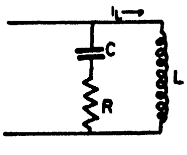
$$x_{\text{input}}=X_{\text{input}}\sin\omega t,$$
$$x_{\text{output}}=X_{\text{output}}\sin\omega(t+\delta).$$

By differentiation of the above equations with respect to time, we find that the ratio of the output to the input velocity equals the ratio of the output to the input amplitudes. This ratio is called the magnification factor and is denoted by the symbol $m$.

## Parallel Damping



Mechanical model



Electrical model

For this model undergoing sine wave oscillations we can set up the following equation for the magnification factor according to the direct electrical analog:

$$m=\frac{i_L}{i}=\frac{R-j/\omega C}{R+j(\omega L-1/\omega C)}. \tag{1}$$

This can be reduced to a more general form by use of $\psi=$the ratio of the observed damped frequency to the free natural frequency of the elastic element, and $d$, a damping coefficient.

$$d=R(C/L)^{\frac{1}{2}} \tag{2}$$

and since the free natural frequency equals $1/(LC)^{\frac{1}{2}}$

$$\psi=\omega(LC)^{\frac{1}{2}}. \tag{3}$$

Then

$$m=\frac{d-j/\psi}{d+j(\psi-1/\psi)}. \tag{4}$$

or

$$|m|^2=\frac{d^2+1/\psi^2}{d^2+\psi^2+1/\psi^2-2}. \tag{5}$$

If we differentiate and set $\partial m/\partial\psi$ equal to zero, the condition for a maximum, or resonance, is fulfilled and we find that

$$d^2=2(1-\psi^2)/\psi^4 \text{ at resonance.} \tag{6}$$

Equation (5) gives us the relation between $\psi$ and the physically measurable $m$. If we compute the shear modulus as if there were no damping, we obtain a quantity, $G_0$, according to the equation

$$G_0=k(f')^2.$$

But we really wish to know the true shear modulus

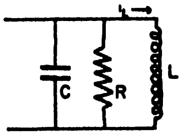
$$G=kf^2$$

where $f'$ is the observed frequency with damping, and $f$ is the free natural frequency.

By definition $\psi=f'/f$:

$\therefore$ $G=G_0/\psi^2$. (This is Eq. (2) in the text.)

## Series Damping



The equation for the magnification factor with the substitutions of $\psi$ and $d$, defined in Eqs. (2) and (3) above, is given below.

$$m=\frac{i_L}{i}=\frac{-j/\psi}{1/d+j(\psi-1/\psi)}, \tag{7}$$

and

$$|m|^2=\frac{(1/\psi)^2}{1/d^2+\psi^2+1/\psi^2-2}. \tag{8}$$

Differentiating with respect to $\psi$ and setting $\partial m/\partial\psi=0$, we find that

$$d^2=1/2(1-\psi^2) \text{ at resonance.} \tag{9}$$

From Eq. (9)

$$m^2=1/[\psi^2(3\psi-4)+1] \text{ at resonance.} \tag{10}$$

This relationship can be used to correct $G_0$ to $G$ as was shown above. Equations (5) and (10) are graphed in Fig. 1.

# On Creep and Relaxation*

B. Gross
*National Institute of Technology, Rio de Janeiro, Brazil*

(Received June 17, 1946)

The creep and the relaxation function of linear systems, for which the principle of superposition is valid, are mutually connected in a simple way. This makes it possible to calculate the distribution function of relaxation times of stress and the distribution function of retardation times of strain, when the relaxation function or the creep function is given. It also allows a transformation formula to be established for the conversion of one distribution function into another. The results of the theory are applied to a detailed discussion of the relaxation process in a particular case.

THE great development in the technique of high polymers has brought a renewed interest in the theory of elastic and dielectric relaxation phenomena. The phenomenological theory of these effects is still based upon the classical work of Boltzmann, Hopkinson, and Volterra. Its recent advance has been made possible by the improvements of the mathematical tools—the Fourier and Laplace transforms, Stieltjes' integral equation, and Heaviside's operational calculus. The classic work on the elastic effect has been carefully reviewed by Leaderman.[1] Modern methods of specification and correlation of the properties of viscoelastic materials were discussed by Alfrey and Doty.[2] The present paper continues in the sense of the phenomenological theory. It treats the relations existing between the creep and the relaxation function, shows how to deduce from them the underlying more fundamental quantities—the distribution functions of retardation time of strain and of relaxation times of stress—and establishes a general transformation formula between these 2 distribution functions.

Permanent deformations shall not be taken into account, because here we are interested only in reversible effects. This does not constitute a serious limitation for the theory; it is possible to deduce from the measured deformation- and load-time curves the corresponding curves, which would be observed, if permanent deformations were absent. Furthermore our considerations are confined to the linear problem. They are entirely based on the assumption that the principle of superposition is valid for creep and for relaxation. On this basis the fundamental relation between the creep and the relaxation function is established.

Even the linear elastic system, under constant strain, does not in general follow the simple exponential law of stress decay, that on theoretical grounds should be expected for a homogeneous material. Soon the hypothesis was formulated that the macroscopic body, that constitutes the object for the measurement, possesses a complex structure, being built up by a multiplicity of different elementary systems, each of them obeying the exponential law and characterized by a proper time constant. The observed curve of decay then represents an integral effect, the linear superposition of the single exponential functions. The distribution function of relaxation times is then more characteristic for a substance than the observed relaxation curve. Wiechert[3] proposed for the distribution function a Gaussian curve; Wagner[4] used the same expression in his theory of the electric after-effect. But *a priori* there seems to be no reason to believe in the existence of a single general law for the distribution function; this function may well have different forms for different materials. Thus the problem arises to deduce the distribution function from the experimental creep and relaxation data. Fuoss and Kirkwood[5] have given an extremely interesting method that allows calcula-

tion of the distribution function of relaxation times, when the admittance function or its real or imaginary part are known. In the field of elastic phenomena, admittance and impedance measurements are not made with the same ease as for dielectrics and they would not lead to the determination of the long time end of the distribution function. Thus one must rely on the interpretation of long time creep and relaxation data. Simha[6] has already shown how to deduce the distribution function of relaxation times, when the creep function is given. Here this problem is treated by a method that is similar to and was suggested by that of Fuoss-Kirkwood; it leads to expressions for the distribution function, which lend themselves readily for analytic or numerical computation.

Parallel with stress relaxation under constant strain goes strain retardation under constant stress. And instead of the first, one can choose the second effect as the adequate basis for a discussion of the structure of the viscoelastic body. Then a reasoning analogous to that outlined above leads to the introduction of the distribution function of retardation times of strain; this derives from the creep function in the same way as does the other distribution from the relaxation function. Thus the problem of its determination is the same and is solved in the same way as the former one.

The two distribution functions are not independent from one another. The present theory establishes the transformation formulae for their mutual conversion. They are expressions which are of a very general scope and well suited for numerical computation.

The results of the general theory are applied to the study of the relaxation process in the particular case in which the creep function is represented by a given analytic expression. To start with, the simple power law is chosen. The corresponding relaxation function is found to be given by a known transcendent, the Mittag-Leffler function, which already has been discussed in detail in connection with various relaxation phenomena. It behaves reasonably at medium values, but does not describe correctly the behavior of the stress for very great values of time, giving too high a value for the amount of stress relaxation. To amend it, an amplitude factor is introduced in the law for the relaxation function, without a modification of the form of the law. With this new expression one calculates backward the creep function, to which it belongs, and gets in this way adequate representations for both the creep and the relaxation function. Then the distribution functions are calculated, and finally the behavior for small times is studied.

## I. RELATIONS BETWEEN THE CREEP AND THE RELAXATION FUNCTION

### Creep

The deformation, which in a viscoelastic body is produced by the application of a constant load $P_0$, increases with time. It contains a purely elastic, constant component $P_0F/E$, $E$ being the instantaneous value of the modulus of elasticity and $F$ a form factor, and a time-dependent, slowly increasing component $P_0\psi(t)F/E$. $\psi(t)$ is called the creep function. The total deformation under constant load is, therefore, given by

$$y(t)=P_0[1+\psi(t)]F/E. \tag{1}$$

The deformation produced by the application of a variable load $P(t)$ can be calculated with the aid of the principle of superposition

$$y(t)=\frac{F}{E}\left[P(t)+\int_{-\infty}^{t}P(\tau)\varphi(t-\tau)d\tau\right], \tag{2}$$

where

$$\varphi(t)=d\psi(t)/dt \text{ (rate of creep).} \tag{3}$$

### Relaxation

The load $P(t)$ necessary to produce in a viscoelastic body a constant deformation $y_0$ decreases with time, because the creep of the system gives rise to a phenomenon of stress-relaxation. There is

$$P(t)=y_0[1-\bar{\psi}(t)]E/F. \tag{4}$$

$\bar{\psi}(t)$ is the relaxation function.

The load necessary to produce a variable deformation $y(t)$ can again be calculated with the aid of the principle of superposition

$$P(t)=\frac{E}{F}\left[y(t)-\int_{-\infty}^{t}y(\tau)\bar{\varphi}(t-\tau)d\tau\right], \tag{5}$$

---

[6] R. Simha, J. App. Phys. 13, 201 (1942).

where

$$\bar{\varphi}(t)=d\bar{\psi}(t)/dt \text{ (rate of relaxation).}^7 \tag{6}$$

### Relations between Creep and Relaxation

The Eqs. (2) and (5) are 2 equivalent expressions of the fundamental experimental fact, on which this theory is based—the validity of the principle of superposition. Their coexistence implies a relation between the creep and the relaxation function. To obtain it easily, substitute $P(t)=\exp(pt)$ in (2) and (5). Since

$$\int_{-\infty}^{t} e^{p\tau}\varphi(t-\tau)d\tau=e^{pt}\int_{0}^{\infty} e^{-p\tau}\varphi(\tau)d\tau, \tag{7}$$

it follows that $y(t)=\text{const.}\exp(pt)$. There results finally

$$\bar{L}(p)+\bar{L}(p)L(p)-L(p)=0, \tag{8}$$

where

$$L(p)=\int_{0}^{\infty} e^{-pt}\varphi(t)dt, \tag{9a}$$

$$\bar{L}(p)=\int_{0}^{\infty} e^{-pt}\bar{\varphi}(t)dt. \tag{9b}$$

The deduction shows that $p$ may be real positive or complex, but it must not be on the negative real axis, because then the integrals would diverge. If $p$ is purely imaginary, equal to say $i\omega$, $L(i\omega)$ stands for the Fourier integral; if $p$ is real positive, $L(p)$ stands for the Laplace integral. Accordingly, 2 equivalent treatments are possible, i.e., by Fourier transforms or by Laplace transforms. Here we consider only the latter one.

Equation (8) is the fundamental relation, on which depend most of the following considerations. It may be solved with respect to $\bar{L}$ or to $L$:

$$\bar{L}(p)=\frac{L(p)}{1+L(p)}, \tag{10a}$$

$$L(p)=\frac{\bar{L}(p)}{1-\bar{L}(p)}. \tag{10b}$$

With the aid of these equations, it is possible to calculate the rate of creep, when the rate of relaxation is given, or *vice versa*.[8] In both cases, the wanted function is given by an integral equation—the Laplace transform. This must be inverted, when one wishes to obtain the explicit expressions for $\bar{\varphi}$ or $\varphi$. The inversion of the Laplace transform has recently been studied extensively.[9] A very general inversion formula now available is the Bromwich-Wagner or complex inversion formula; this was used by Simha[6] in his calculation of the distribution function of relaxation times. But other methods too may be employed, for instance, those of the operational calculus. And frequently one may find the solution with the aid of a table of Laplace transforms. Therefore, there is here no necessity to write down explicitly the formal expressions for the functions $\varphi$ and $\bar{\varphi}$, so more so as in the present case a more simple way of analysis is possible, based on the implicit relations (10). This is possible, because the functions we are dealing with are very particular ones; they are continuous, continuously decreasing and integrable functions, which in their turn can be represented as Laplace transforms.

## II. THE DISTRIBUTION FUNCTIONS FOR CREEP AND FOR RELAXATION

There are 2 fundamental representations of a viscoelastic body by way of models; the Voigt model and the Maxwell model. Alfrey and Doty[2] have given very recently in this Journal a concise discussion of the properties of these models. We, therefore, can confine ourselves to a summary description.

### The Voigt Model

The Voigt element consists of a spring and a dashpot connected in parallel. Creep under constant stress then follows an exponential law $\beta(1-\exp t/\tau)$, the time constant of which is the retardation time of strain. It indicates the time necessary for the time-dependent component of

---

[7] Different cases of creep, creep recovery, and relaxation as well as the deduction of the Eqs. (2) and (5) from (1) and (4) are discussed in detail by Leaderman (reference 1). The symbols used by this author are here conserved, but the functions $\varphi$ and $\bar{\varphi}$ are not normalized. This avoids the introduction of the 2 constants $\beta$ and $\bar{\beta}$, which in the present case are not relevant.

[8] Relations of this type are by no means new. For instance, they are already given by J. R. Carson, *Electric Circuit Theory and Operational Calculus* (McGraw-Hill Book Company, Inc., New York, 1926), pp. 51–52.

[9] See for instance, R. V. Churchill, *Modern Operational Methods in Engineering* (McGraw-Hill Book Company, Inc., New York, 1944).

deformation to reach a fraction $(1-e)$ of its final value. The Voigt model of a complex body consists of a multiplicity of Voigt elements with different time constants placed in series. The stress being the same for all, each element takes its share of the total strain. In the limit, the discontinuous system goes over in a continuous one, characterized by the distribution function $F(\tau)$ of retardation times. $F(\tau)d\tau$ is the fraction of the strain, which under constant stress has a retardation time between $\tau$ and $\tau+d\tau$. With the Voigt model, the fundamental experiment is the measurement of strain retardation, or creep, under constant stress. This gives the creep function, which in terms of the distribution function $F(\tau)$ is given by

$$\psi(t)=\beta\left[1-\int_0^\infty F(\tau)e^{-t/\tau}d\tau\right]; \qquad (11a)$$

$F(\tau)$ satisfies the normalizing condition

$$\int_0^\infty F(\tau)d\tau=1. \qquad (12)$$

### The Maxwell Model

The Maxwell element consists of a spring and a dashpot connected in series. Stress relaxation under constant strain follows an exponential law $\bar{\beta}(1-\exp t/\tau)$, the time constant of which is the relaxation time of stress. The Maxwell model of the complex body consists of a multiplicity of such elements placed in parallel. The strain being the same for all, each element takes its share of the stress, according to the value of its time constant. In the limit, the discontinuous system goes over in a continuous one, characterized by the distribution function $\bar{F}(\tau)$ of relaxation times. $\bar{F}(\tau)d\tau$ is the fraction of the stress, which under constant strain relaxes with a time constant between $\tau$ and $\tau+d\tau$. With the Maxwell model, the fundamental experiment is the measurement of stress relaxation under constant strain. This gives the relaxation function, which in terms of the distribution function $\bar{F}(\tau)$ is given by

$$\bar{\psi}(t)=\bar{\beta}\left[1-\int_0^\infty \bar{F}(\tau)e^{-t/\tau}d\tau\right]. \qquad (11b)$$

$\bar{F}$ satisfies a normalizing condition of the type (12).

### The Distribution Functions for Creep and for Relaxation

For the following it is more convenient to work with the functions $\varphi$ and $\bar{\varphi}$. It is easily seen, that these can be represented as

$$\varphi(t)=\int_0^\infty \rho(s)e^{-ts}ds, \qquad (13a)$$

$$\bar{\varphi}(t)=\int_0^\infty \bar{\rho}(s)e^{-ts}ds. \qquad (13b)$$

The functions $\rho$ and $\bar{\rho}$ introduced in this way are related to $F$ and $\bar{F}$ by the equations

$$\beta F(\tau)d\tau=-\rho(s)ds/s, \qquad (14a)$$

$$\bar{\beta}\bar{F}(\tau)d\tau=-\bar{\rho}(s)ds/s, \qquad (14b)$$

$$s=1/\tau. \qquad (14c)$$

We call $\rho$ the distribution function for creep and $\bar{\rho}$ the distribution function for relaxation. By means of Eqs. (14) it is always easy to go over to the "true" distribution functions $F$ and $\bar{F}$. The normalizing constants $\beta$ are determined with the aid of Eq. (12). Equations (14) show that the distribution functions can indeed be represented as Laplace transforms of "primitive" functions $\rho$. The possibility of this representation does not depend on the validity of the 2 models we have discussed, but ensues from the mathematical properties of the functions $\varphi$ and $\bar{\varphi}$. It is a common feature of all linear theories of relaxation phenomena.

## III. DETERMINATION OF THE DISTRIBUTION FUNCTIONS

Experimental evidence gives the functions $\varphi$ and $\bar{\varphi}$. Physically more interesting are the distribution functions $\rho$ and $\bar{\rho}$, because their knowledge may yield information about the structure of the system and the nature of the relaxation mechanism. One way of analysis consists in writing down an analytic expression for the distribution functions, which on theoretical grounds appears plausible and allows the calculation of the creep or the relaxation function, and then the comparison of the calculated and the measured curves. A second method consists in deducing the distribution functions from the experimentally given set of data. This can be done by an inversion of Eqs. (13).

## Distribution Function for Relaxation from Relaxation Function. Distribution Function for Creep from Creep Function

To obtain the inversion formula in the form needed here multiply both sides of Eq. (13b) by $e^{-pt}$ and integrate from 0 to $\infty$. This gives

$$\int_0^\infty e^{-pt}\bar{\varphi}(t)dt=\int_0^\infty e^{-pt}dt\int_0^\infty \bar{\rho}(s)e^{-st}ds. \quad (15)$$

The left side, according to Eq. (9b), is equal to $\bar{L}(p)$. On the right side the order of integration can be inverted and the integral over the exponential functions can be evaluated. This gives

$$\bar{L}(p)=\int_0^\infty \frac{\bar{\rho}(s)}{s+p}ds. \quad (16)$$

It is again not necessary for $p$ to be real; it may be complex, but it must not be on the negative real axis. Then (16) is Stieltjes' integral equation, which is inverted by[10]

$$\bar{\rho}(p)=\frac{1}{2\pi i}\lim_{\delta+0}[\bar{L}(-p-i\delta)-\bar{L}(-p+i\delta)]. \quad (17)$$

An analogous expression is obtained for $\rho(p)$.

To demonstrate the validity of (17), substitute in Eq. (16), $(-p-i\delta)$ for $p$. There follows

$$\lim_{\delta+0}\bar{L}(-p-i\delta)=\lim_{\delta+0}\int_0^\infty\frac{\bar{\rho}(s)(s-p)ds}{(s-p)^2+\delta^2}+\lim_{\delta+0}i\delta\int_0^\infty\frac{\bar{\rho}(s)ds}{(s-p)^2+\delta^2}. \quad (18)$$

In the first integral, one can put $\delta=0$, provided Cauchy's principal value is taken. To calculate the second integral, we observe that

$$\lim_{\delta+0}\delta\int_0^\infty\frac{\bar{\rho}(s)-\bar{\rho}(p)}{(s-p)^2+\delta^2}ds=0. \quad (19)$$

Indeed, the value of the integral *without* the factor $\delta$ in front of it is certainly finite even in the limit $\delta=0$; thus the expression *including* this factor disappears for $\delta=0$. But

$$\lim_{\delta+0}\delta\int_0^\infty\frac{\bar{\rho}(p)ds}{(s-p)^2+\delta^2}=\bar{\rho}(p)\lim_{\delta+0}\tan^{-1}(s/\delta)\Big|_{-p}^{\infty}=\pi\bar{\rho}(p). \quad (20)$$

The value of the second integral in (18) is, therefore, $i\pi\bar{\rho}(p)$. And

$$\lim_{\delta+0}\bar{L}(-p-i\delta)=\int_0^\infty\frac{\bar{\rho}(s)ds}{(s-p)}+i\pi\bar{\rho}(p); \quad (21a)$$

analogously,

$$\lim_{\delta+0}\bar{L}(-p+i\delta)=\int_0^\infty\frac{\rho(s)ds}{(s-p)}-i\pi\rho(p). \quad (21b)$$

The difference of both expressions gives $2\pi i\bar{\rho}(p)$.[11]

Equations (21) show that $\lim_{\delta+0}\bar{L}(-p-i\delta)$ and $\lim_{\delta+0}\bar{L}(-p+i\delta)$ are conjugate functions:

$$\lim_{\delta+0}[\bar{L}(-p-i\delta)-\bar{L}(-p+i\delta)]=2i\,Im\lim_{\delta+0}\bar{L}(-p-i\delta), \quad (22a)$$

$$\lim_{\delta+0}[\bar{L}(-p-i\delta)+\bar{L}(-p+i\delta)]=2\,Re\lim_{\delta+0}\bar{L}(-p-i\delta). \quad (22b)$$

$\lim_{\delta+0}\bar{L}(-p-i\delta)$ is equivalent to $\lim_{\epsilon+0}\bar{L}(\bar{p}e^{-i(\pi-\epsilon)})$; in a shorthand way this is written as $\bar{L}(pe^{-i\pi})$, provided the right meaning is attached to this expression: given $\bar{L}(p)$, $p$ positive; take the value that this function assumes when the argument is rotated through the under half-plan by an angle $-\pi$.[12] Accordingly, we replace the expressions $Im\lim_{\delta+0}\bar{L}(-p-i\delta)$ and $Re\lim_{\delta+0}\bar{L}(-p-i\delta)$, respectively, by $Im\,\bar{L}(pe^{-i\pi})$ and $Re\,\bar{L}(pe^{-i\pi})$. There results finally

$$\bar{\rho}(p)=Im\,\bar{L}(pe^{-i\pi})/\pi, \quad (23a)$$

$$\rho(p)=Im\,L(pe^{-i\pi})/\pi. \quad (23b)$$

The second equation is obtained by a development identical with that given above. When $\varphi$ and $\bar{\varphi}$ are known, $L$ and $\bar{L}$ can be calculated from (9). Then the distribution functions are obtained in a simple way. The deduction shows that the variable $p$ in (23) is equivalent with the variable $s$ of the Eqs. (14). Thus $\rho(p)dp$ and $\bar{\rho}(p)dp$ are, respectively, identic with $\rho(s)ds$ and $\bar{\rho}(s)ds$.

[11] The evaluation of lim $\bar{L}(-p-i\delta)$ is a particular case of the calculus of the boundary values of a function along a given path. For a general solution of this problem see A. Hurwitz and R. Courant, *Funktionentheorie* (Verlagsbuchhandlung, Julius Springer, Berlin, 1929), pp. 333–335.

[12] Employing this terminology we follow E. C. Titchmarsh, *Introduction to the Theory of Fourier Integrals* (Clarendon Press, Oxford, 1937), pp. 317–319, where a discussion of Stieltjes' integral equation is given.

### Distribution Function for Relaxation from Creep Function. Distribution Function for Creep from Relaxation Function

Frequently another type of relation is of interest. From the experimental point of view it is easier to measure the creep function than the relaxation function; but for theoretical reasons one may want the distribution function of relaxation times. This demands a formula that allows deduction of the distribution function for relaxation from the creep function, a problem that has already been discussed by Simha.[6] The particular type of inversion formula (17) makes it easy to solve this problem. By means of this equation, $\bar{\rho}(p)$ is expressed in function of the Laplace transform $\bar{L}(p)$ of $\bar{\varphi}(t)$; this in its turn is given in function of the Laplace transform $L(p)$ of $\varphi(t)$ by (10a). Substitution of (10a) in (17) directly gives, therefore, the wanted relation

$$\bar{\rho}(p)=\frac{1}{2\pi i}\lim_{\delta+0}\left[\frac{L(-p-i\delta)}{1+L(-p-i\delta)}-\frac{L(-p+i\delta)}{1+L(-p+i\delta)}\right]=\frac{1}{2\pi i}\frac{\lim\limits_{\delta+0}L(-p-i\delta)-\lim\limits_{\delta+0}L(-p+i\delta)}{[1+\lim\limits_{\delta+0}L(-p-i\delta)][1+\lim\limits_{\delta+0}L(-p+i\delta)]}. \quad (24)$$

An analogous expression is obtained for $\rho(p)$. Using the relations (22), the formula is transformed in a way similar to that of Eq. (17). There results after simple algebraic transformations

$$\bar{\rho}(p)=-\frac{1}{\pi}\frac{Im\,L(pe^{-i\pi})}{[1+Re\,L(pe^{-i\pi})]^2+[Im\,L(pe^{-i\pi})]^2}, \quad (25a)$$

$$\rho(p)=-\frac{1}{\pi}\frac{Im\,\bar{L}(pe^{-i\pi})}{[1-Re\,\bar{L}(pe^{-i\pi})]^2+[Im\,\bar{L}(pe^{-i\pi})]^2}. \quad (25b)$$

### An Auxiliary Formula

Equations (23) and (25) give the distribution functions in terms of the Laplace transforms of $\varphi$ and $\bar{\varphi}$, not in terms of the creep and relaxation functions themselves. These Laplace transforms are given by (9); when their values $L$ and $\bar{L}$ are known explicitly, the expressions $Im\,L(pe^{-i\pi})$ and $Re\,L(pe^{-i\pi})$ are easily calculated. For many functions, which are here of interest, the integrals can be evaluated in closed form. But in other cases this may not be so. Formulae, which allow to calculate the distribution functions without the previous explicit knowledge of $L(p)$ and $\bar{L}(p)$ are, therefore, of importance. Their deduction shall be discussed in a mathematical paper to be published elsewhere. The result is

$$Im\,L(pe^{-i\pi})=\int_0^\infty e^{-pt}\,Im\,\varphi(te^{-i\pi})dt, \quad (26a)$$

$$Re\,L(pe^{-i\pi})=-\int_0^\infty e^{-pt}\,Re\,\varphi(te^{-i\pi})dt. \quad (26b)$$

The same relations hold for $\bar{L}$ and $\bar{\varphi}$. They apply, when $\varphi$ in its turn is a Laplace transform.

For the application, the experimentally given set of creep or relaxation data must be represented by appropriate analytic functions, and the integrals (26) be calculated. Their evaluation may not always be possible in closed form, but provided the integrand can be written down explicitly, numerical methods can be employed.

## IV. RELATIONS BETWEEN THE DISTRIBUTION FUNCTIONS

The existence of a relationship between the creep and the relaxation function obviously also implies a direct relation between the corresponding distribution functions. For instance, assuming that the distribution function of relaxation times is represented by Wiechert's function, it must be possible to calculate the corresponding distribution function of retardation times, without previously calculating the creep and the relaxation function. To obtain this relation in a general form, we start with Eq. (24). The functions $\lim\limits_{\delta+0}L(-p\mp i\delta)$ are expressed in terms of $\rho(p)$ by means of (21). There results after simple algebraic transformations

$$\bar{\rho}(p)dp=\frac{\rho(p)dp}{\left[1+\int_0^\infty \frac{\rho(s)ds}{(s-p)}\right]^2+\pi^2\rho^2(p)}, \tag{27a}$$

$$\rho(p)dp=\frac{\bar{\rho}(p)dp}{\left[1-\int_0^\infty \frac{\bar{\rho}(s)ds}{(s-p)}\right]^2+\pi^2\bar{\rho}^2(p)}. \tag{27b}$$

These formulas convert one distribution function into another. They are of a very general scope, well adapted for analytic and numerical computation. Since the integration can be performed by graphical methods it would not even be necessary to represent $\rho$ or $\bar{\rho}$ by an analytic expression. The integrals are principal values, but the singularity at $s=p$ creates no difficulty; the way such integrals are handled has already been discussed in a former paper.[13]

## V. STUDY OF PARTICULAR CREEP AND RELAXATION FUNCTIONS

The simple power law

$$\psi(t)=kt^m, \quad 0<m<1 \tag{28}$$

is one of the functions which most frequently have been proposed as a mathematical expression for experimental creep data. It has the serious fault that it does not reach asymptotically a constant value for very great values of $t$, but yields an ever increasing deformation. But the fact alone that it has survived the many objections raised against it speaks much in favor of it being at least a reasonable approximation to the true fact, valid over a certain interval of time. Thus it is worth while to study the relaxation function that according to this theory is associated with it. The result shall lead us to a generalization of this law that is free of the fault mentioned above.

### The Simple Power Law

The rate of creep is given by

$$\varphi(t)=\beta(t/t_0)^{m-1}. \tag{29}$$

For the following it is convenient to introduce a numerical factor

$$\lambda=\beta t_0\Gamma(m), \tag{30}$$

where $\Gamma(m)$ is the gamma-function $\Gamma(m+1)=m!$[14] Substitution of (29) in (9a) gives

$$L(p)=\lambda(t_0p)^{-m}. \tag{31}$$

Then, according to Eq. (10a), $\bar{L}(p)$ is given by

$$\bar{L}(p)=\frac{\lambda(t_0p)^{-m}}{1+\lambda(t_0p)^{-m}}. \tag{32}$$

To obtain $\bar{\varphi}(t)$, the Laplace transform (9b) must be inverted, with $L(p)$ given by (32). There results

$$\bar{\varphi}(t)=-\frac{d}{dt}E_m[-\lambda(t/t_0)^m]. \tag{33}$$

$E_m(t)$ is a known transcendent, the function of Mittag-Leffler, defined by

$$E_m(t)=\sum_{n=0}^{\infty}\frac{t^n}{\Gamma(nm+1)}. \tag{34}$$

The relaxation function is given by

$$\bar{\psi}(t)=1-E_m[-\lambda(t/t_0)^m]. \tag{35}$$

*The deduction* of (33) is easily obtained by the Heaviside operational calculus.[15] Expand $pL(p)$ in descending powers of $p$. For the sake of simplicity put $\sigma=\lambda t_0^{-m}$. Then

$$p\bar{L}(p)=\sigma p^{1-m}[1-\sigma p^{-m}+\sigma^2p^{-2m}-\sigma^3p^{-3m}+-\cdots]. \tag{36}$$

Replace, according to the Heaviside rule, $1/p^n$ by $t^n/\Gamma(1+n)$. This gives

$$\bar{\varphi}(t)=\frac{\sigma t^{m-1}}{\Gamma(m)}-\frac{\sigma^2t^{2m-1}}{\Gamma(2m)}+\frac{\sigma^3t^{3m-1}}{\Gamma(3m)}-\frac{\sigma^4t^{4m-1}}{\Gamma(4m)}+-\cdots. \tag{37}$$

Observing that $m\Gamma(m)=\Gamma(m+1)$, Eq. (37) is easily identified with the series expansion of the derivative of the Mittag-Leffler function of argument $\{-\lambda(t/t_0)^m\}$. The inversion of the Laplace transform in the present case can also be obtained by the more orthodox method of the complex inversion theorem. This was shown by Moraes and Schoenberg.[16]

An *asymptotic expansion* valid for great values of $t/t_0$ is also obtained in the Heaviside way. Expand $pL(p)$ in ascending powers of $p$.

$$p\bar{L}(p)=p[1-p^m/\sigma+p^{2m}/\sigma^2-p^{3m}/\sigma^3+p^{4m}/\sigma^4-+\cdots]. \tag{38}$$

---

[13] H. Silva and B. Gross, Phys. Rev. 60, 684 (1941). The method indicated in this paper has recently been used by S. T. Ma, Phys. Rev. 68, 166 (1945).

[14] Tables and integral representations of the gamma-function are given by Jahnke-Emde, *Tables of Functions* (B. Teubner, Leipzig, 1933), pp. 86, 96.

[15] Reference 8, p. 28. $\bar{L}(p)$ of the present paper corresponds to Carson's $1/pH(p)$; thus Carson's expansion of $1/H(p)$ corresponds in our case to an expansion of $p\bar{L}(p)$.

[16] A. de Moraes and M. Schoenberg, Ann. Acad. Brasil. Ci. 12, 137 (1940), Section 4.

Replace $p^n$ by $t^{-n}/\Gamma(1-n)$, discard the term with an integer power in $p$ (because $p^1$ gives $1/t\Gamma(0)$; but $\Gamma(0)=\infty$) and get

$$\bar{\varphi}(t)=-\frac{\sigma^{-1}t^{-m-1}}{\Gamma(-m)}+\frac{\sigma^{-2}t^{-2-m1}}{\Gamma(-2m)}-\frac{\sigma^{-3}t^{-3m-1}}{\Gamma(-3m)}+\frac{\sigma^{-4}t^{-4m-1}}{\Gamma(-4m)}-+\cdots. \quad (39)$$

*The Mittag-Leffler function* is a generalization of the exponential function, with which it is identical, when the parameter $m$ is 1. It is already known to be of importance for relaxation phenomena of various kinds. Several of its mathematical aspects as well as its connection with the theory of nerve conduction have been discussed by Davis.[17] In connection with the theory of the discharge and return voltage curves for absorptive capacitors it has been studied by Castro, who has also availed himself of a very useful approximate representation.[18] For certain integer values of $m$ it can be expressed by elementary transcendents. For small values of $m$ a simple approximation formula exists. There is furthermore $E_m(0)=1$ and $E_m(-\infty)=0$.

Very valuable information about the behavior of the expression (33) is contained in a paper by Cole and Cole.[19] A comparison of their formulae (8) and (10) with the Eqs. (37) and (39) of the present paper shows them to be identical, up to a constant, the parameter $m$ corresponding to Cole's $1-\alpha$. (The Coles write $-nm\Gamma(1-nm)$ for $\Gamma(-nm)$.) This shows, that the Cole's expression for the absorption current is identic with our expression (33) for the rate of relaxation; it allows to use Fig. 1 and Table I of the Cole's paper for computation of the rate of relaxation in exactly the same way as those authors use them for the computation of the dielectric absorption current, and relieves us here of the task to give a plot or tabulate the function $\bar{\varphi}(t)$.

For very small values of $t$, $\bar{\varphi}(t)$ is given by the leading term of (37). Thus, when $t$ approaches 0, $\bar{\varphi}(t)$ tends to $\infty$ in the same way as does $\varphi(t)$

$$t\rightarrow 0:\quad \bar{\varphi}(t)=\bar{\beta}(t/t_0)^{m-1}. \quad (40)$$

For very great values of $t$, $\bar{\varphi}(t)$ is given by the leading term of (39). Observing that $\Gamma(m)\Gamma(-m)=-\pi/m\sin\pi m$,[14] there results

$$t\rightarrow\infty:\quad \bar{\varphi}(t)=\frac{m\sin\pi m}{\pi\beta t_0{}^2}(t/t_0)^{-(m+1)}. \quad (41)$$

Thus when $t$ approaches $\infty$, $\bar{\varphi}(t)$ tends to 0 much more rapidly than does $\varphi(t)$. It follows that the integral taken from 0 to $\infty$ remains finite.

It is known that experimental creep data frequently call for a very small value of $m$. In this case a satisfactory elementary approximation for $E_m(t)$ exists.[18] It allows to write $\bar{\varphi}(t)$ in the form

$$\bar{\varphi}(t)=\beta(t/t_0)^{m-1}\frac{1}{[1+\beta t_0(t/t_0)^m/m]^2}, \quad (42)$$

an expression that shows well the general behavior of the function and its departure from the simple power law.

## The Mittag-Leffler Function

It cannot be expected that these formulae describe correctly the experimental relaxation data for great values of $t$, based as they are on a creep law that admittedly fails for such values. Indeed, an inspection of Eq. (35) shows that $\bar{\psi}(t)$ approaches 1, when $t$ approaches $\infty$. This means, that in the case of stress relaxation under constant strain (Eq. (4)) the stress decays to 0, an absurd result that obviously is a consequence of the infinite increase of the creep function (28). In reality the amount of stress relaxation is only a rather small fraction of the total stress. To get a relaxation function that fulfills this condition it is not necessary to modify the general form of the relaxation law (35). It is sufficient to postulate that the amplitude of the function is not 1, but smaller than 1. Thus one must introduce an amplitude factor $a<1$, writing

$$\bar{\psi}(t)=a[1-E_m\{-(t/t_0)^m\}]. \quad (43)$$

A comparison with Eq. (4) shows the significance of $a$; $1-a$ represents the relation between final load $P(\infty)$ and initial load (or stress) $P(0)$.

$$1-a=P(\infty)/P(0). \quad (44)$$

We, therefore, are led to believe that Eq. (43) is an adequate analytic expression for the relaxation function. Now one has to calculate the creep function to which it belongs.

The rate of relaxation is now given by

$$\bar{\varphi}(t)=-a\frac{d}{dt}E_m[-(t/t_0)^m]. \quad (45)$$

The corresponding Laplace transform $\bar{L}(p)$, according to (32) and (33), is

$$\bar{L}(p)=a\frac{(t_0p)^{-m}}{1+(t_0p)^{-m}}. \quad (46)$$

---

[17] H. T. Davis, *The Theory of Linear Operators* (The Principia Press, Bloomington, 1936).

[18] F. M. de Oliveira Castro, Zeits. f. Physik **114**, 116 (1939).

[19] K. S. Cole and R. H. Cole, J. Chem. Phys. **10**, 98 (1942).

Substitution of (46) in (10b) gives

$$L(p)=\frac{a}{1-a}\frac{(1-a)(t_0p)^{-m}}{1+(1-a)(t_0p)^{-m}}. \qquad (47)$$

Therefore,

$$\varphi(t)=-\frac{a}{1-a}\frac{d}{dt}E_m[-(1-a)(t/t_0)^m]. \qquad (48)$$

Both the creep and the relaxation function are now represented by the same general law; they differ only by the values of the parameters. This is very satisfactory; it brings out the experimental fact that those functions are of the same type. By an appropriate choice of $a$, $t_0$, and $m$, a great variety of experimental curves can be represented, varying from the simple power law to the exponential function. The asymptotic expressions (40) and (41) and the approximation formula (42) now apply to creep and to relaxation; they must only be completed by the corresponding amplitude factor. The numerical analysis of creep and relaxation data can be performed by the methods given by Cole and Cole[19] and already mentioned above. But it cannot be the purpose of this paper to enter into details of numerical computation.

The problem could have been approached from the side of the creep function too. The expression (33) is in itself a generalization of the simple power law, coinciding with it for small values, but converging more rapidly at great values, of $t$. This would suggest the possibility of introducing it as a suitable substitute for the power law. In the corresponding electric case, Cole and Cole[19] proceeded in an analogous way, when they represented the dielectric absorption current by such an expression.

## A Functional Relation between Creep and Relaxation Function

Since $\varphi(t)$ and $\bar{\varphi}(t)$ are given by the same general law, a direct relation between them is readily established. It follows from Eqs. (48) and (45) that

$$\bar{\varphi}(t)=(1-a)^{(m-1)/m}\varphi\left[\frac{t}{(1-a)^{1/m}}\right]. \qquad (49)$$

This possibility of direct computation of relaxation data from creep measurements should be of particular interest for technical applications.

## The Distribution Function

The distribution function of relaxation times, that belongs to the relaxation function (43) is easily calculated. Since the Laplace transform $\bar{L}(p)$ of $\bar{\varphi}(t)$ is known explicitly, Eq. (23) applies directly. Replace in (46) $p^m$ by $(pe^{-i\pi})^m$. Then

$$\bar{L}(pe^{-i\pi})=\frac{a}{1+(t_0p)^m(\cos\pi m-i\sin\pi m)}. \qquad (50)$$

To get $\bar{\rho}(p)$ one has to take the imaginary part of this expression. Thus

$$\bar{\rho}(p)dp=-\frac{1}{\pi}\frac{a\sin\pi m\,dp}{(t_0p)^m+(t_0p)^{-m}+2\cos\pi m}. \qquad (51)$$

The distribution function has its maximum at $p=1/t_0$. Introducing a new variable

$$u=\log_e 1/t_0p \qquad (52)$$

normalizing, and observing that $p=1/\tau$, one gets

$$\bar{F}(\tau)d\tau=\frac{1}{2\pi}\frac{\sin\pi m}{\cosh um+\cos\pi m}du. \qquad (53)$$

The distribution function of retardation times is given by the same law, but while for relaxation $u=\log_e\tau/t_0$, there is for creep

$$u=\log_e\{\tau/t_0(1-a)^{1/m}\}.$$

$\bar{F}(\tau)d\tau$ as given by Eq. (53) is easily identified with the distribution function that Cole and Cole[20] have obtained for dielectric relaxation by the Fuoss-Kirkwood method.[6] These authors have discussed in detail the behavior of the function and compared it with the Wiechert-Wagner distribution.

## The Behavior for Small Times

The rates of creep and of relaxation as given by the Eqs. (45) and (48) become infinite at $t=0$, while theoretical expectations let us expect them to be finite. The study of the behavior for

---

[20] K. S. Cole and R. H. Cole, J. Chem. Phys. **9**, 341 (1941). Coles' parameter $1-\alpha$ corresponds to the parameter $m$ of the present paper.

small times should, therefore, be carried out with a class of functions that remain finite for $t=0$. An adequate representation for this interval would be

$$\bar{\varphi}(t)=\beta(c+t/t_0)^{m-1}, \quad c\ll 1. \tag{54}$$

The Laplace transform of this function cannot be written down explicitly. Thus one has to rely on the Eqs. (26). Here we shall confine ourselves to the discussion of the distribution function for relaxation. To obtain it, replace in Eq. (54) $t$ by $te^{-i\pi}$ and take the imaginary part of the expression $\bar{\varphi}(te^{-i\pi})$. This gives

$$Im\ \bar{\varphi}(te^{-i\pi})=\begin{cases}0 & \text{for } t<ct_0,\\ \beta\sin\pi(1-m)\,(t/t_0-c)^{m-1} & \text{for } t>ct_0.\end{cases} \tag{55}$$

The expression (55) is substituted in (26a). The integrand being 0 for $t<ct_0$, the integral now runs from $ct_0$ to $\infty$. By a change of variable, the integral is reduced to a gamma-function; the final result is[21]

$$\bar{\rho}(p)dp=\frac{\beta t_0}{\pi}\Gamma(m)\,\sin\pi(1-m)\frac{e^{-c(t_0p)}}{(t_0p)^{n}}$$

This distribution must be compared with (51). Here we are concerned only with small values of $t/t_0$, i.e., small values of $\tau$. Since $p=1/\tau$, this means, that we must consider only values of $(t_0p)$ very much greater than $c$. For such values, the distribution (51) decreases like $1/(t_0p)^m$, while the new distribution (56) decreases like $e^{-c(t_0p)}/(t_0p)^m$, i.e., much more rapidly than the former one. Practically, this signifies an exponential cut-off of the distribution function for small relaxation times.

I am very indebted to the Director of the Institute, Professor E. L. da Fonseca Costa, who made this study possible.

---

[21] This result can be found in tables of Laplace transforms; see for instance, Carson (reference 8), p. 39, formula (e). Here the deduction is outlined, because it is a good example for the application of Eq. (26).

# Parallel Plate Optics for Rapid Scanning*

S. B. Myers**
*Radiation Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received August 28, 1946)

Rapid scanning using a paraboloid antenna is unsatisfactory; rapid movement of the antenna is mechanically impractical, while motion of the feed near the focus requires long focal length for good optical results. Another attack on the problem is to place the feed between parallel plates which produce a line source near a bifocal reflector. The energy flows along the geodesics of the mean surface between the parallel plates; the problem of shaping the plates so that a circular feed motion produces an oscillating beam at the line source becomes a problem in differential geometry and the calculus of variations. If the mean surface is assumed to consist of two developable surfaces joined along part of their boundaries, the unique solution of the optical problem is a circular disk along the edge of which the feed moves, joined to a section of a 60° cone which is straightened out at the large end to obtain a straight line source. This is the RCA solution of the problem. If the surface is assumed to consist of a surface of revolution which provides a feed circle, and attached to it a circular disk a diameter of which is the aperture, under certain natural restrictions no exact solution of the optical problem is possible, but several approximate solutions exist. Dielectric introduced between the plates of such a surface of revolution scanner effects a great improvement in the optics.

## INTRODUCTION

RAPID scanning by means of movement of a paraboloid antenna is mechanically impractical. If the paraboloid is kept fixed, and the source of energy moved near the focus, the optical results are not satisfactory except with an extremely long focal length. Another approach to the problem is the following. If the energy feed be placed between two curved parallel plates, experiment has shown that the energy

---

* This paper is based on work done for the Office of Scientific Research and Development under Contract OEMsr-262 with the Massachusetts Institute of Technology.

** Now at the University of Michigan.

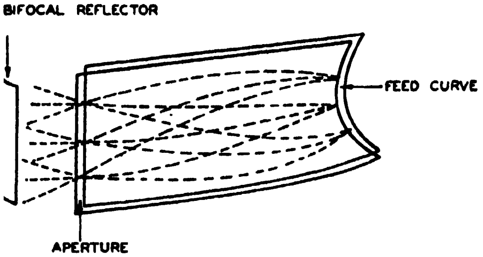

FIG. 1.

will flow along geodesics of the mean surface between the plates; if the parallel plates can be shaped so that a motion of the feed will produce an oscillating beam at a straight aperture, the latter will serve as a line source for a nearby bifocal reflector and the desired scanning is possible. For best illumination it is desirable that the normal ray from every point on the feed curve pass through a fixed point on the aperture; also, it is mechanically desirable that the feed curve be a circle. (See Fig. 1.)

A directed beam will be produced at the aperture by a fixed feed 0 if the phase errors at the aperture vary linearly with length along the aperture. The simplest way to accomplish this is to shape the parallel plates so that the mean surface is planar near the aperture, and the wave fronts are straight (near the aperture). This latter condition implies that the geodesics from 0 are parallel near the aperture. We are thus led to the following geometric problem. To find a surface $S$ containing a straight line $C_2$ and planar near $C_2$, and containing a curve $C_1$ (preferably a circle), with the property that the geodesics issuing from each point 0 of $C_1$ meet $C_2$ at a constant angle (which varies as 0 moves on $C_1$); further, the geodesics normal to $C_1$ must all meet on $C_2$.

This problem involves differential geometry and the calculus of variations. As yet it is not known whether a surface exists which meets all these requirements. Further, additional stringent restrictions as to size and shape of the antenna are usually imposed in any practical application. In this paper we discuss several approximate solutions of the problem, which seem suitable for application.

In Section 2 we take up a solution discovered by RCA; it yields perfect scanning optics (i.e., produces an oscillating beam at the aperture), but fails to meet the illumination requirement. The mean surface consists of a circular disk along the edge of which the feed moves, and a section of a 60° cone which is straightened out at the large end to obtain a straight line aperture (see Fig. 2). It is the only known surface which solves the optical problem exactly, and it is shown here that it is the unique method of joining two developable surfaces so as to obtain such optics. In Section 3, the "surface of revolution" solution is studied. Here the mean surface consists of a surface of revolution which provides a feed circle, and attached to it a circular disk a diameter of which is the aperture (see Fig. 3). Such a solution satisfies all requirements except the optical conditions. It is proved that these optical conditions cannot be satisfied exactly by any such surface if the radius of the surface is bounded by the radii of the feed circle and aperture disk. An investigation of the problem of minimizing the optical errors reveals that by shaping the surface in any one of several simple ways these errors can be made very small. In Section 4 it is shown that this same solution can be improved by use of dielectric between the parallel plates.

## 1. SURFACES AND GEODESICS[1]

Let a surface $S$ be given by equations $x=x(u, v)$, $y=y(u, v)$, $z=z(u, v)$. From the usual formula

$$ds^2=dx^2+dy^2+dz^2=A(u, v)du^2 +2B(u, v)dudv+C(u, v)dv^2$$

is obtained the expression for the length of a curve $u=u(t)$, $v=v(t)$.

$$s=\int(Au'^2+2Bu'v'+Cv'^2)^{\frac{1}{2}}dt =\int F(u, v, u', v')dt.$$

A geodesic may be defined as a shortest arc joining its endpoints. Using $s$ as parameter, the geodesics on $S$ are solutions of the equations

$$\frac{d}{ds}\left(\frac{\partial F}{\partial u'}\right)=\frac{\partial F}{\partial u},$$

$$F(u, v, u', v')=1.$$

Along a geodesic $g$, the geodesic curvature is zero (geodesic curvature of a curve $g$ at a point $P$ is by definition the curvature of the projection of $g$ on the tangent plane to $S$ at $P$).

Two fundamental properties of geodesics needed here are: (1) through every point on a surface and in every direction there is a unique geodesic, (2) if a constant length is measured off on geodesic rays through a point 0 the locus (geodesic circle) thus obtained is perpendicular to the rays through 0 (in other words, wave fronts from a point source are normal to the rays from the source). It can be shown that a geodesic crossing a sharp bend in a surface must make equal angles with the bend on both sides.

A developable surface is one which can be deformed locally onto a plane without stretching or tearing, thus preserving lengths. This is equivalent to the identical vanishing of the Gauss curvature. The fundamental form for a developable is the same as for the plane, $ds^2=du^2+dv^2$ or in polar coordinates, $dr^2+r^2d\theta^2$. Examples of developables are cylinders and cones. Two developables $S_1$ and $S_2$, $S_1$ containing a curve $C$ and $S_2$ containing a curve $C'$, can be joined along $C, C'$ as common curve without deforming $S_1$ if the curvature of $C$ at each point is greater than the geodesic curvature of $C'$ at the corresponding point. The geodesics on a developable become straight lines when the surface is developed onto a plane.

## 2. THE RCA SOLUTION

We take up the problem of finding a surface $S$, formed by joining two developables $S_1$ and $S_2$ along a common edge $\gamma$ (see Fig. 4), with the property that $S_1$ contains a curve $C_1$ and $S_2$ a straight line segment $C_2$ such that all geodesics from one point 0 of $C_1$ to the points of $C_2$ have equal lengths (this is equivalent to the condition that all these geodesics be perpendicular to $C_2$), and all geodesics from each point of $C_1$ near 0 to the points of $C_2$ have lengths which vary linearly with length along $C_2$ (this is equivalent to the condition that these geodesics meet $C_2$ at constant angle).

Let $S_1$ and $S_2$ be two developables joined along a common edge $\gamma$. Suppose each developable is developed into planar form, the curve $\gamma$ becoming two curves $\gamma_1$ and $\gamma_2$. Let 0 be a point in $S_1$ and let $\gamma_1$ and $\gamma_2$ be in contact at the foot of the normal from 0 to $\gamma_1$. Using coordinates as shown in Fig. 5, let the polar equation of $\gamma_1$ be $r=r(\theta)$. Now

$$ds^2=dr^2+r^2d\theta^2 \text{ along } \gamma_1,$$
$$ds^2=dx^2+dy^2 \text{ along } \gamma_2.$$

---

[1] See, for example, L. P. Eisenhart, *A Treatise on the Differential Geometry of Curves and Surfaces* (Ginn and Company, New York, 1909).

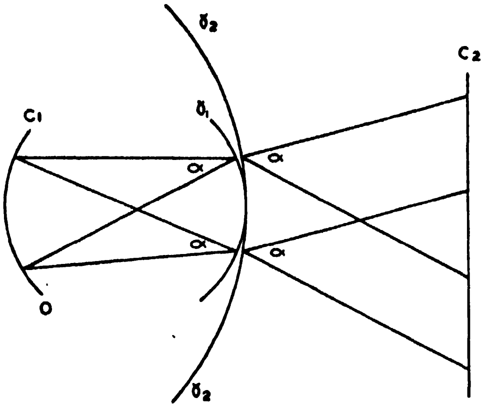

FIG. 6.

If the aperture $C_2$ is to be a wave front for rays from 0 when $\gamma_1$ and $\gamma_2$ are made to coincide, we must have $x=r(\theta)$ along $\gamma_2$. Hence $dx=dr$, $dy=rd\theta$ and the cartesian equations of $\gamma_2$ are

$$x=r(\theta),$$
$$y=\int_0^\theta r(\theta)d\theta. \tag{1}$$

If $C_2$ is to continue to cut the rays from the source 0 at equal angles as 0 moves along a feed curve $C_1$, then each pair of points on $C_1$ must subtend a constant angle $\alpha$ at all points of $\gamma$. Therefore $\gamma_1$ is a circle passing through each pair of points of $C_1$; hence $C_1$ and $\gamma_1$ are parts of the same circle $r=2a\cos\theta$. From (1) it follows that $\gamma_2$ has equations

$$x=2a\cos\theta$$
$$y=2a\sin\theta$$

and is a circle whose radius is double that of $\gamma_1$ (see Fig. 6).

If one-half of the circle $\gamma_2$ is made to coincide with $\gamma_1$, leaving $S_1$ fixed, the surface $S_2$ is deformed into the lateral surface of a cone inclined at a 60° angle to the circular disk $S_1$ (see Fig. 2). The aperture $C_2$ is now a curve on the side of a cone, but the figure can be deformed so that $C_2$ becomes straight in space. As the feed 0 rotates through a central angle $\beta$ on $C_1$, the beam issuing from $C_2$ tilts through an angle $\beta$.

This is the RCA solution. It furnishes the unique method of joining two developables so as to get exact scanning optics and is the only known method of obtaining such optics. However as 0 moves along $C_1$ the illumination pattern along $C_2$ changes, since the rays normal to $C_1$ do not pass through the same point of $C_2$.

### 3. SURFACE OF REVOLUTION SCANNER

A promising type of surface $S$ is composed of a surface of revolution $S_1$ with a base disk $S_2$ attached to it along a circular cross section (see Fig. 3). The feed curve $C_1$ is a circular cross section of $S_1$ and the aperture $C_2$ is the diameter of $S_2$. All the geodesics normal to $C_1$ pass through the center of the aperture, so that the illumination requirement is satisfied. Symmetry properties of $S$ show that if the geodesics from one point 0 of $C_1$ meet $C_2$ at a constant angle, so will the geodesics from any other point of $C_1$. We will show that such perfect optics are impossible if the radius of the surface is bounded by the radii of $C_1$ and $S_2$, and will investigate the question of shaping the surface so as to minimize the optical errors.

If $S_1$ is formed by rotating the curve $y=y(r)$ about the $y$ axis we obtain[2]

$$ds^2=dr^2+r^2d\theta^2+dy^2=(1+y'^2)dr^2+r^2d\theta^2,$$
$$y'=\frac{dy}{dr},$$
$$s=\int\left((1+y'^2)\left(\frac{dr}{dt}\right)^2+r^2\left(\frac{d\theta}{dt}\right)^2\right)^{\frac{1}{2}}dt.$$

The equations of geodesics on $S_1$ can be integrated once to give

$$r^2(d\theta/ds)=h,$$

where $h$ is a constant along each geodesic. But if

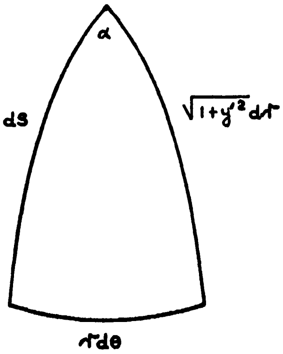

FIG. 7.

---

[2] Cf. Eisenhart, reference 1, pp. 205–206.

we denote by $\alpha$ the variable angle at which a geodesic meets a meridian, it is easy to see (Fig. 7) that

$$d\theta/ds=\sin\alpha/r.$$

Therefore along a geodesic $r\sin\alpha=h$. Since

$$\cos\alpha=(1+y'^2)^{\frac{1}{2}}\frac{dr}{ds},$$

we find that along a geodesic

$$r^2\left[1-(1+y'^2)\left(\frac{dr}{ds}\right)^2\right]=h^2.$$

Let 0 be the point on $C_1$ such that the plane through 0 and the axis of the surface is normal to the aperture $C_2$, let $g$ be a geodesic issuing from 0, and suppose that at 0 $r=r_0$ and $\theta=0$. Let $r_1$ be the radius of the base circle, $s_1$ the length of $g$ from 0 to the base circle, and $\alpha_0$, $\alpha_1$ the initial and final values of $\alpha$ on $g$ (see Fig. 8). Then

$$\left.\begin{aligned} s_1&=\left|\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}r\,dr}{(r^2-h^2)^{\frac{1}{2}}}\right|,\\ \theta_1&=h\left|\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{r(r^2-h^2)^{\frac{1}{2}}}\right|,\\ \alpha_1&=\arcsin\frac{h}{r_1}.\end{aligned}\right\}\qquad\text{(A)}$$

As $g$ enters the base disk, it becomes a straight line, whose perpendicular distance from the center of the aperture is $h$. Since the meridian geodesic from 0 meets the aperture at right angles, the problem of obtaining perfect optics is that of making all geodesics from 0 be normal to the aperture $C_2$; that is, we want $\theta_1=\alpha_1$ (see Fig. 9).

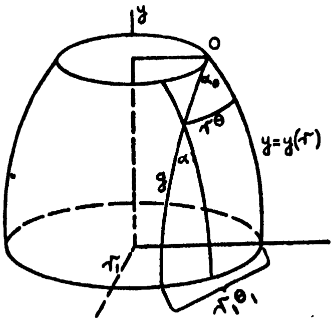

FIG. 8.

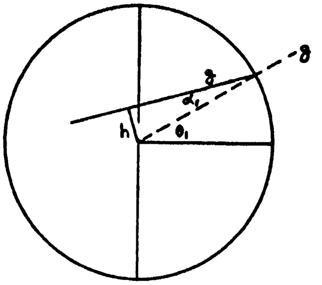

FIG. 9.

If $\theta_1-\alpha_1$ is expanded in a series about $h=0$, we obtain

$$\theta_1-\alpha_1=\sum_{n=1}^{\infty}A_{2n-1}\frac{h^{2n-1}}{2n-1}\frac{1\cdot3\cdot5\cdots(2n-1)}{2^{n-1}(n-1)!(2n-1)},$$

where

$$A_{2n-1}=(2n-1)\left|\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{r^{2n}}\right|-\frac{1}{r_1^{2n-1}}.$$

We now prove the impossibility of $\theta_1=\alpha_1$ for all $h$ by showing that

$$A_{2n+1}>\frac{A_{2n-1}}{\bar{r}^2},$$

where $\bar{r}$ is the larger of $r_0$, $r_1$, so that it is impossible that $A_{2n-1}=0$ for all $n$.

Let $F(r)=(1+y'^2)^{\frac{1}{2}}$. If $r_1>r>r_0$,

$$A_{2n+1}=(2n+1)\int_{r_0}^{r_1}\frac{Fdr}{r^{2n+2}}-\frac{1}{r_1^{2n+1}}$$

$$>(2n-1)\int_{r_0}^{r_1}\frac{Fdr}{r_1^2r^{2n}}-\frac{1}{r_1^{2n+1}}=\frac{A_{2n-1}}{r_1^2}.$$

If $r_0>r>r_1$,

$$A_{2n+1}=(2n+1)\int_{r_1}^{r_0}\frac{Fdr}{r^{2n+2}}-\frac{1}{r_1^{2n+1}}$$

$$=(2n+1)\int_{r_1}^{r_0}\frac{(F-1)dr}{r^{2n+2}}-\frac{1}{r_0^{2n+1}}$$

$$>(2n-1)\int_{r_1}^{r_0}\frac{(F-1)dr}{r_0^2r^{2n}}-\frac{1}{r_0^{2n+1}}=\frac{A_{2n-1}}{r_0^2}.$$

This proof can also be carried through for the case of a contour curve of the more general type $r=r(t)$, $y=y(t)$ provided that the upper and lower radii $r_0$ and $r_1$ are extreme values of $r$.

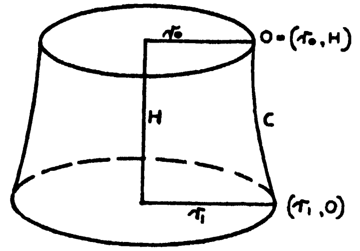

FIG. 10.

If $r_1>r_0$.

$$A_{2n+1}=(2n+1)\int_{t_0}^{t_1}\frac{\left[\left(\frac{dr}{dt}\right)^2+\left(\frac{dy}{dt}\right)^2\right]^{\frac{1}{2}}dt}{r^{2n+2}}$$

$$\frac{1}{r_1^{2n+1}}>\frac{A_{2n-1}}{r_1^2}.$$

If $r_0>r_1$,

$$A_{2n+1}=(2n+1)\int_{t_0}^{t_1}\frac{\left[\left[\left(\frac{dr}{dt}\right)^2+\left(\frac{dy}{dt}\right)^2\right]^{\frac{1}{2}}+\frac{dr}{dt}\right]dt}{r^{2n+2}}$$

$$\frac{1}{r_0^{2n+1}}>\frac{A_{2n-1}}{r_0^2}.$$

Thus we have proved the existence of phase errors at the aperture, provided that $r$ remains between $r_0$ and $r_1$ on the surface.

The size of these errors depends on the contour curve $C$, the upper and lower radii $r_0$ and $r_1$, and the height $H$. For fixed $r_1$, $H$ the phase errors approach zero as $r_0\rightarrow\infty$. But practical considerations restrict $r_0$, $r_1$, $H$. In view of applications the following problem is formulated.

For fixed $r_0$, $r_1$, $H$ what is the contour curve $C$ which maximizes the amount of the aperture for which the phase errors remain less than a pre-assigned amount?

The length of a geodesic from 0 to the aperture is easily computed to be

$$s_1+r_1\frac{\cos\theta_1}{\cos(\theta_1-\alpha_1)},$$

where $s_1$, $\theta_1$, $\alpha_1$ are given by Eqs. (A). The phase errors are given by the difference between this length and the length of the meridian ray from 0 to the aperture.

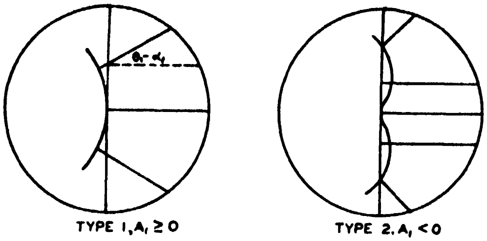

FIG. 11.

The maximizing problem stated above seems too difficult to approach directly, and we replace it by the problem of maximizing the amount of the aperture for which the angular error $|\theta_1-\alpha_1|$ remains less than a pre-assigned amount. This in turn we replace by the following first approximation (see Fig. 10).

What is the curve $C$: $y=y(r)$ in the $(r, y)$-plane which furnishes a minimum value to $A_3$ among all curves of the form $y=y(r)$ joining $(r_0, H)$ to $(r_1, 0)$ and making $A_1=0$? ($A_1$ and $A_3$ as before are the first terms occurring in the expansion of $\theta_1-\alpha_1$.)

The graph of a wave front is either of two types shown in Fig. 11, depending on whether $A_1\geqq 0$ or $A_1<0$.

The problem just formulated is equivalent geometrically to flattening the wave front of Type 1 at its center as much as possible. Analytically, we are led to an isoperimetric problem[3] in the calculus of variations—to find the curve $y=y(r)$ which belongs to the class of curves joining $(r_0, H)$ to $(r_1, 0)$ and making

$$\left|\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{r^2}\right|-\frac{1}{r_1}=0,$$

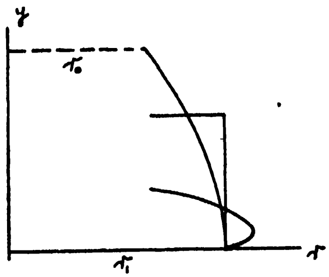

FIG. 12.

---

[3] See, for example, O. Bolza, *Vorlesungen über Variationsrechnung* (B. G. Teubner, Leipzig, 1933), Chapter 10.

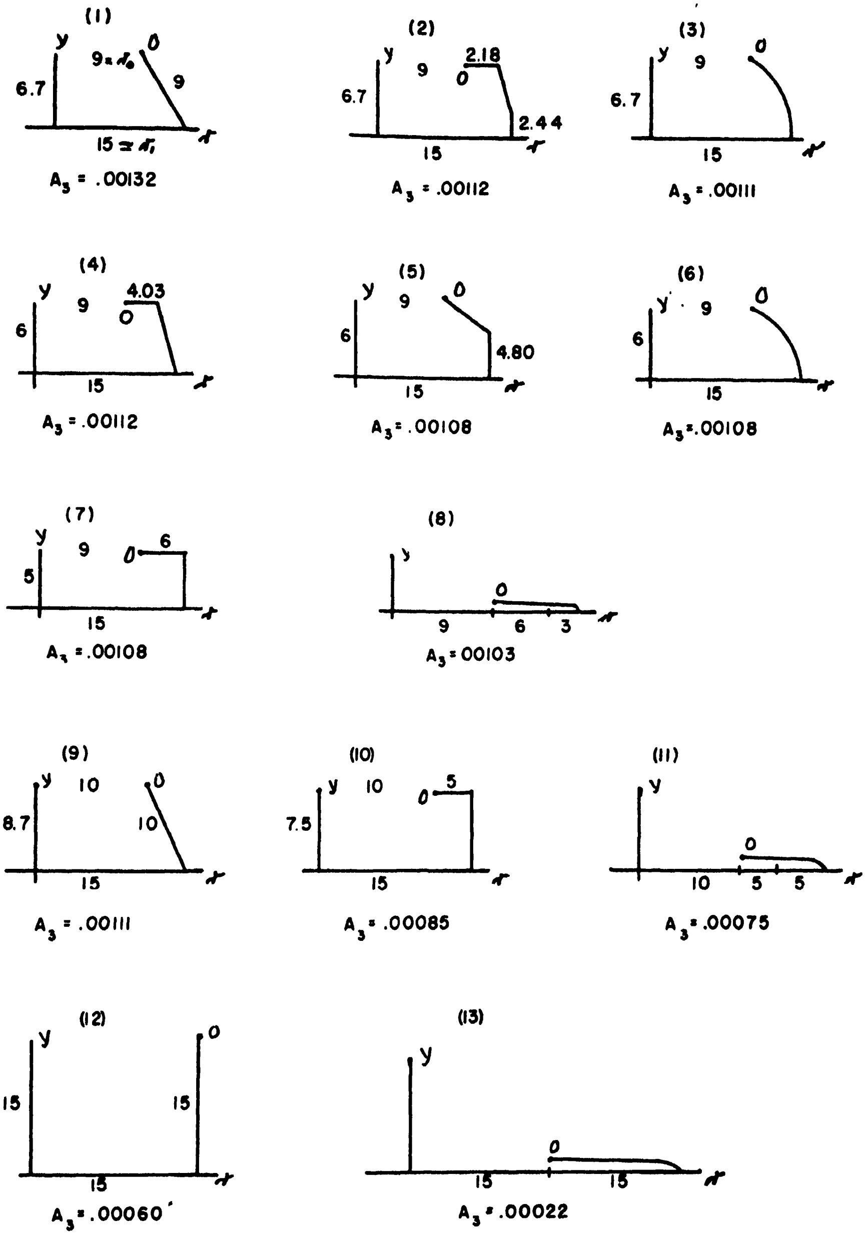

FIG. 13. (Arbitrary units.)

and minimizes

$$\left|\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{r^4}\right|-\frac{1}{3r_1^3}$$

in that class of curves. The Euler-Lagrange equation for this problem is

$$\frac{d}{dr}\left[\frac{y'}{r^4(1+y'^2)^{\frac{1}{2}}}+\frac{\lambda y'}{r^2(1+y'^2)^{\frac{1}{2}}}\right]=0,$$

where λ is a constant (Lagrange multiplier). Upon integration we obtain

$$y=\left|\int_{r_0}^{r}\frac{dr}{\left(\left(\frac{1+\lambda r^2}{kr^4}\right)^2-1\right)^{\frac{1}{2}}}\right|, \qquad \text{(B)}$$

where $k$ is a constant. To determine λ, $k$ we have

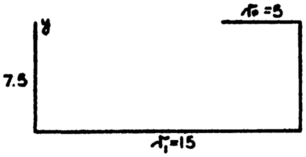

FIG. 14.

the equations

$$\left|\int_{r_0}^{r_1}\frac{dr}{r^2\left(1-\left(\frac{kr^4}{1+\lambda r^2}\right)^2\right)^{\frac{1}{2}}}\right|=\frac{1}{r_1},$$

$$\left|\int_{r_0}^{r_1}\frac{dr}{\left(\left(\frac{1+\lambda r^2}{kr^4}\right)^2-1\right)^{\frac{1}{2}}}\right|=H.$$

By approximate integration, these equations can be solved in any numerical case and the curve (B) found graphically. Figure 12 shows the curve (B) for $r_0, r_1$ fixed, with $r_0 \leqq r_1 \leqq 2r_0$, and for various $H$. As $H$ decreases toward zero, the value of $A_1$ furnished by the curve (B) decreases. Figure 13 illustrates this fact and the fact that the optics improve as $r_0$ increases. In each drawing of the table $A_1=0$. In (3), (6)–(8), (10), (11) the contour curve is of the minimizing type (B). For the cylindrical type of surface (7), (10), (12) we have

$$0=A_1=\int_{t_0}^{t_1}\frac{(r'^2+y'^2)^{\frac{1}{2}}dt}{r^2}-\frac{1}{r_1}=\int_{r_0}^{r_1}\frac{dr}{r^2}$$
$$+\int_0^H\frac{dy}{r_1^2}-\frac{1}{r_1}=\frac{1}{r_0}-\frac{2}{r_1}+\frac{H}{r_1^2},$$

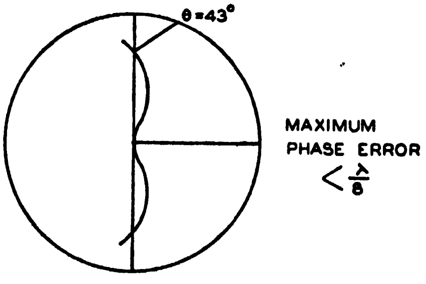

FIG. 15.

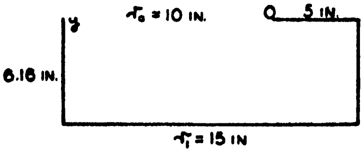

FIG. 16.

so that

$$H=r_1^2\left[\frac{2}{r_1}-\frac{1}{r_0}\right].$$

The limiting degenerate case $H=0$, $r_1=2r_0$ is illustrated by (8), (11), (13), and is a Schmidt circular reflector.

One particular application has already arisen for which $r_0$, $r_1$, $H$ were severely restricted. The wave-length to be used was $\lambda=1.25$ cm, $r_1$ was assigned as 15 inches, $r_0$ was to be $\leqq 10$ inches (for mechanical reasons). Due to lack of space no contour curve which forced the curve (B) to bulge out beyond $r_1$ was allowable, so that it was necessary that $H$ be $\geqq r_1^2(2/r_1-1/r_0)$. The cylindrical case (10) (see Fig. 14) seemed the most practicable. Computation of path lengths for this case shows that the phase errors at the aperture remain less than $\lambda/8$ for approximately $\frac{2}{5}$ of the aperture. If the height $H$ of the cylinder is lowered slightly, the effect is to destroy the equation $A_1=0$, and change to $A_1<0$ and a wave front of Type 2. The height can be adjusted ($H=6.16$ inches) so that the extremum points on the wave front are $\lambda/8$ off the aperture (see Figs. 15, 16). In this case the phase errors remain less than $\lambda/8$ for approximately $\frac{3}{5}$ of the aperture. If the allowable error were $\lambda/4$, by adjusting $H$ to 5.55 inches the phase errors would remain less than $\lambda/4$ for almost 7/10 of the aperture.

## 4. SURFACE OF REVOLUTION WITH DIELECTRIC

If dielectric is introduced into part of the region between the parallel plates of a surface of revolution scanner of the type described in the previous section (see Fig. 17), various degrees of improvement in the optics can be obtained. For

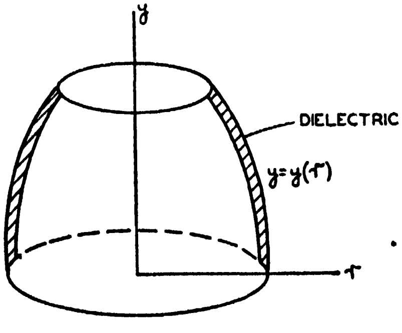

FIG. 17.

example if dielectric of index of refraction $\mu(r)$ is used as shown in Fig. 17, the result is a discontinuity in $\alpha$ at the base disk. Introducing optical length $s$ along a geodesic we obtain

$$s_1=\left|\int_{r_0}^{r_1}\frac{\mu^2 r(1+y'^2)^{\frac{1}{2}}dr}{(\mu^2r^2-h^2)^{\frac{1}{2}}}\right|,$$

$$\theta_1=\left|h\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{r(\mu^2r^2-h^2)^{\frac{1}{2}}}\right|,$$

$$\alpha_1=\arcsin\frac{h}{r_1}$$

where $\alpha_1$ is the angle the geodesic makes with a radius of the base immediately *after* emerging into the base.

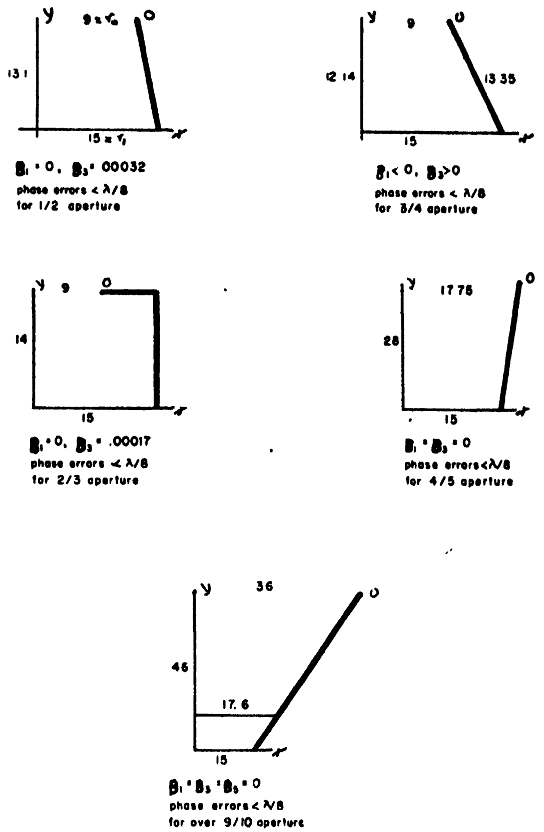
The series for $\theta_1-\alpha_1$ becomes

$$\theta_1-\alpha_1=\sum_{n=1}^{\infty}\frac{h^{2n-1}}{2n-1}B_{2n-1}\frac{1\cdot3\cdot5\cdots(2n-1)}{2^{n-1}(n-1)!(2n-1)},$$

where

$$B_{2n-1}=\left|(2n-1)\int_{r_0}^{r_1}\frac{(1+y'^2)^{\frac{1}{2}}dr}{\mu^{2n-1}r^{2n}}\right|-\frac{1}{r_1{}^{2n-1}}.$$

If $\mu=1.6$, and these results are applied to the case considered at the end of Section 3, Fig. 18 shows the type of improvement obtainable. The last two figures show that if we allow $r_0>r_1$, an extremely high degree of optical accuracy is obtainable. Of course, the feasibility of the use of dielectric depends on the amount of absorption of energy that occurs.



$B_1=0$, $B_3=.00032$
phase errors < $\lambda/8$
for 1/2 aperture

$B_1<0$, $B_3>0$
phase errors < $\lambda/8$
for 3/4 aperture

$B_1=0$, $B_3=.00017$
phase errors < $\lambda/8$
for 2/3 aperture

$B_1=B_3=0$
phase errors < $\lambda/8$
for 4/5 aperture

$B_1=B_3=B_5=0$
phase errors < $\lambda/8$
for over 9/10 aperture

FIG. 18. (Units are inches; $\lambda=1.25$ cm.)

This paper is a condensation of a laboratory report based on work done at the Radiation Laboratory, Massachusetts Institute of Technology, during the summer of 1944. The physical motivation of the problems considered, as well as some of the mathematical development, is due to L. J. Chu, C. V. Robinson, and R. C. Spencer. For obvious reasons, the emphasis is on approximate solutions suitable for practical use rather than the general solution of the mathematical problems involved.

# Space Charge Frequency Dependence of Magnetron Cavity*

W. E. LAMB, JR. AND M. PHILLIPS†
*Columbia Radiation Laboratory, Columbia University,*** *New York, New York*

(Received July 15, 1946)

The effect on the resonant frequencies of a magnetron cavity produced by the presence of a thin layer of charge surrounding the cathode is investigated theoretically. The corresponding experimental procedure is the "cold impedance testing" of a magnetron with a hot cathode in the presence of a magnetic field and a low d.c. cathode-anode voltage. A small amplitude theory is used, based on the single stream steady state. The correction to the frequency of the empty cavity due to a thin cloud of charge surrounding the cathode is given by a resonance-like formula about the "cyclotron frequency," $eB/2\pi m$. In the "Rising-Sun" tube the curve of $\nu$ *vs.* $\nu_c$ for constant d.c. voltage is asymmetric, apparently because of the presence of the "zero" mode. The validity of the theory is limited to low level oscillations, but the comparison of theory with experimental results seems to support the existence of the single stream steady state for non-operating magnetrons.

## I. INTRODUCTION

THE investigation reported here was undertaken with a view to the use of a non-operating magnetron structure as a tuning device. The tuning unit could either be built into the magnetron to be tuned, utilizing an auxiliary cathode coaxial wth the working cathode, or be coupled externally as an accessory tuner. Since any one of a great variety of coupling possibilities will introduce further complexities, however, and since the validity of the theory is limited to low level oscillations, we shall consider primarily the effect of space charge on the resonant frequencies of the magnetron cavity. The results can be applied to tuning if coupling considerations are taken into account, but in themselves describe the results of cold impedance testing a magnetron with the cathode hot, in the presence of a magnetic field, and with a d.c. voltage below that needed for operation. Our considerations also appear to throw some light on general magnetron theory. The perturbation of circulating space charge has been investigated by Blewett and Ramo[1] and Brillouin.[2] In both these papers it is assumed that the cathode radius is very small in comparison with other dimensions of the apparatus, an assumption not justified for modern magnetrons. Furthermore, their investigations are concerned only with the charge cloud itself, not its effect on anode block frequencies. It has already been pointed out[3] that in reference 1 the neglect of the effect of the constant magnetic field on the perturbations of the electron motion is not justifiable.

A small amplitude theory for magnetrons has been given by Bunemann,[3] who makes use of a velocity potential, analogous to that used in hydrodynamics. The r-f velocity potential is considered as a small perturbation of the d.c. velocity potential associated with the single stream steady state. The impedance presented at the boundary of the charge cloud is computed and, in principle, matched to that of the remainder of the cathode-anode space.

Although some question has been raised[4] as to the stability of the single stream steady state (also sometimes called the Hull or Brillouin steady state) we shall, like Bunemann, take it as our starting point. The validity of a small amplitude theory as applied to a magnetron under operating conditions need not concern us here, since we make no attempt to describe self-sustained oscillations. It turns out that there is very little further complication in handling perturbations of the fields themselves, instead of the velocity potential, while there are advantages

in using the fields for the purpose of matching to the anode cavities. Also the theory of the zero mode, of interest in "rising sun" tubes, appears naturally in our formulation, while Bunemann's hydrodynamical analogy failed to show it. This was caused by his neglect of the vector potential, and setting the curl of the electric field equal to zero. Only in the discussion of boundary conditions at the cathode do we need refer to a velocity potential.

An analysis of the limitations of our theory, and the difficulties involved in satisfying the usual cathode boundary conditions, is undertaken in the concluding section of the present paper.

## II. GENERAL METHOD

We shall use a fixed set of coordinates, $r$, $\theta$, $z$, and assume that the tube is sufficiently long that the dependence on $z$ can be neglected. The unperturbed fields, charge density, and velocity of the single stream steady state are, in rationalized m.k.s. units:[5]

$$\mathbf{E}_0=(m/e)(\omega_c^2/4)(1-b^4/r^4)\mathbf{r}, \tag{1}$$

$$\rho_0=(m/e)(\epsilon_0/2)\omega_c^2(1+b^4/r^4), \tag{2}$$

$$\mathbf{v}_0=-\omega_c/2(1-b^2/r^2)r\hat{\theta}, \tag{3}$$

where $\omega_c=eB_0/m$, the "cyclotron" angular velocity, $b$ is the cathode radius, and $B_0$ the externally applied magnetic field in the $z$ direction. The equation of motion for an electron at a fixed point in space, correct to the first order in the perturbation $(m/e)d\mathbf{v}/dt=\mathbf{E}+\mathbf{v}\times\mathbf{B}$, becomes

$$(m/e)d\mathbf{v}_0/dt+(m/e)d\mathbf{v}_1/dt$$
$$=\mathbf{E}_0+\mathbf{E}_1+\mathbf{v}_0\times\mathbf{B}_0+\mathbf{v}_1\times\mathbf{B}_0+\mathbf{v}_0\times\mathbf{B}_1. \tag{4}$$

The single stream steady state satisfies the zero-order equation, so that the perturbation equation becomes

$$\partial v_1/\partial t+(\mathbf{v}_0\cdot\nabla)\mathbf{v}_1+(\mathbf{v}_1\cdot\nabla)\mathbf{v}_0$$
$$=(\mathbf{E}_1+\mathbf{v}_1\times\mathbf{B}_0+\mathbf{v}_0\times\mathbf{B}_1)(e/m). \tag{5}$$

The first-order field equations are

$$\mathrm{curl}\mathbf{E}_1=-\mu_0\dot{H}_1, \tag{6}$$

$$\mathrm{curl}H_1=\epsilon_0\dot{E}_1+\rho_0\mathbf{v}_1+\rho_1\mathbf{v}_0, \tag{7}$$

where $\rho_1=\mathrm{div}\mathbf{E}_1$. It will be noted that the zero-order quantities do not satisfy the zero-order curl$H$ equation; but since $\rho_0\mathbf{v}_0$ gives a correction to the applied magnetic field which is of order $v_0^2/c^2$, the neglect of this term is consistent with a non-relativistic calculation.

If the time and angular dependence of all quantities is given by the factor $\exp i(n\theta-\omega t)$, where $n$ is the mode number, the field equations in component form become

$$i\omega\mu_0H=(1/r)(\partial/\partial r)(rE_\theta)-inE_r/r, \tag{8}$$

$$inH/r=-i\omega\epsilon_0E_\theta+\rho_0v_r, \tag{9}$$

$$-\partial H/\partial r=-i\omega\epsilon_0E$$
$$+\epsilon_0v_0/r\{\partial(rE_r)/\partial r+inE_\theta\}+\rho_0v_\theta. \tag{10}$$

The equations of motion take the form

$$-i\omega v_r+(v_0/r)inv_r=(e/m)E_r+v_\theta\omega_c+(e/m)v_0\mu_0H, \tag{11}$$

$$-i\omega v_\theta+(v_0/r)inv_\theta+v_r\partial v_0/\partial r=(e/m)E_\theta-v_r\omega_c. \tag{12}$$

Here the subscripts denoting perturbation fields and velocities have been dropped, only the zero subscripts being retained.

Equations (11) and (12) may be solved for $v_r$ and $v_\theta$ in terms of the fields, and substituted in the field equations. These may then be combined to give a single second-order differential equation in $E_\theta$, or $E_r$. This equation is too complicated to be very useful without extended numerical integration, but for the limiting case of thin layers of charge on the cathode conclusions as to the effect on the resonant frequencies may be easily drawn.

The boundary condition at the cathode demands that the tangential component of the electric field be equal to zero, and the differential equation for $E_\theta$ admits of a solution in powers of $(r-b)=y$, starting with the first power. For a very thin charge cloud, $E_\theta$ varies as $y$. The first-order $y$ dependence of the other field quantities can then be found by making use of the field equations. This approximation breaks down for frequencies too near the cyclotron frequency, since the coefficients of higher powers of $y$ contain the factor $(\omega_c^2-\omega^2)$ in the denominator.

To justify the use of this approximation we may investigate the radius of the charge cloud under steady conditions. One has only to demand

---

[5] Reference 2, part I, sections 2 and 3.

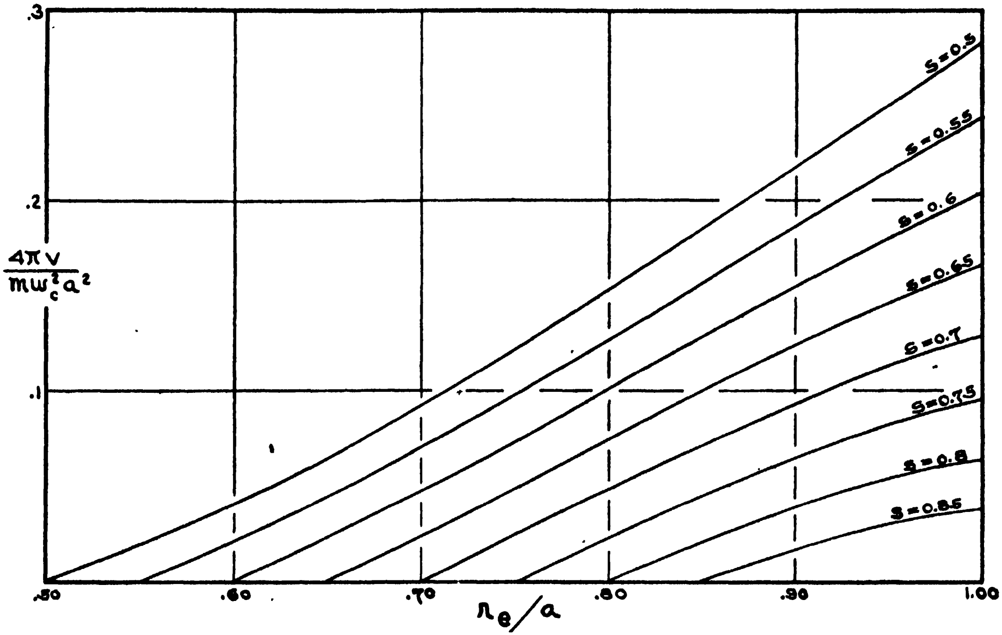

FIG. 1. A plot showing the radius of the boundary of the single stream steady state charge cloud as a function of applied cathode-anode voltage, for cathode diameter to anode diameter ratios ranging from 0.5 to 0.85.

that the fields be continuous across the boundary of the cloud, at $r_e$, and that the total difference of potential between cathode and anode is the applied voltage. The equation for the applied voltage is

$$V=(m/e)(\omega_c^2/8)r_e^2[(1-b^2/r_e^2)^2 +2(1-b^4/r_e^4)\ln(a/r_e)]. \quad (13)$$

Here $a$ is the inside radius of the anode. A plot of $4eV/m\omega_c^2a^2$ against $r_e/a$ has been made for a variety of $b/a$ ratios (Fig. 1), but for low voltages the relation between $y_e$ and $V$ is linear, and well represented by the simple formula

$$y_e/b=(e/m)(V/\omega_c^2b^2)/\ln(a/b).$$

For $\omega_c$ of the order of $10^4$ megacycles, as it is for the experimental tests made, $y_e/b$ is seen to be extremely small, of the order of $10^{-3}$.

### III. APPLICATION TO MODES WITH $n\neq 0$

If $n$ is not equal to zero it is justifiable to neglect the last term of Eq. (11), and to assume that the curl of **E** equals zero. This corresponds to a similar simplification in Bunemann's theory. Even under the simplifying assumptions the exact equation for $E_\theta$ is very cumbersome, although it can be derived in a straightforward way as indicated above. For large $nb/y$ it becomes fairly simple, especially if written in terms of the variable $\eta$, defined by $r/b=\exp(\eta/n)$:

$$(\omega'^2-\omega_c^2)d^2(rE_\theta)/d\eta^2+2\omega_c^3/\omega' d(rE_\theta)/d\eta = [2\omega_c^4/\omega'^2+(\omega'^2-\omega_c^2)](rE_\theta). \quad (14)$$

Here

$$\omega'=\omega+n\omega_c(1-b^2/r^2)/2=\omega+\eta\omega_c.$$

All terms of first order in $\eta$ are kept, in Eq. (13), but not in $\eta/n$, i.e., the effects of curvature alone are neglected, an approximation justified for fairly large $n$. Away from $\omega_c$, $y=0$ or $\eta=0$ is not a singular point, and the power series solutions start with $y$ or a constant. This is also true of the more complicated exact equation, awkward as it is to write down. For the plane magnetron, with a time and $x$ dependence given by $\exp i(\kappa x-\omega t)$, the corresponding equation is

$$(\omega\omega'-\omega_c^2)d^2E_x/dy^2+2\kappa\omega_c^3/\omega' dE_x/dy = (2\omega_c^4/\omega'^2+(\omega\omega'-\omega_c^2))\kappa^2E_x, \quad (14a)$$

where $\omega'=\omega+y\kappa\omega_c$.

The impedance[6] presented by the charge cloud at its boundary, correct to the first order in the

---

[6] See, for example, S. A. Schelkunoff, Bell Sys. Tech. J. 17, 17 (1938), or J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill, Book Company, Inc., New York, 1941), p. 282.

thickness of the charge layer outside the cathode, is then easily computed directly from Eqs. (8) to (12) above. If $E_\theta = \mathcal{E}y/b$, $\mathcal{E}$ being inserted as a constant to supply the right dimensions, then from (8) $E_r = \mathcal{E}/in$

from (12)

$$v_\theta = (e/m)iE_\theta/\omega = (e/m)iy\mathcal{E}/\omega b,$$

from (11)

$$v_r = \frac{i}{\omega}(e/m)E_r + \frac{i\omega_c}{\omega}v_\theta,$$

and from (9)

$$H = (\mathcal{E}/in)(i\omega E_r + \omega_c^2 m v_r/e)$$

$$= b\epsilon_0\mathcal{E}(\omega_c^2 - \omega^2)/in^2\omega.$$

$$\therefore \quad Z_{\mathrm{el}} = E_\theta/H = \frac{in^2y}{b^2\epsilon_0\omega}\,\frac{\omega^2}{\omega_c^2-\omega^2}$$

$$= i(\mu_0/\epsilon_0)^{\frac{1}{2}}\frac{n^2}{bk}\,\frac{y}{b}\,\frac{\omega^2}{\omega_c^2-\omega^2}\ \text{ohms}, \qquad (15)$$

where

$$k = \frac{2\pi}{\lambda} = \frac{\omega}{c}.$$

Since it is approximately $ny\omega^2/b(\omega_c^2-\omega^2)$ which enters as an expansion parameter, this expression may be considered valid for $ny/b < (\omega_c^2-\omega^2)/\omega^2$. The failure of $E_r$ to satisfy the conventional condition at the cathode corresponding to space charge limited emission will be discussed later.

To determine the resonant frequencies of the magnetron when the cathode is surrounded by the sheath of space charge this impedance is used as a boundary condition instead of the simple demand that $E_\theta = 0$ in the usual method.[7, 8]

We shall confine our attention to the symmetric anode. The equation for matching the fields at the openings to the anode cavities[9] for the $n$th mode is:

$$\cot kL = \frac{N\Theta}{\pi}\sum_{m=n+lN}^{\infty}\frac{J_m'(ka)+\alpha_m N_m'(ka)}{J_m(ka)+\alpha_m N_m(ka)} \times\left(\frac{\sin m\Theta}{m\Theta}\right)^2, \qquad (16)$$

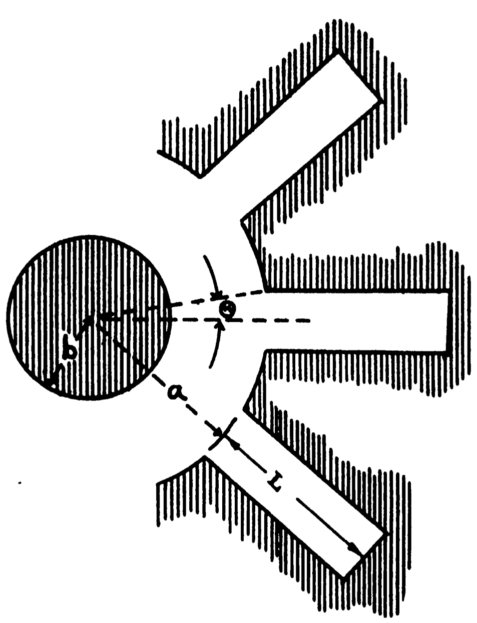

FIG. 2. Partial section of symmetrical anode magnetron. $b$ is the cathode radius, $a$ the inside radius of the anode, $L$ the length of a slot, and $\Theta$ is half the angle subtended by each slot.

where $2\Theta$ is the angular aperture of the cavities, $a$ is the anode radius, and $L$ is the length of the anode slots, as shown in Fig. 2. $\alpha_m$ is the parameter arising from the presence of the cathode or the cathode charge layer boundary condition. It has been shown that a consideration of the cathode radius in an empty cavity introduces very little change in the frequency except for the lowest mode numbers, and that for any $n$ the preponderance of the effect arises from the fundamental. This should remain true for the effect of thin layers of charge on the cathode. For this reason we may neglect all harmonics and determine $\alpha_n$ by simply matching the electron impedance at the edge of the cloud to that given by the solution for a cylindrical cavity. Furthermore, since $kb \ll 1$ for most tubes we may substitute for each Bessel and Neumann function the first term in its power series expansion about the origin.

The matching then involves using

$$H \simeq J_n(kr) + \alpha_n N_n(kr),$$

$$E \simeq -i\mu_0\omega/k[J_n'(kr) + \alpha_n N_n'(kr)],$$

so that

$$Z_{\mathrm{cavity}} = E_\theta/H = \frac{i\sqrt{\mu_0}}{\sqrt{\epsilon_0}}\,\frac{J_n'(kr)+\alpha_n N_n'(kr)}{J_n(kr)+\alpha_n N_n(kr)} \qquad (17)$$

[8] N. Kroll and W. E. Lamb, Jr., "Resonant modes of the "rising sun" anode," NDRC Div. 14, Report No. 323 (Oct. 25, 1944).

[9] Cf. Goldstein, reference 7, p. 9.

is determined by the condition $Z_{01}=Z_{\text{cavity}}$ at the boundary of the space charge, i.e.,

$$\frac{n^2 y_e}{kb^2}\frac{\omega^2}{\omega_c^2-\omega^2}=-\frac{J_n'(kr_e)+\alpha_n N_n'(kr_e)}{J_n(kr_e)+\alpha_n N_n(kr_e)}, \quad (18)$$

where $r_e=b-y_e$ is the radius of the charge cloud. It follows that

$$\alpha_n=-\frac{J_n'(kr_e)}{N_n'(kr_e)}\left\{1+\frac{2ny_e}{b}\frac{\omega^2}{\omega_c^2-\omega^2}\right\}$$
$$=\left(\frac{kb}{2}\right)^{2n}\frac{\pi}{n!(n-1)!}\left\{1+\frac{2ny_e}{b}\frac{\omega^2}{\omega_c^2-\omega^2}\right\}. \quad (19)$$

This expression for the boundary condition parameter is to be compared with the corresponding expression in the absence of the layer of space charge,

$$\alpha_n=-\frac{J_n'(kb)}{N_n'(kb)}=\left(\frac{kb}{2}\right)^{2n}\frac{\pi}{n!(n-1)!}. \quad (20)$$

The matching equation at the anode radius, from which the resonant frequencies of the whole resonating cavity are determined, becomes

$$\cot kL=\frac{N\Theta}{\pi}\sum_{m=n+lN}^{\infty}\left(\frac{\sin m\Theta}{m\Theta}\right)^2\frac{J_m'(ka)}{J_m(ka)}$$
$$\times\left\{1+2\left(\frac{b}{a}\right)^{2m}\left(1+\frac{2my_e}{b}\frac{\omega_c^2}{\omega_c^2-\omega^2}\right)\right\}. \quad (21)$$

This is to be compared with Eq. (15), of reference 4, *viz.*,

$$\cot kL=\frac{N\Theta}{\pi}\sum_{m=n+lN}^{\infty}\left(\frac{\sin m\Theta}{m\Theta}\right)^2\frac{J_m'(ka)}{J_m(ka)}$$
$$\times\left\{1+2\left(\frac{b}{a}\right)^{2m}\right\}. \quad (22)$$

From the fact that $(ny_e/b)(\omega^2/(\omega_c^2-\omega^2))$ appears as a small quantity in the solution of our differential equation for $E_\theta$ it is not permissible to use this correction for $\omega_c=\omega$, but if $y_e$ is sufficiently small (21) may be valid for frequencies very near the cyclotron frequency. It is seen that the maximum tuning predicted safely by Eq. (21) will be of the order of the correction to the frequency caused by the finite cathode.

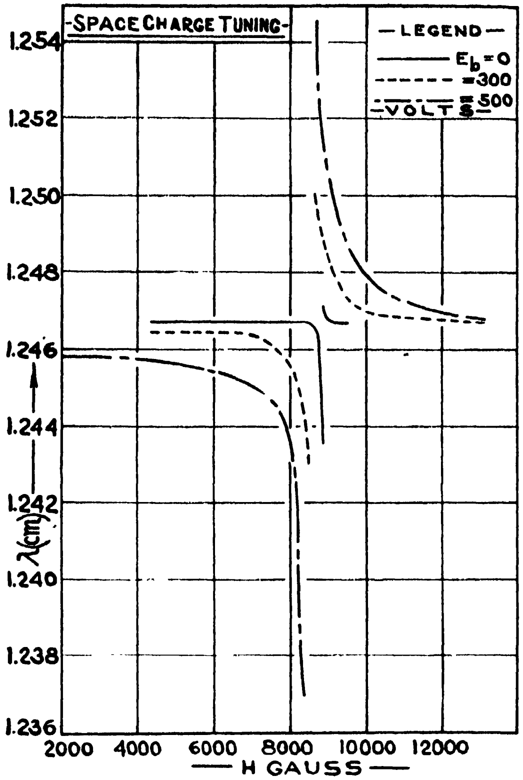

FIG. 3. Wave-length of rising-sun magnetron cavity as a function of magnetic field for cathode-anode voltages shown in the legend.

For $\omega_c<\omega$, i.e., for low magnetic fields, it will be in the direction of cancelling the cathode effect, decreasing the resulting resonant wave-length. For modes of higher $n$, where the fields at the center are small, there will be no appreciable effect; none, at least, which can be predicted with confidence from Eq. (21).

Some preliminary measurement of the tuning effects of the space charge layer about a magnetron cathode were made by Mr. B. Hildebrand of this laboratory. A number of 1.25-cm wave-length magnetrons were "cold impedanced" with a hot cathode in the presence of an axial magnetic field and d.c. radial electric field. The resonant wave-length was measured as a function of the applied fields. The r-f used was obtained from a local oscillator and had an intensity of a few milliwatts. The voltages used were insufficient to allow appreciable leakage current and back bombardment of the cathode, except at the lower magnetic fields. No detectable r-f of microwatt intensity was generated by the magnetrons, which were designed for pulsed operation at well over 10 kv.

Figure 3 shows the resonant wave-length ($\pi$ mode) of a rising sun magnetron cavity as a function of magnetic field for three values of d.c. voltage, 0, 300, and 500 volts. Within the limits of the field calibration, the sharpest tuning effects occur as expected at the cyclotron frequency. The tuning observed for zero anode voltage may be ascribed to the thermal motion of the electrons, for no tuning was observed with five volts of reversed potential.

These experiments are being continued with better cavity geometry and more careful control of cathode emission. A quantitative comparison between theory and experiment will be made when more complete data are available.

If one tries to make more rigorous use of the equation for $E_\theta$ in determining the impedance of the charge cloud, the first correction is a displacement of the singularity toward higher frequencies by an amount of the order of magnitude of $ny_e\omega/b$. The singularity in terms of $B_0$ is shifted toward lower magnetic fields according to the equation

$$\omega_c'=\omega_c\left(1+\frac{3}{2}\frac{ny_e}{b}\right).$$

Experimentally this means that the singularity in the curves of $\omega$ against $B_0$ should be displaced slightly as the d.c. potential and thus the thickness of the charge cloud is increased. The experiment is not conclusive on this point.

## IV. THE ZERO MODE

The case of the zero mode, of importance in rising sun tubes,[8] is somewhat different. This mode corresponds to a circular current in the tube. Here curl$E$ is not equal to zero, and the correction term in the magnetic field, $v_0B_1$, must also be kept. The absence of any dependence on $\theta$ makes the equations simpler, however, and if the layer of charge is sufficiently thin to justify the assumption that the magnetron is plane the differential equation for $E_\theta$ becomes

$$[1-k_c^2y^2/(1-\gamma^2)]d^2E_\theta/dy^2-\frac{2k_c^2y}{1-\gamma^2}dE_\theta/dy$$
$$-k_c^2(1-\gamma^2)E_\theta=0, \quad (23)$$

where $k_c=\omega_c/c$, $\gamma=\omega/\omega_c$.

This equation somewhat resembles Legendre's equation, and is satisfied by a power series containing only odd powers of $y$, but again the solution is not valid for $\omega=\omega_c$, since the coefficient of $y^3$ is $k_c^2(2+(1-\gamma^2)^2)/6(1-\gamma^2)$. Also,

$$E_r=\frac{i[E_\theta+ydE_\theta/dy]}{\gamma(\gamma^2-1)}. \quad (24)$$

To obtain a charge cloud impedance which does not depend critically on the frequency, it is necessary to take account consistently of the second term in the expansion in $y$. Working to this order also involves taking into account the deformation of the boundary layer. If a point on the surface of the charge cloud differs from its unperturbed value by an amount $\delta$, the value of $H$ to be used in matching differs from that inside the cloud by the contribution of the surface current, $\rho_0v_0\delta$.

To compute the impedance presented at the edge of the cloud we need

$$E_\theta\sim y+\frac{k_c^2y^3}{3(1-\gamma^2)},$$

$$H=\frac{1}{i\mu_0\omega}\frac{dE_\theta}{dy}-\rho_0v_0\delta.$$

Since $r_e=\text{constant}+\delta$, it follows that $\delta=iv_r/\omega$, evaluated at $r=r_e$. Since $v_r=i\omega\epsilon_0E_r/\rho_0$,

$$H=1/i\mu_0\omega[1-k_c^2y^2/(1-\gamma^2)] \quad (25)$$

and

$$Z_{c1}=i\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}ky[1+2k_c^2y^2/(1-\gamma^2)]. \quad (26)$$

The coefficient of the resonance term would be affected by including corrections to be caused by the current and the relativistic change of mass with velocity, and so is not to be interpreted too literally. This impedance is to be matched to that of the cylindrical part of the cavity, for which the dominant term is

$$Z_{cav}=i\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}\frac{J_1(kr)+N_1(kr)}{J_0(kr)+N_0(kr)}. \quad (27)$$

$$\therefore\quad Z_{cav}=\pi\left(\frac{kr_e}{2}\right)^2\left[1-\frac{2y}{r_e}\left(1+\frac{2}{3}\frac{k_c^2y^2}{1-\gamma^2}\right)\right]. \quad (28)$$

The zero-order Bessel and Neumann functions need not be expanded if use is made of the relation $J_0(x)N_1(x)-N_0(x)J_1(x)=-2/\pi x$, so that the approximations are as valid as those for modes with $n$ not equal to zero.

Matching at the anode radius leads to the equation

$$\cot kL=-\frac{N\Theta}{\pi}\frac{J_0(ka)}{J_1(ka)}$$

$$\times\left\{1+\left(\frac{b}{a}\right)^2\left[1-\frac{2y}{b}\left(1+\frac{2}{3}\frac{k_c{}^2y^2}{1-\gamma^2}\right)\right]\right]\right\}. \quad (29)$$

The effect of the charge cloud is thus always such as to cancel the cathode correction, by an amount which is larger for $\gamma<1$ than for $\gamma>1$.

It will be noticed that all amplitudes of vibration of the charge go to zero at the cathode, so that there is here no difficulty about satisfying the conventional boundary conditions. From the curl$H$ equation,

$$\frac{1}{r}\frac{\partial H}{\partial\theta}=0=\epsilon_0E_r+\rho v_r,$$

it appears that insofar as it is legitimate to neglect any $z$ dependence there is no emission at any time directly into this mode. Nevertheless, where the mode exists, by virtue of its mixture with the $\pi$ mode of rising sun tubes, for example, the tuning effect owing to its presence will be important for the same reason that a consideration of the cathode size is important, because the fields are large near the center of the cylindrical space. This effect probably accounts for the lack of symmetry in the frequency curves found in the cold test experiments carried out with rising sun tubes. Apart from the critical frequency dependence there is a correction in the presence of zero mode excitation which varies linearly with the depth of the charge cloud, and always tends to cancel the effect of the finite radius.

## V. CATHODE CONDITIONS AND VALIDITY OF THE THEORY

The linear equations used in the small amplitude theory preclude the imposing of the usual boundary conditions at the cathode if the mode number is different from zero. The two-power series solutions of the differential equation for any field quantity begin with the zero and first powers of $y$, respectively, and the field equations lead to the conclusion that if $E_\theta$ varies as the first power of $y$, then $E_r$ has a term independent of $y$. Thus if one demands that $E_\theta$ and $v_\theta$ are zero at $r=b$, one cannot also demand that $E_r$ and $v_r$ are zero at that radius, the usual condition for space charge limited emission. Taken seriously, this would mean that the radial field at the cathode is alternatively positive and negative, with the same $\exp\{i(\omega t-n\theta)\}$ dependence as other perturbation quantities. In other words the cathode is here defined merely as a surface on which the tangential field is zero.

Quite apart from a consideration of cathode conditions the small amplitude theory might not be expected to hold all the way into the cathode. In the impedance matching at the edge of the cloud we were interested only in the ratio of the perturbation fields, not their absolute magnitudes, but it might be expected that the theory would break down for $E_r$ of the order of $E_\theta$. The assumption that $|E_r|<E_\theta$ would mean, in terms of distances, that $\delta$, the amplitude of radial oscillations of the electrons is subject to the condition $\delta<y$, and that the small amplitude theory would not be valid for distances less than $y_1\sim\delta$.

The reasons for demanding the strict observance of space charge limitation of any possible emission in the absence of equilibrium conditions are not entirely clear, and in our own case there is no total current, and hence possibly no emission. Nevertheless, in view of the large part played by conventional cathode conditions in magnetron theory, it was thought feasible to attempt to match solutions of the exact equations to the fields predicted by the small amplitude theory at some distance $y_1<y_c$.

The hydrodynamical formulation has the advantage of added elegance and formal simplicity over the expansion of the field quantities and velocities separately, so that we choose this method of presentation similar to that used by Cherry.[10] Fixed coordinates may be used if the vector potential is included, which also enables us to include in the description the motion corresponding to the zero mode of the cavity.

---

[10] General Theory of the Magnetron, Council for Sci. and Ind. Research, Rept. MUM1, Sydney (April 1, 1943).

Let $m\mathbf{v}+e\mathbf{A}=-\mathrm{grad}\psi$. The proof that curl $(m\mathbf{v}+e\mathbf{A})=0$ is maintained (if there is no $H_n$) has been given, e.g., by Gabor.[11]

If $\mathbf{B}=\mathrm{curl}\mathbf{A}$ and $\mathbf{E}=-\mathrm{grad}\phi-\dot{A}$, the equation of motion leads to

$$e\phi=-mv^2/2+\psi=-\frac{(\mathrm{grad}\psi+e\mathbf{A})^2}{2m}+\psi. \qquad (30)$$

The fields, velocities, and charge density may be written in terms of $\psi$, the hydrodynamical potential or "stream function," and $\mathbf{A}$. We then demand that $E_{\mathrm{tan}}$ and $\mathbf{v}$ be zero on the cathode, and that $B_{\mathrm{tan}}$ and $\rho\mathbf{v}$ be finite. For an infinitely long cathode there is no normal component of $B$. These conditions mean that if there is any emission the charge density is infinite at the cathode surface, so that this surface is a "front" in the language of hydrodynamics.

If $\psi$ and $\mathbf{A}$ are now expanded in powers of $y$, with coefficients subject to the above condition, there follow limitations on the lowest allowed power of $y$, as well as relations between the coefficients of successive powers.

For the formal relations which must be borne in mind it is convenient to set up a system of right-handed cartesian coordinates, with $x$ in the direction of $-\hat{\theta}$. In addition to (30) and the definition of $\psi$ these relations are:

$$B=\partial A_y/\partial x-\partial A_x/\partial y=\mathrm{curl}\mathbf{A}, \qquad (a)$$

$$E_x=-\frac{\partial\phi}{\partial x}-A_x, \qquad (b)$$

$$E_y=-\frac{\partial\phi}{\partial y}-A_y, \qquad (c)$$

$$\epsilon\rho=\mathrm{div}\mathbf{E}=-\frac{\partial^2\phi}{\partial x^2}-\frac{\partial^2\phi}{\partial y^2}-\frac{\partial A_y}{\partial y}-\frac{\partial A_x}{\partial x}, \qquad (d)$$

and

$$\mathrm{div}\mathbf{A}=-\mu_0\epsilon_0\phi=\frac{\partial A_x}{\partial x}+\frac{\partial A_y}{\partial y}, \qquad (e)$$

$$\epsilon_0\dot{\rho}+\mathrm{div}\rho\mathbf{v}=0. \qquad (f)$$

The Lorentz condition (e) shows that there are only two, not three, independent series, which we can take as $\psi$ and $A_x$. Consideration of (a), remembering that $B$ must be finite but not identically zero on the cathode, leads to

$$A_x=-[B_0+\alpha_x(\theta,t)]y+\text{higher terms in } y.$$

If $\psi=\psi_l(\theta,t)y^l+$higher terms in $y$, the vanishing of $v_y$ on the cathode means that $l>1$, but $l=2$ leads to $v\sim y$, $\rho=$const., and no emission. To obtain emission the introduction of fractional powers is necessary. The conditions are satisfied by $l=5/3$, so that

$$\psi=\frac{3}{5}\psi_5(\theta,t)y^{5/3}+\frac{3}{6}\psi_6(\theta,t)y^{6/3}+\frac{3}{7}\psi_7(\theta,t)y^{7/3}+\cdots$$

is a convenient form for the series. It follows that

$$\rho v_r=\frac{\epsilon_0}{m^2e}\frac{2}{9}\psi_5^3(\theta,t)+0(y^{1/3})+\cdots. \qquad (31)$$

$\psi$ is then determined by the emission, and $A_x$ by the value of $B$ on the cathode, arbitrarily. As Cherry has pointed out, $E_y\sim y^{1/3}$, $E_\theta\sim y$, $v_r\sim y^{2/3}$, $v_\theta\sim y$, $\rho\sim y^{-2/3}$, for small $y$.

The apparent arbitrariness of the emission, determining $\psi_5$, is closely related to the question of convergence, a fact which has not been pointed out by previous authors. The coefficients $\psi_6$, $\psi_7$, etc., may be determined by substituting in the continuity equation and collecting terms in the same power of $y$. It turns out that $\psi_6\sim\psi_5/\psi_5$ and that $\psi_7$, $\psi_8$, etc., also go to infinity as $\psi_5$ goes to zero. Thus the series fails if the emission is ever equal to zero, or changes sign. This seems to indicate that the standard conditions for space charge emission, derived historically for steady constant currents, are not appropriate to the discussion of oscillations of emission about zero. This may correspond to Brillouin's finding a double stream, and not a single stream, in the case of final current.[12] An exact solution, involving emission, contradicts the single stream assumption for the cathode layer. So long as the oscillations are small, however, Brillouin found no indication that the double stream produced at the cathode extends far into the charge cloud.

An attempt was made by us to work out the single stream hydrodynamical theory on the strict basis of no emission under saturation conditions. This is formally easy: the stream func-

---

[11] Gabor, Proc. I.R.E. 33, 792 (1945).

[12] App. Math. Panel 129.3R, p. 30 *et seq.* and p. 51.

tion $\psi$ is then zero, and all quantities can be expressed in terms of **A**. $E_\theta$ and $v_\theta$ vary as the first power of $y$, as before, but $E_r$ and $v_r$ now also vary as $y$ for small $y$, with a finite charge density at the cathode. No Fourier analysis in the time is possible, however, so that the solutions cannot be matched to those of the linear equation.

The question of the stability of the single stream steady state under a periodic perturbation thus involved the cathode conditions very intimately. Those proofs of instability which are based on the assumption of ideal equilibrium cathode conditions seem to us of doubtful validity. In the absence of knowledge of the nature of the cathode surface, and the applicability of the demand that $E_r=0$, the qualitative experimental verification of theoretical results whose existence depends on there being such a steady state seems as good a way as any of testing the matter. It would remain to show that our results do indeed depend on the existence of a single stream steady state.

While it is impossible to make a general and categorical answer to this question, the observed resonance curves indicate a resonance frequency dependence which does depend on the existence of a magnetic field and the attendant circulation of the charge, and not merely on the charge density. This is easily shown. Maxwell's equation can be set up for a charge cloud of cylindrical symmetry, having the density $\rho=\epsilon_0\omega_c^2m/e$. For a thin sheath of static charge about the cathode the resulting equations can be solved, and the impedance looking into the sheath can be computed. For this case

$$Z_{el}=-i\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}\left\{\frac{n^2y}{b^2}\frac{c}{\omega}\left(\frac{\omega^2}{\omega^2-\omega_c^2}\right)^{\frac{1}{2}}\right\}, \tag{32}$$

corresponding to the results in the plane case well known in the theory of the ionosphere.[6] It is seen that at $\omega=\omega_c$ the impedance matching breaks down, and there is a change from reactive to resistive impedance. Contrary to this prediction the experimental curve, Fig. 3, shows a typical resonance pattern.

If, on the other hand, the effect of the applied magnetic field on the motion is taken into account, but not the zero-order velocity, the field equations and the equations of motion lead to

$$Z_{el}=i\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}\frac{n^2y}{b^2}\frac{c}{\omega}\frac{\omega^2-\omega_c^2}{\omega^2-2\omega_c^2}. \tag{33}$$

This is again ruled out by the experimental results. Thus the experiments indicate a perturbation of circulating individual electrons, and constitutes evidence for something like the single stream steady state.

Another solution of the stationary state problem has been given recently by Gabor,[13] who introduces "ergodic disorder," retaining conservation of energy and angular momentum for each individual electron. This is in reality an infinite stream steady state. It is interesting to see the differences and similarities between this solution and the one we have used. Gabor's method depends on the existence of a non-zero velocity of emission, although the assumption of equilibrium conditions means zero field at the cathode. If the initial velocity $u_0$ is small the tangential velocity at any point in the swarm of electrons is distributed about the $v_0$ of the single stream steady state, the width of the distribution being just $2au_0/r$, while there are small random velocities in the $r$ and $z$ directions to preserve the energy intact. The value of the saturation density arrived at by Gabor[14] also agrees with that of the single stream steady state for a thin layer about the cathode, although this is not true for thick clouds. Unfortunately the kinetic energy of an electron in a thin cloud is not in general much greater than the thermal energies corresponding to the cathode temperature, so that this agreement must not be taken too seriously. The same kind of difficulties as to how such a state is set up occur here as with the single stream steady state.

# The Reduction of Microphonics in Triodes

A. H. WAYNICK
*Ordnance Research Laboratory, School of Engineering, The Pennsylvania State College, State College, Pennsylvania*

(Received September 6, 1946)

An analysis is presented showing the effect of grid displacement on the plate current of a planar triode. This is defined in terms of a new parameter called the motional transconductance. The analysis indicates that a useful mechanical displacement indicator may be constructed by moving the grid and noting the change in plate current. The analysis also indicates that the effect of certain modes of grid displacement on the plate current may be eliminated under conditions which are stipulated. Since microphonic effects are, in great part, caused by the mechanical motion of grid structures, the analysis indicates how microphonism may be reduced. It is shown that the electrical transconductance is large under these conditions, for the case investigated, so that the tube functions normally as an amplifier. Preliminary experimental results for comparison with the theory are presented.

## INTRODUCTION

A RECENT patent[1] describes an electron tube whose plate current is varied by displacement of the grid, relative to the rest of the tube structure, while holding the applied tube potentials at constant values. The grid is mechanically connected through a vacuum-tight member so that it may be moved by the application of suitable forces to the tube envelope.

The following analysis was initially carried out to determine the feasibility of this idea when it had been determined that this type of tube had not been reduced to practice. The patent disclosure itself did not prove this.

The analysis indicates the plate current variations that may be expected in terms of a parameter called the motional transconductance. Inspection of the relation giving this parameter shows that, under suitable conditions, the effect of grid displacement on the plate current vanishes. This suggests a method of design, or mode of operation, by which the microphonism of a tube may be reduced since, as is well known, most of the microphonic difficulties encountered in tubes are caused by the mechanical movement of the grid. Design and operation relations are developed for this case.

Preliminary experiments are then described which indicate that the theory is fundamentally correct.

## THEORY OF A PLANAR TRIODE[2]

Consider a planar triode as illustrated in Fig. 1. Here $K$ is the cathode; $A$ is the anode; and $G$ is the grid structure. The grid is assumed to be made of equi-distant parallel rods having a radius $R$ and a rod center spacing of $1/n$.

The distance $dg$ is the cathode-grid center distance. The distance $dp$ is the cathode to plate distance. The distance $dq$ is the cathode to an equivalent plate distance, of an equivalent diode, which would give the same space-charge-free off cathode field intensity as the triode with the grid removed. The plate current obtained with the equivalent diode is the same as that obtained with the triode.

By a suitable conformal transformation of Fig. 1, the triode amplification factor, $\mu$, can be

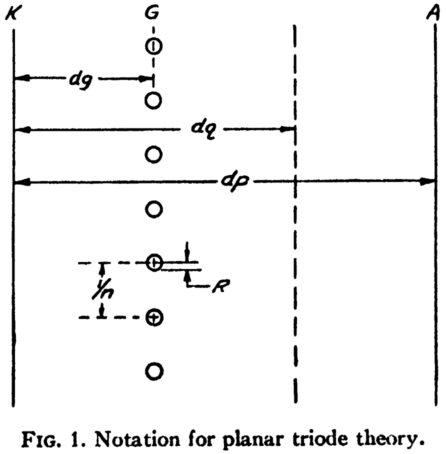

FIG. 1. Notation for planar triode theory.

[1] "Microphonic Electron Tube," issued to J. Rothstein, November 27, 1945, U. S. Patent No. 2,389,935.

[2] See W. G. Dow, *Fundamentals of Engineering Electronics* (John Wiley & Sons, Inc., New York, N. Y., 1937), Chapter 2.

determined by electrostatic theory utilizing the quantities enumerated above.[3] The relation is

$$\mu=\frac{2\pi n(dp-dg)-\log_e \cosh 2\pi nR}{\log_e \coth 2\pi nR}$$

and applies with sufficient accuracy when $R<1/10n$.

For $2\pi nR<1$, $\cosh 2\pi nR\rightarrow 1$ and $\log_e \cosh 2\pi nR \rightarrow 0$. Similarly,

$$\coth 2\pi nR=\frac{\cosh 2\pi nR}{\sinh 2\pi nR}\rightarrow\frac{1}{2\pi nR}$$

since $\sinh 2\pi nR\rightarrow 2\pi nR$. Hence, we can write

$$\log_e \coth 2\pi nR=\log_e\frac{1}{2\pi nR},$$

and the above relation becomes

$$\mu=\frac{2\pi n(dp-dg)}{\log_e\dfrac{1}{2\pi nR}}. \qquad (1)$$

For the space-charge-free case with an equivalent diode plate voltage of $Eg+Ep/\mu$ the equivalent diode spacing has been found to be[4]

$$dq=dg\left[1+\frac{1}{\mu}\frac{dp}{dg}-\frac{\mu+2}{2\pi n\mu dg}\log_e \cosh 2\pi nR\right].$$

Under the conditions given above, the last term may be set equal to zero leading to

$$dq=dg\left[1+\frac{1}{\mu}\frac{dp}{dg}\right]. \qquad (2)$$

As an approximation, Child's Law for the space charge limited equivalent diode may be written:[5]

$$Ip=\frac{2.33\times 10^{-3}A}{dq^2}\left(Eg+\frac{Ep}{\mu}\right)^{\frac{3}{2}}. \qquad (3)$$

Where $A$ is the equivalent diode plate area, equal to the actual triode plate area, $Eg$, the triode grid-cathode voltage, $Ep$, the triode plate-cathode voltage, and $Ip$ is the total plate current in milliamperes.

As abbreviations write

$$K=\frac{1}{2\pi n}\log_e\frac{1}{2\pi nR},$$

$$K'=2.33\times 10^{-3}A. \qquad (4)$$

Substituting (1) and (2) into (3) in view of (4) yields

$$Ip=\frac{K'\left[Eg+\dfrac{KEp}{(dp-dg)}\right]^{\frac{3}{2}}}{\left[dg+\dfrac{Kdp}{(dp-dg)}\right]^2}\text{ ma} \qquad (5)$$

for the total plate current of the triode in terms of triode parameters.

The triode transconductance is defined as

$$Sp\equiv\left(\frac{\partial Ip}{\partial Eg}\right)_{Ep=\text{constant}}\text{ in }\frac{\text{ma}}{\text{volt}},$$

where, for the present case, other tube parameters are also held constant.

Carrying out of the indicated differentiation on (5) yields

$$Sp=\frac{\frac{3}{2}K'\left[Eg+\dfrac{KEp}{(dp-dg)}\right]^{\frac{1}{2}}}{\left[dg+\dfrac{Kdp}{(dp-dg)}\right]^2}\frac{\text{ma}}{\text{volt}}. \qquad (6)$$

We wish to compare the effect of a grid displacement for constant $Eg$, $Ep$, and other parameters with (6). Consequently, we define a mechanical transconductance as

$$Mp\equiv\left(\frac{\partial Ip}{\partial dg}\right)_{\text{other parameters constant}}$$

in $\dfrac{\text{ma}}{\text{unit grid displacement}}$.

Carrying out of the indicated differentiation on (5) yields, after suitable rearrangement of

Plate area (4, ½ sections) $= A = 4.22$ in.$^2$.

TABLE II. Tube factors of 6A3. $Ep = +200$ volts, $Eg = -30$ volts.

| Factor | Handbook data | Theoretical | Equation No. |
|---|---|---|---|
| $\mu$ | 4.25 | 3.8 | (1) |
| $Sp$ | $6\frac{\text{ma}}{\text{volt}}$ | $7\frac{\text{ma}}{\text{volt}}$ | (6) |
| $Mp$ | | $3.6\frac{\text{ma}}{\text{in.}\times 10^{-3}}$ grid displacement | (7) |

terms,

$$Mp=Sp\left\{\frac{KEp}{(dp-dg)^2}-\frac{4}{3}\,\frac{\left[Eg+\dfrac{KEp}{(dp-dg)}\right]\left[1+\dfrac{Kdp}{(dp-dg)^2}\right]}{\left[dg+\dfrac{Kdp}{(dp-dg)}\right]}\right\}\tag{7}$$

in milliamperes/unit grid displacement.

From a comparison of $Sp$ with $Mp$, it should be possible to determine the relative effectiveness of the two methods of obtaining plate current variations.

### MAGNITUDE OF THE MOTIONAL TRANSCONDUCTANCE FOR A TYPICAL TUBE

In order to compare the above theory with handbook data, and to determine the magnitude of $Mp$, an RCA 6A3 was selected as a typical tube whose characteristics could be easily determined. One of these tubes was taken apart, and the dimensions appearing in Table I were determined.

The 6A3 is comprised of two tube structures in parallel enclosed in a common envelope. Each structure has an $M$ type filamentary cathode. The grid and plate electrodes are nearly rectangular in form. Consequently, the tube is treated as though it were four planar triode structures in parallel in the above table.

The tube parameters of interest, shown in Table II, were obtained from handbook curves[6] for $Ep = +200$ volts and $Eg = -30$ volt. The voltage values indicated were chosen so that the point on the tube surface under consideration lies on a plane region of the surface. This point also constitutes a compromise between the space-charge-free assumption involved in Eq. (2), and the space-charge-limited case involved in Eq. (3).

The parameters given in Table I were substituted in the relevant theoretical relations, under the voltage conditions mentioned above, and the theoretical values of Table II determined.

In view of the accuracy of the measurements in Table I, and the approximations employed in the theory, the results indicated in Table II with respect to the first two factors are considered satisfactory. We may conclude, therefore, that the value of $Mp$ obtained is correct to within about the same accuracy without experimental verification.

### CONDITIONS FOR THE MOTIONAL TRANSCONDUCTANCE BEING EQUAL TO ZERO

Inspection of Eq. (7) indicates there are several interesting facts concerning the magnitude and sign of $Mp$ under certain conditions. For $Eg$ negative and $Ep$ positive, as is the case for normal amplifiers, the magnitude and sign of the bracket factor vary somewhat as follows. For

$$|Eg|>\frac{KEp}{(dp-dg)},$$

the right-hand term of the bracket factor is negative and large so that the bracket factor is positive and large. Since $Sp$ is positive, $Mp$ is positive and large. For

$$|Eg|<\frac{KEp}{(dp-dg)},\tag{8}$$

the right-hand term of the bracket factor be-

---

[6] RCA Tube Handbook HB-3, Vol. 1-2, Tube Division, Radio Corporation of America, Harrison, New Jersey.

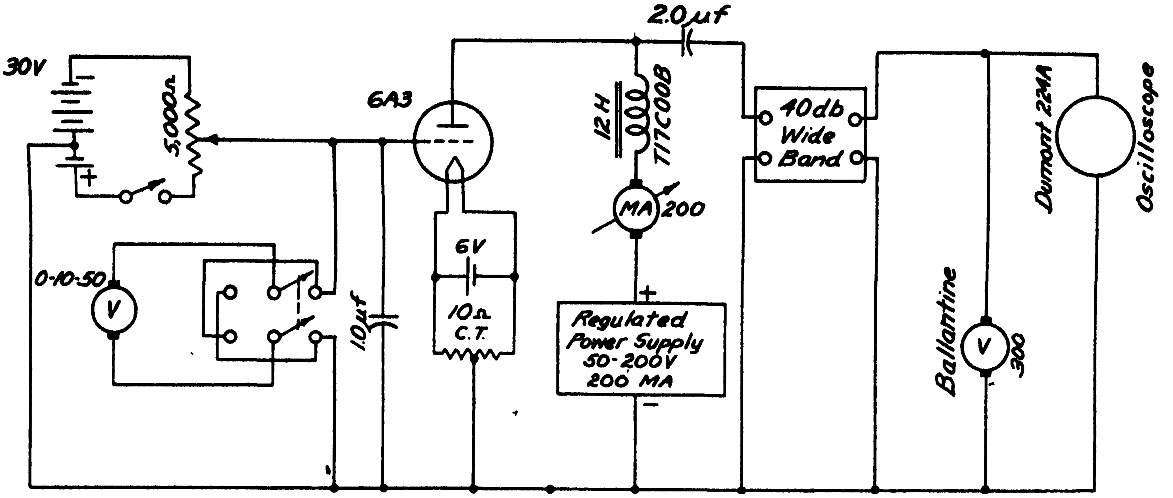

FIG. 2. Schematic diagram of the experimental arrangement.

comes positive and larger as the $|Eg|$ decreases to zero; and as $Eg$ subsequently becomes positive. Hence, the bracket factor passes through zero, when the second term equals the first term, and then goes negative and larger in magnitude as the $|Eg|$ decreases to zero; and as $Eg$ subsequently goes positive. Since $Sp$ remains positive, $Mp$ passes through zero and becomes negative and large in magnitude.

It is well known that, for triodes, $Sp$ increases monotonically as $Ip$ increases. Further, that $Ip$, for fixed positive $Ep$, increases as the $|Eg|$ decreases for $Eg$ negative and continues to increase as $Eg$ goes through zero and becomes positive for normal maximum positive values.

Hence, we can conclude that, in practice, $Mp$ may be zero or small in the normal operating voltage range of triodes where $Sp$ is large so that the tube will still amplify normally as far as electrical fluctuations in grid voltage are concerned.

Since microphonic effects are known to be caused, in great part, by mechanical motion of the grid rods, it is evident that microphonics may be reduced or eliminated by operating a tube, or designing a special tube, under the conditions for $Mp$ to be zero or small.

## EXPERIMENTAL ARRANGEMENT

A simple experiment was set up to check Eq. (7) by mechanically driving a tube and measuring the resulting "microphonic" output signal. Inspection of Eq. (7) indicates that this may be done most easily by varying $Eg$, with $Ep$ fixed, so that the only other variable is $Sp$. This varies in a known manner in terms of $Ip$, which in turn is a known function of $Eg$ for $Ep$ constant.

The schematic diagram of the experimental arrangement is shown in Fig. 2. A 6A3 was operated with battery filament supply to permit

TABLE III. Dominate driving frequencies of microphonic output for a 6A3 and other data. $Ep=+100$ volts; $Eg=-10$ volts; $E_f=6$ volts; volts across speaker $=1.0$.

| Case | Driving frequency for maximum output c.p.s. | Frequencies at which the output is 3 db down from the maximum output c.p.s. | Remarks concerning the output wave form |
|---|---|---|---|
| Transverse Excitation | | | |
| 1 | 194 | 192–202 | Very complex wave form |

hum-free operation. The grid bias was varied by means of the potentiometer across the grid bias battery and its magnitude determined by the grid voltmeter. A.c. pick-up in the grid circuit was avoided by grounding the grid at a.c. by means of the 1-mfd condenser.

The plate supply was a heavy duty, electronically regulated power supply whose output voltage was adjustable over the limits indicated. A voltmeter, not shown in the figure, was connected from plate to ground to indicate the plate voltage. A 12-henry heavy duty choke was used as a plate load in order to obtain a low value of d.c. drop in the plate load over the large range of d.c. plate currents employed.

The resulting "microphonic" output voltage developed across the plate load was impressed, through the 2-mfd d.c. blocking condenser, across the input of a stable, wide band amplifier having a voltage gain of 40 db. The output of the amplifier was indicated by a Ballantine model 300 voltmeter and was also observed on an oscilloscope screen. The no signal output of the circuit was well below the minimum signal measured.

The mechanical arrangement employed is shown in Fig. 3. The output of a sine wave audio oscillator was impressed across the voice coil of a small dynamic speaker. The oscillator output was measured by a Ballantine voltmeter and was held constant throughout the experiment at 1 volt.

Two types of mechanical excitation were employed. As shown in Fig. 3A, the transverse case, the tube was placed on a heavy table top so that the grid planes were parallel with the table top. The speaker was placed on top of the tube envelope so that the speaker diaphragm was pressed tightly against the tube. The speaker was then taped to the table top so that it would maintain this position. It is evident that mechanical excitation of the tube for this case will result in grid rod displacement perpendicular to the plane of the grid.

Figure 3B illustrates the mounting used for the longitudinal case. For this arrangement mechanical excitation of the tube will result in grid rod displacement in the plane of the grid or parallel to the longitudinal axis of the tube.

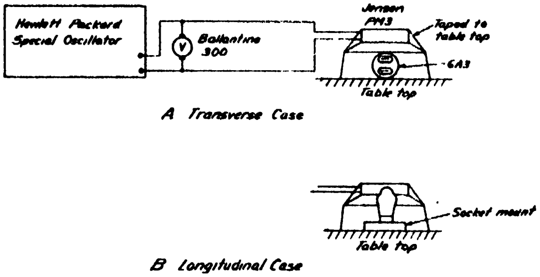

FIG. 3. Mechanical layout of the experimental arrangement.

## EXPERIMENTAL PROCEDURE AND RESULTS

The experimental procedure involved setting the driving oscillator at some constant output voltage and varying the frequency of the oscillator while observing the "microphonic" output on the oscilloscope. The magnitude of the output was highly frequency-sensitive in that the output would vary by as much as 40 db in passing through a frequency range of a few cycles. It is considered that these variations in output are associated with mechanical resonances of the tube structure; and, in particular, with mechanical resonances of the grid rods.

In some frequency ranges the output wave form was greatly dependent on the excitation frequency, indicating complex modes of vibration. In other cases the output wave form was sinusoidal and only the amplitude of the output signal was frequency dependent.

For the particular tube tested, it was found that there were seven dominant frequency ranges for the transverse case and six for the longitudinal case in the excitation frequency range of 100 c.p.s. to 10,000 c.p.s. These are tabulated in Table III below with other relevant information such as a statement concerning the observed wave form and an estimate of the width of the dominate frequency range in terms of the frequencies at which the output signal amplitude, as measured by the Ballantine voltmeter, are 3 db down from the output at the frequency of maximum output. In obtaining these data, the following were held constant: $E_f = 6$ volts, $Ep = +100$ volts, volts across speaker $= 1.0$, and $Eg = -10$ volt. The magnitudes of $Ep$ and $Eg$ were found to effect the output amplitude and wave form, as discussed below, but not the frequency at which the maximum output was obtained.

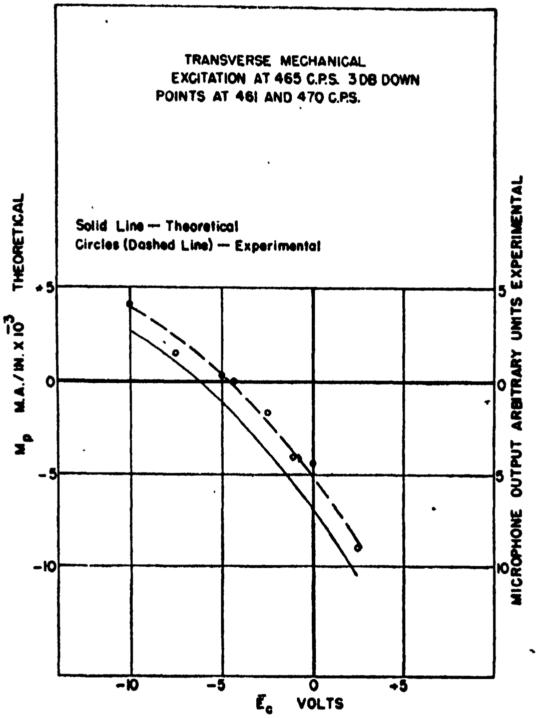

FIG. 4. An experimental check of Eq. (7) with $\bar{E}_c$ as the variable and sine wave mechanical excitation normal to the grid plane.

An experimental check of Eqs. (7) and (8) was then attempted in the following manner. With the driving oscillator accurately set at a frequency of maximum "microphonic" output, as indicated by the output Ballantine voltmeter, the grid bias was varied and the "microphonic" output as a function of grid bias determined. *Ep* was carefully held constant at +100 volts. This value of plate voltage was chosen so that the plate dissipation rating of the tube, 15 watts, was not exceeded at the largest positive grid bias voltage used during the experiment. The latter was +2.5 volts.

Many very interesting factors were noted; some of which are summarized below:

1. With *Eg* varied in the voltage range from −10 volts to +2.5 volts a minimum was noted in the "microphonic" output for the following cases of Table III. For transverse excitation 4 cases, number 1, 3, 4, and 7. For longitudinal excitation 1 case, number 11. This factor is discussed in greater detail below.
2. For the transverse case 2 and longitudinal case 8 the "microphonic" output increased as *Eg* was varied from −10 volts to +2.5 volts in about the same amount that *Sp* increased.
3. For the remaining cases the "microphonic" output decreased in varying amounts as *Eg* was varied from −10 volts to +2.5 volts.
4. For many cases, and in particular for case 6, oscilloscope examination of the output signal indicated that one component of a complex vibration spectra minimized as in 1, while other components did not.

In view of the above, it was assumed that cases 4 and 9 probably represented the gravest mode of vibration of the grid rods so that these cases are studied in detail below. Upon completion of the experiment, an attempt was made to observe the vibration of the grid rods under a low power microscope while the tube structure was vibrated under conditions similar to those of Fig. 3A. This experiment failed since the amplitude of vibration was too small to be detected with the apparatus used.

Considering case 4 of Table III, the experimental results obtained are tabulated in Table IV below.

The results of Table IV are plotted as circles on Fig. 4. The solid line of this figure was obtained by substituting the tube parameters of Table I and the experimental parameters of Table IV in Eq. (7) and solving for *Mp*. To do this, *Sp* was calculated from Eq. (6) under the same conditions.

It is evident that the shape of the experimental curve closely approximates that of the theoretical curve. Considering the type of measurements involved, this is considered a rather good check with the theory in spite of the displacement of the two curves. In addition, the following should be noted:

1. The theoretical value of $Eg(=\bar{E}_c)$ for $Mp=0$

TABLE IV. Experimental results for transverse case with driving frequency of 465 c.p.s. $Ep=+100$ volts; $Eg=\bar{E}c$ = variable; $E_f=6$ volts; volts across speaker = 1.0. 3 db down points 461 c.p.s. and 470 c.p.s.

| $\bar{E}c$ volts | Output volts | Normalized output volts | 11 × normalized output for scale factor | Driving frequency for maximum output c.p.s. |
|---|---|---|---|---|
| −10 | 0.49 | 0.37 | 4.09 | 465 |
| − 7.5 | 0.36 | 0.13 | 1.44 | 465 |
| − 5 | 0.14 | 0.02 | 0.22 | 465 |
| − 4.3 | 0.12 | 0 | 0 | 465 |
| − 2.5 | 0.27 | 0.15 | 1.65 | 465 |
| − 1 | 0.49 | 0.37 | 4.08 | 465 |
| 0 | 0.52 | 0.40 | 4.40 | 465 |
| + 2.5 | 0.94 | 0.82 | 9.00 | 465 |

is −6.2 volts under the conditions of the experiments. This compares with the experimental value of −4.3 volts.

2. When *Mp* changes sign the phase of the "microphonic" output voltage should shift 180°. This was noted experimentally although not indicated on the figure.

3. Most of the residual output signal near and at the minimum value of output is at the second harmonic of the driving frequency.

4. The maximum range in output signal variation greatly exceeded that of the example in some cases. As an example, in case 7 the range of maximum to minimum signal, as a function of $\bar{E}_c$, was over 30 db.

The theory does not cover the case of displacement of the grid rods in the grid plane. Experimentally, this case is probably complicated by phase relations between the vibrations of adjacent grid rods and by transverse components of the resulting vibrations. Experimental results for this case, case 9, are plotted in Fig. 5 as circles to illustrate the results obtained. As noted, the driving frequency is nearly the same as for case 4. The absolute magnitude of the output signal for $Eg = -10$ volts was nearly the same in both cases. This is not considered significant, however, since there is not reason to believe that the driving forces for the two cases are the same.

## CONCLUSIONS

1. The method of utilizing the displacement of the grid relative to the rest of the tube structure to obtain plate current variations which are a function of the displacement, and hence of the mechanical force causing the displacement, is feasible from an electronic standpoint.

2. Microphonism of tubes, under certain conditions, may be reduced as indicated by the theory developed and in terms of two factors or a combination thereof:

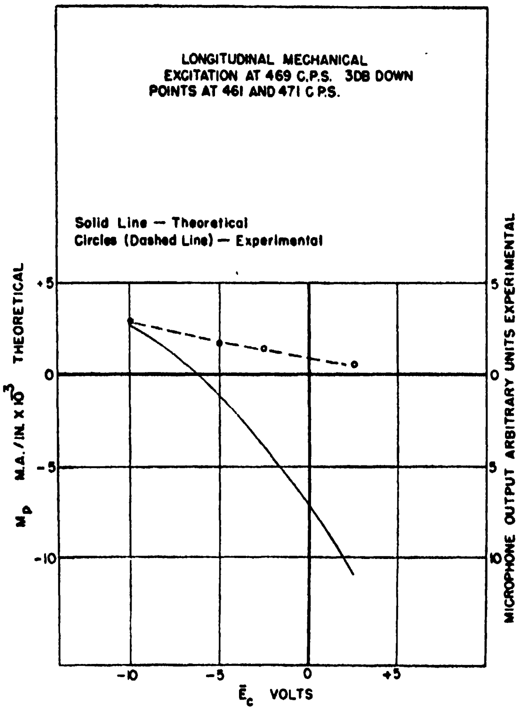

FIG. 5. Similar to Fig. 4 with mechanical excitation approximately in the grid plane.

(a) By designing a tube for minimum *Mp* given the operating potentials or (b) for a given tube to select the optimum operating potentials so as to obtain a minimum *Mp*.

In view of the latter, it may well be advantageous to operate the input stage of a high gain automatic volume controlled amplifier with fixed bias to reduce microphonics even though the flatness factor of the system may be decreased.

The above is thought to be interesting and useful, but from the practical standpoint further theoretical work should be done for the cylindrical triode and multi-grid tube cases. The construction of a planar triode whose grid can be moved relative to the cathode and plate should also be attempted. It is hoped that further work along these lines can be carried out in the future.

# The Effect of Hydrostatic Pressure on the Fracture of Brittle Substances

P. W. BRIDGMAN
*The Physics Laboratory, Harvard University, Cambridge, Massachusetts*

(Received November 11, 1946)

An arrangement is described permitting the fracture of brittle materials under the action of tensile stress superposed on hydrostatic pressure. The hydrostatic pressures range up to 30,000 kg/cm$^2$. The tensile stress superposed on the pressure required to break Pyrex glass is a strong function of the material by which pressure is transmitted to the lateral surface of the glass, but in all cases of fracture produced at pressures above 25,000 kg/cm$^2$ the net stress at fracture was compressive, that is, tensile fracture takes place against the direction of the stress. Beryllium and phosphor bronze lose the brittleness which characterize them at atmospheric pressure and fracture in tension under pressure after marked plastic deformation. Carboloy remains brittle in tension under pressure, but its tensile strength may increase by a factor of three. NaCl elongates plastically in tension under pressure with no obvious disturbance of the optical homogeneity. Pipestone remains completely brittle under pressure and of very low strength. In simple compression combined with hydrostatic pressure Pyrex glass increases greatly in strength. Single crystal $Al_2O_3$ under the same conditions exhibits plastic slip on the basal plane without fracture. In the discussion the importance of the condition of energy release as a factor controlling fracture is emphasized. The Griffith conception of fracture as resulting from stress concentration at the ends of microscopic cracks is consistent with many qualitative aspects of the situation, but probably cannot be carried through quantitatively.

## INTRODUCTION

IN a number of previous papers[1] I have described the effect of hydrostatic pressure in increasing the ductility of substances like mild steel under the action of tensile forces. In this paper the experiments are extended to a number of materials ordinarily brittle, like glass.

The effect of pressure is investigated on both compressive and tensile strength. Measurements of compressive strength may be made straightforwardly, but the tensile tests require a special technique. Under ordinary conditions there are technical difficulties in making tests on substances like glass with the conventionally shaped tension specimen, because of the effect of stress concentration at the corners of the specimen, resulting in capricious fracture. Most fortunately it turns out that a technique which is simply adapted to the application of tension under hydrostatic pressure at the same time uses specimens of such a shape that the difficulty from stress concentration disappears, making the investigation of the tensile properties under pressure much easier than at atmospheric pressure.

The experiments on tension to be described in the following are in a certain sense an extension of experiments made long ago on what I called the "pinching-off" effect.[2] In these experiments rods of glass or other brittle substances passed completely through the pressure vessel, emerging through stuffing boxes, the part within the vessel being exposed to hydrostatic pressure. On raising pressure high enough, the glass rod fractured by a clean tensile break at some place inside the pressure vessel. These experiments were mostly qualitative in nature, and no attempt was made to get consistent values for the pressure required to produce fracture. The chief result from these experiments was to emphasize that it is possible to have tensile fracture across a plane across which there is no stress component. This is, from the point of view of some of the traditional conceptions of fracture, a highly paradoxical thing. The conclusion which I drew from these experiments has, therefore, understandably been met with considerable scepticism in some quarters, and with the attempt to explain away the phenomenon as caused by various secondary effects. For a long time I have had it in mind to make a more exact study of the "pinching-off" effect. A few years ago I found, in some unpublished experiments, that the precise pressure at which the "pinching-off" fracture is produced in glass is

---

[1] P. W. Bridgman, J. App. Phys. 17, 201 and 692 (1946). Rev. Mod. Phys. 17, 3 (1945).

[2] P. W. Bridgman, Phil. Mag. p. 63 (July, 1912).

extraordinarily sensitive to surface conditions. This indicated the necessity for a more elaborate investigation of the whole effect. With these new experiments, this extended examination is now possible. We have now two degrees of freedom in the stress system, whereas formerly there was only one. Formerly the set-up was such that the longitudinal component of stress was continually zero, and the two equal lateral components were increased until fracture occurred. Now, the longitudinal component and the two equal lateral components may be independently varied, so that fracture may be studied over a much wider range of conditions. The paradox that characterized the "pinching-off" effect is now carried much further, for now tensile fractures can be produced across planes on which the stress is a *compressive stress* so high as to be beyond any possible experimental error. Thus. to mention only a single example, tensile fracture has been produced in glass under a mean hydrostatic pressure of 26,000 kg/cm$^2$ with a superposed tension of 11,000 kg/cm$^2$, so that the net stress across the plane on which the tensile break occurred was a compressive stress of 15,000 kg/cm$^2$.

## THE METHOD

The method and the general nature of the problems encountered may be indicated by means of a highly idealized mental experiment. Figure 1 represents a compound tension specimen consisting of a central cylinder *A* of the brittle substance to be tested, and of two "pull" pieces *B* with shoulders and the same small diameter as the specimen, mounted together in the thin cylindrical sheath *C* which is attached by solder or otherwise to the pieces *B* at *D* in such a way as to be liquid tight. The whole compound specimen is immersed completely in a liquid, to which any desired hydrostatic pressure is applied, and, superposed on the hydrostatic pressure, a tensile force is then applied to the pull pieces *B*. The situation is idealized by supposing that the pull pieces are infinitely strong, that the lateral contraction of *A* and *B* under the complete stress system is the same, so that their diameters continue to be the same, and that the sheath *C* has negligible longitudinal strength, offers zero friction on its inside surface, and is infinitely stiff so that it cannot be pushed by the external pressure into any cracks which might be formed on the surface of *A* or *B*. We now inquire what will happen if the pressure is first raised to some high value, at which it is kept constant, and the tension is then increased indefinitely. It is evident in the first place that the compound specimen cannot separate at the surface of separation between *A* and *B* as long as the tension is less numerically than the pressure. For if incipient separation should start at this surface, the surfaces of separation would be pushed back into contact by the pressure, which is greater than the tension. All the more, if separation cannot occur at surfaces already free between *A* and *B*, it cannot occur in the material of the solid rod *A*. That is, under a hydrostatic pressure, *P*, the tensile strength of the material *A* is, under these conditions, at least as high as the pressure *P*. Ideally, it seems impossible to place any limit to this behavior, so that by increasing indefinitely the hydrostatic pressure the tensile strength may also be indefinitely increased. This means that the numerical value of the pressure coefficient of tensile strength approaches unity under these conditions. This in itself is highly anomalous. It

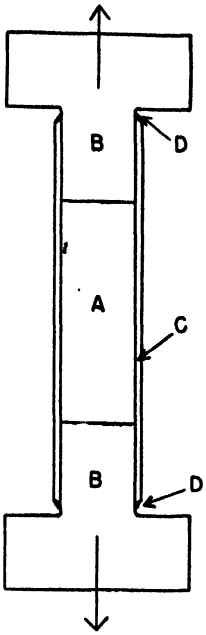

FIG. 1. Tension specimen, *A*, with steel pull pieces, *B*, and sheath, *C*, as used in combining hydrostatic pressure and tension.

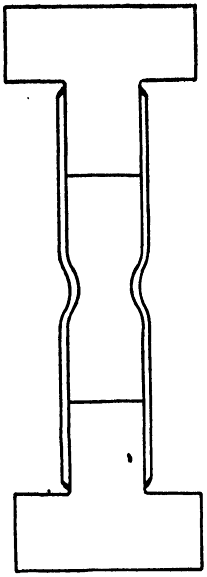

FIG. 2. Modification of arrangement of Fig. 1 in which the tension is concentrated in a neck, permitting the fracture in tension of the stronger materials.

is a matter of experience that the pressure coefficient of most physical properties of substances like glass is of the order of magnitude of perhaps $10^{-5}$, if the unit of pressure is taken as the kilogram per square centimeter. Yet here we have the necessity for a coefficient $10^5$ times as high. The situation is also anomalous when considered from the point of view of strain. Under combined tension and pressure the specimen $A$ elongates, and we have apparently the necessity for an indefinitely great elongation with no fracture. To say that beyond a certain point the specimen will receive plastic set on release of stress does not relieve the paradox of the situation while the stress is in action.

This idealized experiment, leading to such paradoxical conclusions, may be made the basis of the actual experiment, and also suggests the direction in which the experimental results may be expected to go, which is indeed the direction of paradox. In practise the pull pieces $B$ may be made of heat-treated steel, and the specimen $A$ made of the brittle substance under examination, such as glass or brittle alloy or what not. The sheath $C$ may be made of copper, a few thousandths of an inch thick. We now see at once that we have a method of applying tension to a brittle specimen without shoulders or regions of stress concentration on the specimen itself. The pull pieces $B$ may be re-used from experiment to experiment, so that the preparation of the specimen could not well be simpler. In the simple form shown in Fig. 1 any tension can be applied up to the magnitude of the pressure itself, assuming that there are no limiting complications in practise. These complications do, in fact, occur, since the copper is not infinitely rigid, and would eventually blow into the surface of separation between $A$ and $B$ before tension reaches its theoretical upper limit. This difficulty may be avoided by artificially fashioning a neck on the tension specimen, as shown in Fig. 2. The neck may be easily made of such proportions that there is no harmful stress concentration in the neighborhood. By making the neck of suitable dimensions, any tensile stress may be applied in this manner, without grips, to any material up to the fracture point, whether that is above or below the surrounding hydrostatic pressure. This arrangement has been used, for example, in testing the tensile strength of Carboloy under pressure, the tensile strength being much higher than the highest hydrostatic pressure that was applied.

The material of the sheath is a vital factor in the result, for not only may it be blown between the surface of separation of $A$ and $B$, but it may also be blown into any incipient cracks which appear in the surface of the specimen $A$. One would anticipate, therefore, that the measured tensile strength would be a strong function of the surface conditions, as exemplified by the material of the sheath. This did indeed prove to be the case. Various materials were tried. In practise the sheath sometimes was made compound, still keeping copper over the surface of separation of $A$ and $B$, but replacing the central part by some other substance such as lead or rubber, which must naturally be attached in such a way as to prevent access of liquid. It would have been desirable if conditions could have been pushed to the limit by permitting contact between the liquid and the specimen all over its lateral surface, while preventing entry of the liquid into the interface between $A$ and $B$, but no feasible way of doing this presented itself. As it was, a sufficiently wide range of external conditions was attained by the use of copper, lead, and rubber to indicate the general nature of what might be expected.

The arrangement indicated in Figs. 1 and 2 has points of resemblance to an arrangement probably first used by Richart, Brandtzaeg, and Brown[3] in studies of the effect of compound stresses on concrete and later by Balsley[4] working with Griggs on minerals. Both these investigators used straight cylindrical steel pull pieces, attached to the specimen by a sheath. The pull pieces were taken out of the pressure chamber through stuffing boxes, and on the outside were subjected to an independent compressive stress, which, as it varied from greater to less than the internal hydrostatic pressure was capable of exposing the specimen to a superposed stress either of compression or tension. There are technical difficulties with this arrangement, however. The stuffing boxes have to be accurately aligned and are not capable of as wide a pressure range as that used here. The maximum pressure in the Illinois experiments was 300 kg/cm², and in those of Balsley 10,000 kg/cm². Neither of these experimenters used necked specimens in order to permit raising the tension to values exceeding the hydrostatic pressure, but there is no reason why necked specimens should not be used with externally projecting pull pieces.

During the war Gurney and Rowe[5] in England made a large number of measurements of the pinching-off effect (which they describe as fracture by "radial" pressure) on glass and several plastics, and in a number of instances used necked specimens, thus permitting any desired tensile stress depending on the dimensions of the neck. These experiments were limited, however, because of the extension of the specimen itself through stuffing boxes, to hydrostatic pressures not greater than the "pinching-off" pressure of the straight cylindrical specimen.

In addition to the effect of one-sided tension, the effects of one-sided compression were also studied under pressure. These experiments were perfectly straightforward, and the details need not be specially indicated, for there is no such complication as with the tension specimens, but the stress may be applied to simple cylindrical specimens by compressing between platens. The specimen may be imbedded in lead or other suitable soft material when it is desired to prevent access of the transmitting liquid.

The various other details of the experiment, such as methods of applying and measuring the force, were the same as in my previous experiments, and the details have already been sufficiently described. An improved method of measuring the deformation was used in these present experiments, which has not yet been described in print. This employed a new insulating plug with seven terminals and a potentiometer method, which permitted measurement of the changes of dimensions from the inside of the pressure vessel, instead of from the outside, as hitherto. However, since these deformations during the action of stress are to play no role in the following, the description of this new arrangement can be deferred until the compressibility measurements in which it played an essential role are described.

## THE EXPERIMENTS

### Tensile Tests

#### *Glass*

The experiments on glass were made on Pyrex, all specimens being taken from the same batch. Five experiments were made in all. In the first a copper sheath was used 0.016 inch thick over the junction between steel and glass, turned down to a thickness of 0.005 inch over the central part of the glass. No extravagant precautions were taken with the glass, which was 0.44 inch long and 0.12 inch diameter. The lateral surface was the natural surface of the rod as provided commercially. The ends were lapped by hand with a fine carborundum stone perpendicular to the axis. Care was taken not to chip the edges. This specimen was exposed to a pressure of 27,000 kg/cm², and then a superposed tension added up to 19,000 kg/cm², when separation occurred between glass and one steel pull piece. The glass was undamaged, as was found by dissolving off the copper sheath in acid. The pull pieces were found to be too soft, and under this tension received a permanent elonga-

tion of 1.5 percent. This flow of the steel may have been responsible for the separation. The glass received no measurable permanent change of dimensions.

In the next experiment, copper ferrules were used over the surface of separation of glass and steel, but the central part of the glass was covered with a soft Neoprene tube, extending over the copper ferrules. At a hydrostatic pressure of 25,000 kg/cm$^2$ and a superposed tension of 5900 kg/cm$^2$, making the net compressive stress in the glass 19,100 kg/cm$^2$, this failed by a tensile break at the edge of the copper ferrule. On removing the ferrules from the glass, the glass fell apart into several disks separated from each other by clean tensile breaks. In this experiment the edges of the ferrules were comparatively thick, and it seemed probable that the fracture was in some way connected with a discontinuity of stress at the edge. The experiment was accordingly repeated, but with the edges of the copper ferrules feathered down to vanishing thickness. At a hydrostatic pressure of 25,300 kg/cm$^2$ and a superposed tension of 11,400, failure occurred at the interface. The entire central portion of the glass, where it had been exposed to the Neoprene, was separated into thin disks, still hanging lightly together. In the fourth experiment, copper ferrules again guarded the surface of separation of glass and pull pieces, and the central part of the glass was covered with a heavy lead sheath, soldered to the copper, The central part of the glass was necked down by grinding and polishing from .120 to 0.106 inch in order to concentrate the tensile stress at the center and locate the fracture. Under a hydrostatic pressure of 28,000 kg/cm$^2$ this broke in clean tensile fracture across the smallest diameter of the neck under an average superposed tensile stress at the neck of 15,500 kg/cm$^2$. Tensile fracture, therefore, occurred here against a net compressive stress of 12,500 kg/cm$^2$. The lead was melted off, and the copper dissolved off in aqua regia. An additional tensile break appeared on thus stripping the specimen, and the entire mass of the remaining glass was copiously fissured with fine disking cracks, the glass still hanging lightly together. In the fifth experiment, the glass was necked down at the center from .120 to 0.080 inch by grinding, polishing, and fire polishing to remove the last trace of mechanical cracks. The glass, together with the pull pieces, was mounted in a heavy straight copper sheath 0.21 inch in diameter, which was then collapsed tightly around the neck in the glass by a preliminary exposure to 8000 kg/cm$^2$, and then turned down to a thickness of 0.005 inch over the neck. Under a hydrostatic pressure of 27,000 kg/cm$^2$, this failed by a clean tensile break across the neck at an average superposed tension at the neck, corrected for the strength of the copper, of 24,500 kg/cm$^2$. This makes fracture to have occurred at a net compressive stress of 2500 kg/cm$^2$.

### *Carboloy*

Tests were made on Carboloy of grade 999, which is the grade containing the smallest quantity of binder furnished by the General Electric Company. To increase the stress the specimen was necked by grinding with diamond. Two unsuccessful preliminary experiments were made in which the strength of the Carboloy was not estimated high enough and the neck diameter accordingly was not made small enough. In two final experiments the area at the neck was made somewhat less than one quarter the area at the ends. In the two final experiments hydrostatic pressure was raised to 27,000 kg/cm$^2$. In the first of the two, there was a leak at the maximum load, suddenly throwing an uncontrolled and unmeasured increment of tension on the sample, under which it fractured. The best estimate of the superposed tensile load at the neck at fracture was somewhere between 56,000 and 60,000 kg/cm$^2$. In the second, there was no mishap and tensile fracture occurred at a superposed tension at the neck of 54,500 kg/cm$^2$. In both cases the break was a clean fine-grained tensile break square across the narrowest part of the neck, with no evidence whatever of any plastic flow in the neck, and no trace of the little shearing rim around the edge of the break that is almost always found in hardened steel.

The tensile strength under 27,000 is thus between two and three times as high as any value that has ever been recorded for any grade of Carboloy at atmospheric pressure by the method of the bending of slender rods. It was a surprise that there was no evidence of plasticity. Under one-sided compressive stress this grade of

Carboloy permits plastic shortening up to at least 10 percent.

### *Beryllium*

Beryllium as ordinarily obtained commercially, even in the purest form, breaks at atmospheric pressure in tension with no appreciable elongation and with tensile strength not more than 2000 kg/cm². Being a crystalline material it was anticipated that under hydrostatic pressure it might exhibit a degree of plasticity. The first experiment with beryllium, which was kindly furnished by Professor John Chipman of the Massachusetts Institute of Technology, employed steel pull pieces, by the same technique as used for glass and Carboloy. The specimen was necked to 0.7 of the full diameter, and mounted in a copper sheath, collapsed around it as in the last experiment on Pyrex. Under a pressure of 27,500 kg/cm² this broke at the neck with a further reduction of area at the neck of 48 percent, thus showing the anticipated ductility under the action of pressure. The neck at the break was very jagged, and the contour was finely corrugated around the periphery in an unusual way. The superposed tensile stress at fracture was 7900 kg/cm², on the original area of the neck. Two other experiments were made with beryllium, in which the conventional shaped tensile specimens were used, like Fig. 1, entirely fashioned out of a single bar. Mr. Charles Chase skillfully found how to fashion the beryllium rod with a Carboloy tool. In these two experiments the beryllium was directly exposed to the action of the pressure transmitting liquid, a mixture of iso-pentane and commerical "pentane." In the first experiment the specimen pulled apart at the shoulder under a hydrostatic pressure of 23,000 kg/cm². This was evidently the effect of stress concentration. There was, however, measurable extension in the body of the specimen. In the second specimen, the fillet at the shoulder was given a larger radius and the center of the specimen was further necked down to localize the break. Under a pressure of 18,000 kg/cm², this broke across the center of the neck with a coarse granular break, with a 20.6 percent reduction of area, and a maximum superposed tensile stress of 5400 kg/cm² calculated on the original area.

There would seem to be no reason to think that the transmitting liquid exercises any effect in the case of this material. It would appear that increasing hydrostatic pressure progressively raises the ductility and the tensile strength.

### *Phosphor Bronze*

For commercial welding a bronze is used consisting of 93 percent copper and 7 percent phosphorus. Under atmospheric conditions this material as ordinarily supplied in the cast condition is coarsely crystalline and completely brittle. It was of interest to find whether ductility is imparted by pressure. Three experiments were made. The specimens were made in one piece from the commercial cast rod, and were exposed to direct contact with the pressure liquid. The first two of these were not pulled to fracture, the ductility proving to be greater than anticipated, so that the dimensions originally given did not permit extension to fracture. The first of these was pulled under 22,000 kg/cm² to a reduction of area of 12.6 percent, and the second under 29,000 kg/cm² to 18.5 percent reduction. The elongation of both these specimens was uniform, necking not having yet started. The maximum superposed tensile load on the second specimen was 8700 kg/cm². In the third experiment the original specimen was turned down further over the central portion, to locate the break. Under a hydrostatic pressure of 29,900 kg/cm² this broke with an 80.2 percent reduction of area. The break was a burnished shearing break at approximately 45° across the narrowest part of the neck. The load at fracture was not obtained.

A control run on a similarly shaped specimen at atmospheric pressure yielded, as expected, a completely brittle fracture at the bottom of one fillet.

### $Al_2O_3$ (*Synthetic Sapphire*)

The Linde Air Products Company has recently developed a method of making single crystal rods of $Al_2O_3$, which have found various industrial uses. One of these rods was tested in tension, and I am much indebted to the Linde Company for making the specimen available. The hexagonal axis was oriented, as determined by the Linde laboratory, at an angle of 20° with the length of the specimen. It was mounted with steel pull pieces, copper ferrules, and Neoprene over the

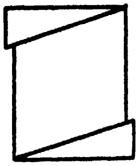

FIG. 3. Schematic indication of the manner of fracture of Pyrex glass in simple compression when supported by hydrostatic pressure.

central part. The central part was necked down by grinding with fine diamond powder from an original diameter of 0.100 to 0.070 inch, in order to locate the break. Although the final grinding was with the finest powder on hand, about No. 500, fine scratches were visible on the surface of the ground part. This material as ordinarily supplied is by no means as perfect as the crystals which are formed in nature, but usually there are imperfections visible to a low power glass in the form of minute bubbles irregularly scattered through the interior. The specimen used for this test was unusually perfect in this respect, however, and showed no such visible imperfections. This was pulled at a pressure of 24,700 kg/cm$^2$. At a superposed tensile load of 4900 kg/cm$^2$ it fractured on a plane perpendicular to the axis, not at the neck, nor at the edge of the copper ferrule, but at a place where the diameter was the full original diameter, situated about half-way between the edge of the ferrule and the neck. The conclusion forced by this is that the material is very inhomogeneous. The neck withstood without fracture a stress of 10,200 kg/cm$^2$ at the same time that the ruptured part was giving way under 4900. The surface of the break itself was not homogeneous. About half the area of the break was a mirror-like plane, with fine ripple marks around the edge, but the remainder of the section had a mat appearance, perhaps caused by the presence of bubbles too small to see with the hand glass.

### *Pipestone* (*Catlinite*)

This material, an iron-rich clay-stone, has a typical composition: $SiO_2$ 57.4, $Al_2O_3$ 25.9, $Fe_2O_3$ 8.7, $H_2O$ 7.4, MgO and CrO trace. Mechanically it seems to be an exceedingly fine-grained cemented aggregate. I have used it extensively for the insulation of electrical leads into the high pressure chamber, and in this usage it is capable of supporting high shearing and compressive loads without appreciable flow. When it does yield in this usage it disintegrates to a fine powder. Advantage was taken of the new technique to study its behavior in tension, it being quite impossible to make the conventional tension tests at atmospheric pressure. The specimen used was a single straight cylinder 0.180 inch in diameter and 0.438 inch long, mounted between steel pull pieces in a copper sheath turned to a thickness of 0.005 over the central part. At a pressure of 27,400 kg/cm$^2$, this failed on a clean tensile plane well within the central portion of the specimen, and with a reduction of diameter at the break of not more than 0.0005 inch. The superposed tension at fracture was only 430 kg/cm$^2$. There was no evidence of the copper sheath being blown into the fracture, but the copper was cleanly sheared through at the break. In view of experience with other materials, such a negligibly small effect of pressure on tensile properties was hardly anticipated. It is doubtless connected with the unusual mechanical composition of this material.

### *NaCl*

Under normal conditions at atmospheric pressure rocksalt breaks brittlely in tension on one of its numerous cleavage planes. It is well known, however, that under special conditions, as when properly supported or when in aqueous solution, it may be made to support plastic deformation. Two tests were made of the effect of hydrostatic pressure. Both specimens were cut from the same natural crystal, with one of the natural cleavage planes perpendicular to the length. They were used in the form of straight cylinders, mounted between steel pull pieces. The first was used with a copper sheath 0.007 inch thick over the central part, and the second with copper ferrules and lead over the central portion. The first was pulled under a hydrostatic pressure of 29,800 kg/cm$^2$ to a reduction of area of 20 percent under a superposed "true" tension as calculated on the final diameter, of 520 kg/cm$^2$. At the necked part there was no loss of optical homogeneity—no evident slip planes or other evidence of crystal structure, and the cross section remained round. The second specimen, with lead sheath, was pulled under 29,300 kg/cm$^2$ pressure. The experiment was terminated by leak, which prevented the measurement of the tension, but the specimen necked down to a reduction of area of 14.6 percent. Again the specimen retained its perfectly homogeneous appearance.

Voigt[6] experimented on the effect of gas pressures up to 60 kg/cm² exerted by $CO_2$ on the tensile strength of NaCl. He found that up to this pressure the superposed tensile load required to fracture was independent of pressure, and that the fracture continued to be a clean brittle break with no trace of plastic flow. Break occurred on the cleavage planes, and the superposed stress to cause fracture was 57 kg/cm². Evidently his pressures were not high enough to bring about the plasticity which is exhibited at higher pressures. It is to be noted that Voigt's tensile strength was only one-tenth of the stress which at high pressure produced only flow without fracture.

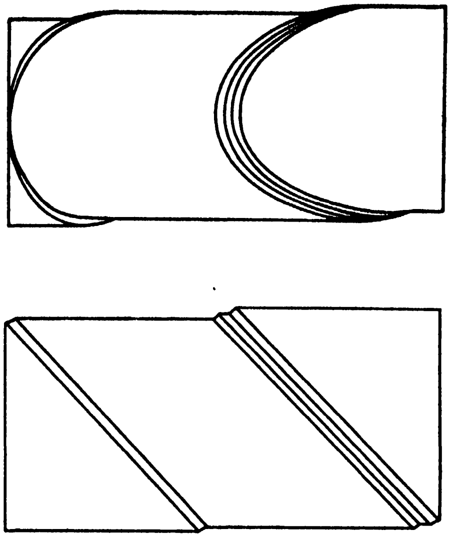

FIG. 4. The slip planes developed in single crystal $Al_2O_3$ under simple compressive stress when supported by hydrostatic pressure.

## Compressive Tests

### *Glass (Pyrex)*

Two experiments were made on glass of the same origin as that of the tension tests. The first specimen was 0.235 inch long and 0.125 inch in diameter. It was compressed in the regular way between Carboloy platens, after soldering into a lead sheath to prevent contact with the pressure liquid. Compressive load was applied at a hydrostatic pressure of 28,000 kg/cm². At an additional compressive load of 18,900 kg/cm² the capacity of the grid to measure compressive stress was reached, and the experiment had to be discontinued. The glass was found undamaged except for a slight chipping around one edge. In the second experiment, the specimen was made smaller, 0.131 inch long and 0.069 inch diameter. The method of mounting was as before. Compressive load was applied under a hydrostatic pressure of 28,000 kg/cm². The specimen failed under a superposed compressive load of 47,000 kg/cm², calculated on the original area. The lead sheath maintained the fragments in approximate position; when the sheath was removed the specimen was found with the appearance suggested in Fig. 3. Two wedge-shaped regions on the ends had slipped sidewise on planes at an angle with the axis of about 65°; the material in these wedges was completely comminuted to a fine powder, opaque and white. The central portion was filled with conchoidal fracture surfaces; the fragments were much larger than at the ends and were transparent.

It is to be noticed that the effect of hydrostatic pressure is markedly greater in increasing the compressive strength of glass than in increasing its tensile strength.

### *$Al_2O_3$*

A number of tests were made on material of the same origin as that of the tensile tests. The results on this material were very capricious, and would hardly merit description here if it were not for one remarkable feature. Four specimens were tested at atmospheric pressure as controls. The crushing strengths of these were 40,000, 8000, 12,000, and 38,300 kg/cm², respectively. Three specimens tested under hydrostatic pressures of 23,800, 25,300, and 22,200 kg/cm² failed completely at additional superposed compressive loads of 18,300, 7700, and 9200 kg/cm², respectively. The failure of these specimens under pressure was remarkable in that it was not catastrophic, but was preceded by a long period of yield under approximately constant compressive load, as in a tension specimen that shows

---

[6] W. Voigt, Göttinger Nachrichten 521 (1893).

high plastic extension. Another experiment was, therefore, made in which the experiment was terminated before the final failure, so as to permit examination of the specimen. This was exposed to 24,000 kg/cm² hydrostatic pressure and a superposed simple compression of 6300 kg/cm². The appearance was as indicated in the sketch, Fig. 4, which I owe to the kindness of Mr. McCandless, of the Linde Air Products Company. The slip planes, which were inclined at approximately 45° to the compression axis, were identified by Mr. McCandless as the basal 0001 plane of the crystal. This is *not* the plane of cleavage when a sapphire rod is broken at a neck by tension-plus-bending. The cleavage plane under these conditions is $10\bar{1}1$. It may be that in this case fracture occurred on 0001 because it by accident happened to coincide with the plane of maximum resolved shear. It would seem, therefore, that under sufficiently high supporting hydrostatic pressure internal slip without fracture is possible in a *crystalline* substance as brittle under normal conditions as sapphire. The crystal structure obviously plays a decisive role; no tendency to plastic flow has ever been found in glass.

The maximum compressive strength found under pressure in the experiments above is much less than that previously found under pressure for $Al_2O_3$ of other origin.[7] For this, compressive strengths as high as 70,000 kg/cm² have been observed. The difference is doubtless connected in some way with fine scale inhomogeneities. There seemed to be no correlation between the compressive strengths obtained in these new experiments and the crystal orientation.

*Note added on reading proof January 17, 1947.*

I have just found similar slip bands in *tension* on the basal plane, at angles of 45° and 30° to the length, when the specimen is enclosed in a copper sheath.

### *Sintered Carbides*

A number of observations have been made on these materials incidentally in the course of explorations for materials best suited for the construction of high pressure vessels. It has already been stated that Carboloy (tungsten carbide cemented with cobalt) will support plastic shortening in simple compression when supported by high hydrostatic pressure. The pistons of the piezometers used in measuring compressions to 100,000 kg/cm² are made of Carboloy, and because of this, considerable work has been done in examining the behavior of the piston material. In general the grades of Carboloy containing small percentages of cobalt are best suited for pistons. I have used the grades known as 905, and lately exclusively 999. Shortenings in simple compression up to 10 percent have been observed at hydrostatic pressures around 30,000 kg/cm². Carboloy does not work harden when it yields plastically in compression, but the shortening continues proportionally to time. Compressive stresses as high as 150,000 kg/cm² have been obtained in Carboloy for a short time. The rate of yield under these conditions is, however, so high as to make the use for pistons infeasible. My pistons in the compression measurements have seldom been carried above 110,000, and more usually are not carried above 105,000. Under these stresses the total plastic shortening of the pistons is something of the order of one quarter of a percent for a duration of maximum stress of fifteen minutes. There is considerable variation in piston material of ostensibly the same composition, and it pays to make a preliminary examination in order to pick out the best pieces.

It is not inconceivable that other materials than Carboloy would be better adapted for standing high compressive stress when supported by hydrostatic pressure, even though the material might not be so well adapted for ordinary conditions of use. The natural direction in which to seek for improvement is in diminishing the amount of binder, since it would appear that the plastic flow takes place in the binder. A cursory examination was made of some of the more obvious or easy possibilities, but with no improvement. In fact, none of the materials tried approached Carboloy in performance; doubtless we went too far in the direction of minimizing the binder. In this exploration I was fortunate to obtain the cooperation of Mr. deWald, who has specialized in the subject, and who prepared the specimens for me at Massachusetts Institute of Technology, where he enjoyed the facilities of the Department of Metallurgy. The following materials were tried with the following results.

---

[7] P. W. Bridgman, J. App. Phys. 12, 461 (1941).

(1) A mixture of 97 percent TaC, 2 percent VaC, and 1 percent $Mo_2C$ with no binder. Under a pressure of 23,000 kg/cm$^2$ this failed with a completely brittle fracture under a superposed compressive stress of 36,000 kg/cm$^2$.

(2) WC with 0.25 percent Co as binder. Under 25,000 kg/cm$^2$ this failed brittlely under 47,500 kg/cm$^2$ superposed compressive stress.

(3) TaC with 0.25 percent Ni as binder. Under 25,000 kg/cm$^2$ hydrostatic pressure this failed brittlely under 30,700 kg/cm$^2$ superposed compressive stress.

There is room for much more work on this subject. In particular, systematic investigation should be made of the effect of varying the grain size and the time and temperature of sintering.

## DISCUSSION

This should be regarded as a first paper on this subject, in which the general nature of the effects is suggested; there is obviously need for much more investigation in detail, both with a wider range of materials and a wider range of stress conditions.

Perhaps the most important single result is to emphasize the reality of a condition of fracture which may often be disregarded. This is: fracture cannot occur unless the process of fracture is an energy releasing process. The reason that in the idealized experiment with which we started our exposition tensile fracture could not occur until the superposed tension reached a value at least equal to the ambient hydrostatic pressure was merely that fracture under these conditions was not an energy-releasing process. For if fracture were to occur, the work done against the hydrostatic pressure would be greater than the work received from the force producing the tension. The fact that fracture occurs in the actual experiment under tensions less than the hydrostatic pressure, that is, against a net compressive stress, is a consequence of the difference between the ideal and the actual case. This difference is in the lateral conditions. In the ideal case, there was an infinitely rigid sheath shielding the lateral surface from entry by the pressure liquid if a crack should appear. In the actual case, the sheath is not infinitely rigid, and if the external pressure is high enough, the sheath may be forced into incipient cracks, and this is an energy-releasing process. According to this view, tensile fracture of a brittle substance in a medium carrying hydrostatic pressure starts on the external surface. This view is confirmed by the extreme sensitiveness of tensile fracture under these conditions to the surface conditions. Thus in the case of glass, we may have fracture by the "pinching-off" effect at a pressure of 1500 kg/cm$^2$ if the external medium is water, and at a pressure of 3000 or 4000 if the medium is oil, or otherwise expressed, fracture at superposed tensions of 1500 and 3000 or 4000, respectively. But if the external medium is Neoprene or lead or copper we have seen that tensile fracture occurs at superposed tensions of 5900, 15,500, and 24,500 kg/cm$^2$, respectively. There is a specific effect of hydrostatic pressure concealed in this comparison, but this effect does not obscure the main result. The surface conditions at glass are doubtless complicated, and at least in the case of water involve a chemical factor as well as a purely mechanical factor, since it is known that water is forced by pressure into the surface layers of glass. Brittle substances thus differ essentially from the substances which flow plastically before yielding in tension which have been made the subject of previous study. In the case of these ductile substances, fracture starts in the interior on the axis, where the tensile stress is a maximum, because of the stress redistribution produced by the necking itself, and always at values of the tensile stress materially higher than the ambient hydrostatic pressure. Fracture under these circumstances is again an energy-releasing process, because although work is done against the external pressure when a cavity appears in the inside, nevertheless the work received from the tensile stresses more than compensates because of their greater intensity. The fact that fracture starts at the inside explains the consistency of the results on fracture of ductile substances as contrasted with the capriciousness of the results for a brittle substance like glass.

From the point of view of energy release it is easy to understand the very much greater strength of glass to compressive stresses when supported by hydrostatic pressure than to tensile stresses. In the experiments above under a hydrostatic pressure of 27,000 or 28,000 kg/cm$^2$ the maximum superposed tensile stress supported was 24,500 kg/cm$^2$ (copper sheath), whereas a superposed compressive stress of 47,000 was observed. When fracture occurs under tensile stress combined with hydrostatic pressure two processes occur, both energy-releasing. The force producing the tension does work, and the pressure does work, because when tension is released the volume of the specimen decreases. But when fracture occurs under one-sided compressive stress, only one of the processes is energy-releasing. The force producing the compressive stress again does work during the fracture, but, since the volume increases on release of compressive stress, work is done against the pressure by the fracture.

From the point of view of energy release there is no particular significance as to whether the superposed tensile stress under which fracture occurs is greater or less than the hydrostatic pressure, that is, whether the tensile fracture occurs against a net tensile or compressive stress. For in either case the process of fracture may be resolved into two components, both energy-releasing. The significant thing is the lateral conditions, and the extent to which the surrounding hydrostatic pressure may follow through into any crack which appears, doing work in the process. In the case of ductile materials, when a crack appears on the surface the propagation is by a process of slip, which is not energy-releasing for the pressure, so that the fracture does not spread.

Both the strong dependence on the surface conditions in brittle fracture under hydrostatic pressure and the condition of energy release emphasize that there can be no single criterion of fracture in terms of stress and strain at a point only.

The actual experimental conditions differ from those of the idealized experiment in another important respect than the rigidity of the sheath, namely in the molecular structure of the specimen under test. In the idealized experiment, the material was thought of as structureless, and capable of indefinite and microscopically homogeneous distortion, as in the mathematical equations of elasticity theory. Actually, the material is composed of molecules, which have a certain impenetrability preventing indefinite approach, so that when strain is pushed too far individual molecules must be forced out of their positions by a series of discrete operations. It is doubtless something of this sort that is responsible for the remarkable separation of the glass tension specimens into thin disks, often, but not invariably, observed after simultaneous exposure of glass to pressure and tension. As tension increases, lateral contraction increases, and there must ultimately come a time when some of the molecules are brought into such close contact that they are forced out of their normal positions into neighboring spaces that have been opened by the simultaneous longitudinal extension. This process of molecular transfer is irreversible. When stress is released these displaced molecules act like internal wedges, distending the structure, which eventually fractures as in tension when stress is reduced far enough. A similar sort of thing has been found in other situations; fracture on release of stress would appear not to be uncommon. A somewhat similar state of affairs may be brought about in glass if foreign molecules are forced into the interior at the surface. Thus disking was almost always found in glass after a failure by the pinching-off effect in water as the transmitting medium.

The question has been much discussed of the great discrepancy between the experimental values of fracture stress and those calculated theoretically from various points of view. These considerations may have some bearing on this question. Strength in tension for a brittle substance we have seen to be an indeterminate matter, depending on the surface conditions. Under hydrostatic pressure breaking strengths in tension may be expected, with proper surface conditions, up to at least the magnitudes of the hydrostatic pressure. With pressures of the magnitude reached in these experiments, this is bringing the breaking stress up within reach of the theoretical values. In compression, dependence on the surface conditions is not to be anticipated, because the surface action that would take place at fracture is not energy releasing. Very large values of compressive strength can be reached, as for example 47,000 kg/cm$^2$ in Pyrex glass against some 2000 under ordinary conditions, or an increase of some 25-fold, again getting within sight of theoretical expectations.

It seems probable that the increases in compressive strength brought about by hydrostatic pressure are much greater for glass-like substances than for crystals. This is caused by the interlocking of the molecules in a glass, which is accentuated by pressure, making relative displacement more difficult. The effect is analogous to the very large increase of viscosity under pressure observed in some liquids with complicated molecules. In a crystal, on the other hand, the regular structure provides the possibility of internal slip. The plastic distortion of the crystal of $Al_2O_3$ is a case in point. The behavior of a crystal under compression is doubtless a highly specific property of the kind of crystal; I have never been able to produce measureable flow in crystalline quartz, although experiments on the collapsing of negative crystals show that some flow must be present.

Certain of the points emphasized here recall the point of view of Poncelet in a paper in Volume VI of Alexander's *Colloidal Chemistry*. Poncelet regards brittle fracture in tension as originating at the surface, and also emphasizes the role played by the "particulate" structure of ordinary matter as distinguished from the homogeneous isotropic structure assumed in the mathematical theory of elasticity.

Rowe and Gurney[8] have concluded from their experiments on the fracture of glass under "radial" pressure (my "pinching-off" effect) that Griffith's theory of fracture is essentially correct. According to this theory an actual specimen of glass is filled with minute crevices, with corners so sharp that under ordinary tensile load there may be stress concentrations at the corners by as much as a factor of 600. The breaking strength of geometrically perfect glass would thus be of the order of 6,000,000 p.s.i., which is of the order of the theoretical value, whereas the strength of an actual piece of glass is of the order of only 10,000 p.s.i. Under radial pressure fracture starts at the surface cracks. Rowe and Gurney have shown that assuming stress concentrations of 600, failure under radial pressure would be expected to occur at a pressure very approximately equal numerically to the ordinary breaking stress in tension, and this does in fact approximately agree with their experimental results. I think it must be admitted that qualitatively the Griffith point of view has considerable to recommend it. The strong dependence of fracture on surface conditions, for example, is consistent with its picture.

Qualitatively, Griffith's picture would lead to the expectation of pressure coefficients of tensile strength of completely sheathed brittle material of the order of magnitude of unity, and this also agrees with the experimental results above, and again indicates a real value in Griffith's point of view. It would not be easy to make a more precise calculation of the exact coefficient to be expected for completely sheathed specimens, however, because of the complicated nature of the surface conditions, and various other over-simplifications discussed in the next paragraph.

I question, however, whether other considerations do not play a vital role and whether the Griffith's picture is not much over-simplified. For instance, the surface conditions are in fact complicated, and involve chemical as well as purely mechanical factors, as shown by the very great effect of pressure media such as water or alcohol as contrasted with the oil used by Rowe and Gurney. Again, the ordinary concepts of stress and strain are carried down to a fineness of scale where there are stress concentrations of 600, whereas stress and strain are properly macroscopic concepts. At this scale of magnitude, the conditions of fracture are applied in the form that fracture occurs when the maximum tension reaches a critical value, irrespective of the other components of stress and independent of the strains. This condition of fracture does not seem to me to have any greater plausibility on the microscopic scale than on the macroscopic scale. The assumption of such a criterion amounts, among other things, to postulating that a pure hydrostatic pressure exerts no specific effect on the fracture properties of a substance. This is certainly not the case for ductile substances, as shown by my experiments on the enormous increase of the ductility of steel under pressure. The same thing is shown by the experiments of Rowe and Gurney themselves on plastics, which under their conditions of radial pressure tolerated an elongation before fracture eighteen times greater than under normal conditions. These results can properly be described as an increase of ductility under pressure. If plastic materials have their properties thus drastically altered by hydrostatic pressure it would seem to be only reasonable to expect some effect also on brittle substances. This is strongly suggested by the great increase of strength to simple compressive stresses found above for glass under high pressure.

---

[8] C. Gurney and P. W. Rowe, Second reference under 5.

The high tensile strength acquired by Carboloy under pressure is worthy of notice. The tensile stress at fracture is much higher than the surrounding hydrostatic pressure in the case of this material, so that the net stress at fracture is a tension. It is not necessary in this, or similar cases, therefore, to suppose that surface conditions play any role in the process, and the increase of strength may be a specific effect of pressure. The absolute value of the tensile strength, between 50,000 and 60,000 kg/cm$^2$, is not far from that which has been observed in steel, pulled to the limit of ductility and strain-hardened under pressure. A possible explanation of the effect in Carboloy is that it is associated with the cementing film of cobalt on the surface of each grain of carbide; the cobalt becomes ductile under pressure and strain-hardens in a way similar to steel.

A question that naturally presents itself in connection with these experiments is under what conditions does a substance lose its brittleness and become ductile under pressure? In order to deal with this question it is necessary to consider the concept of brittleness itself. It is not uncommon to speak of a brittle fracture, and in fact this usage has been followed in this paper. Such usage, however, employs a specialization and extension of meaning, because "brittle" properly does not refer to the process of fracture, but to what comes before the fracture. If the substance fractures before it receives permanent set, as shown by a permanent change of dimensions on release of stress, then the substance is brittle; if the substance fractures after it has received permanent set, then it is plastic or ductile. So far as the act of fracture itself is concerned it may be characterized as a shearing fracture or a tensile fracture, but not as a brittle fracture. When a brittle fracture is spoken of, what is meant is the fracture of a brittle substance. But strictly, from this point of view, all fractures might be spoken of as brittle, for a plastic substance which has been work-hardened to the limit and then fractures is, when at the point of fracture, a brittle substance. There is thus a considerable verbal element in the concept of brittle. Furthermore, the concept is not sharp, because if measurements are increased in sensitiveness plastic flow may be discovered before fracture where formerly with rougher measurements none appeared. In practise all that can be meant is fracture with no noticeable preliminary distortion.

In answer to our question as to what substances lose their brittleness under pressure, it may now be said that as a rough qualitative matter a crystalline substance, particularly if it is cubic, is more likely to become measureably plastic under pressure than an amorphous substance like glass. The observed plasticity of crystalline $Al_2O_3$ described in this paper lends plausibility to this statement. The limits are not sharp, however, and there is enormous variation in the numerical magnitude of the effect, as illustrated by the variation from soft steel to beryllium. In fact, even in the case of quartz crystal or glass an infinitesimal amount of flow must exist in principle, as shown by the spontaneous breakage of these materials under some circumstances a long time after exposure to high pressure.

# Addendum and Erratum: the Thermoluminescence and Conductivity of Phosphors*

[J. App. Phys. 17, 743 (1946)]

ROBERT C. HERMAN AND CHARLES F. MEYER
*Applied Physics Laboratory, Johns Hopkins University, Silver Spring, Maryland*

(Received November 21, 1946)

IN a recent paper with the above title,[1] the variations in the luminescence and conductivity of zinc sulphide type phosphors during infra-red illumination were discussed. The solutions given for the differential equations describing these processes are valid only in the case in which the retrapping of electrons is negligible. Recently, Klasens and Wise[2] derived the solution for the

---

* A portion of the work described in this paper has been supported by the Bureau of Ordnance, U. S. Navy, under contract NOrd-7386.

[1] R. C. Herman and C. F. Meyer, J. App. Phys. 17, 743 (1946).

[2] H. A. Klasens and M. E. Wise, Nature 158, 483 (1946).

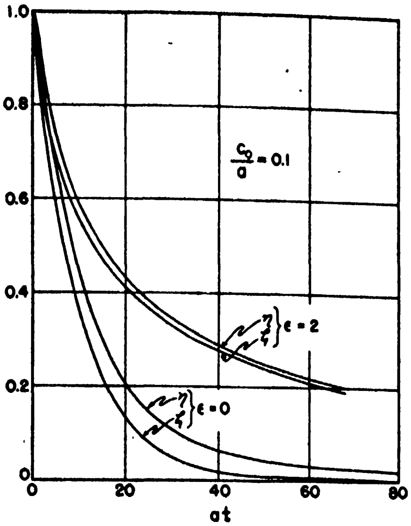

FIG. 1. The fraction of empty luminescent centers, $\eta$, and the fraction of trapped electrons, $\zeta$, *versus at* for $c_0/a = 0.1$ and $\epsilon = 0, 2$.

special case in which the cross section for capture of a conduction electron into a trap is equal to the cross section for capture into an empty luminescent center or hole. At the present time we are obtaining general solutions to this problem by means of a differential analyzer and wish to indicate some of the preliminary results.

The general solutions of Eq. (1) in reference 1 involve the following parameters[3]: $\epsilon$, the ratio of the cross sections for electron capture into empty traps and empty luminescent centers or holes and the parameter $c_0/a$, where $c_0 = \sigma I_0/h\nu$, and $a = AN_1$. In Fig. 1, the fraction of empty luminescent centers, $\eta$, and the fraction of trapped electrons, $\zeta$, are plotted *versus at* for $\epsilon = 0$ and 2 with the time $t$ in seconds. The corresponding variations of the luminescent intensity, $I$, proportional to $\xi\eta$, are plotted in Fig. 2. The behavior of $\xi$, which is proportional to the current $i$, can be obtained from Fig. 1 since $\xi = \eta - \zeta$.

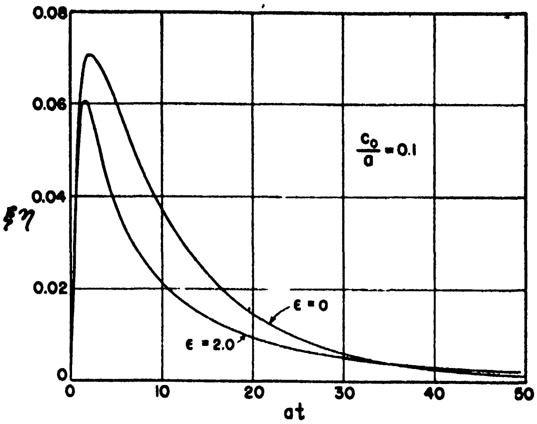

FIG. 2. The variations of $\xi\eta$, proportional to the luminescent intensity, *versus at* for $c_0/a = 0.1$ and $\epsilon = 0, 2$.

We take this opportunity to point out that Eq. (12) in our recent paper[1] should be written as follows:

$$\eta^{-1} = \exp(y - a/c_0) - (a/c_0)[Ei(-y) - Ei(-y_0)] \exp y$$

where $y = (a/c_0) \exp(-c_0 t)$, $y_0 = a/c_0$, $a = AN_1$, and $\eta = n_0/N_1$. This modifies Fig. 4 of the original paper in the manner shown for $\epsilon = 0$ in Figs. 1 and 2 of this note. The conclusions drawn from Fig. 5 remain unaltered.[1]

More detailed information on the effect of the retrapping of electrons on the luminescence and conductivity of phosphors during infra-red illumination as well as on the phenomenon of thermoluminescence will be published in the future.

We express our appreciation to Drs. G. C. Munro and D. T. Sigley of the Applied Physics Laboratory for their interest in this problem and thank the differential analyzer staff of the Moore School of Electrical Engineering, University of Pennsylvania for their cooperation.

---

[3] Note that $A = \sigma V$, where $\sigma$ is the cross section for capture into a hole, $V$ the velocity of a conduction electron; $I_0$ is the intensity of the incident infra-red light, and $N_1$ the number of electrons per cm$^3$ trapped originally.

# Letters to the Editor

## On the Action of Cutting Oils

G. P. Brewington
*Lawrence Institute of Technology, Detroit, Michigan*
December 5, 1946

ERNST and Merchant[1] have studied the efficiency (cutting ratio) of a number of cutting fluids on several metals and, for aluminum, have attempted to relate various physical properties of these fluids with observed cutting performance. They conclude ". . . that no relationship whatever appears to exist between the physical property and the cutting ratio." Even though the data given either in the paper referred to in reference 1 or in other sources are not as extensive as desired, it appears that some relationship does exist.

Those materials having a high cutting ratio appear to belong to that group of compounds having a sulfur ($-SH$) or chlorine in a low state of valence at the end of a short chain hydrocarbon. This would suggest that some of the higher valences of the sulfur and chlorine become active in the strong force fields known to exist at the newly formed surfaces of the work and chip, with the result that the molecule then adheres to the surface, thus reducing its activity and tendency to seize. The element fluorine exhibits only one valence but does form an analogous group of compounds similar to those of chlorine; it should be interesting, therefore, to compare the cutting ratios of these two fluids. The results obtained from cutting measurements on aluminum using a series of alcohols as cutting fluids may be due to a more common type of chemical action. If certain assumptions in the use of thermochemical data can be granted, the methanol-aluminum surface reaction must be sufficiently energetic to remove completely an aluminum atom, while the higher alcohols tend to attach themselves, through the $-OH$ radical, to the surface and form a monomolecular film. It would appear that an approach somewhat different from that used by Ernst and Merchant could be found in the surface energy studies of Bartell *et al.*[2]

The literature in the field of cutting oils is largely in the form of advertising and, while quite readily available, does not yield much quantitative information. Apparently innumerable experiments have been performed and reported only by word of mouth. Among such is a statement of high success associated with the use of a small stream of dry HCl gas playing on the cutting edge of a tool cutting steel. Should the HCl gas be as good as reported, and the cutting ratio as a function of cutting speed curve, as observed by Ernst and Merchant,[1] change materially, some indication as to the role of diffusion of the active agent in cutting phenomena might be obtained. Certainly the mobility of HCl gas would be much higher than that of larger organic molecules dissolved in liquids. It also should prove very interesting, if further data were available, to attempt to correlate the "cutting ratio" of various fluids with electron configurations of the active end of the molecule.

The cutting process viewed from any angle is extremely complicated and anyone who attempts to single out one phenomena for consideration is on dangerous ground. Assuming however, for this discussion, that tool failure at least depends on fatigue, which frequently can be associated with oscillation or standing wave phenomena, the varying force experienced by a tool tip must set up a standing wave pattern, possibly of ultrasonic frequencies, in the tool itself. This would suggest that the tool shape, particularly in carbide tools, should be such as to offer less opportunity for well-developed standing wave patterns to become established. One isolated unintentional experiment, reported verbally to the author, in which an "irregular chunk" of carbide brazed in a tool gave very good life, tends to suggest that other than the conventional form of tools might be further investigated.

The author wishes to thank Mr. H. A. Montgomery, president of the H. A. Montgomery Oil Company, for first suggesting that a problem, somewhat related to that discussed above, should be studied and also to Mr. W. Woijtowicz for many discussions of similar phenomena.

## Approximation for Absorption Displacement in X-Ray Diffraction by Highly Absorbing Cylindrical Samples

Zigmond W. Wilchinsky
*Esso Laboratories, Standard Oil Company (N. J.), Baton Rouge, Louisiana*
November 18, 1946

IN an article by Warren[1] treating displacement of diffracted x-rays caused by absorption in cylindrical samples, it was shown that for very high absorption, the displacement $\Delta S$ on the film is given by

$$\Delta S=(1+R/D)r\cos\theta\left\{\frac{\sin 2\theta-2\theta\cos 2\theta}{4\sin\theta+4\cos^2\theta\ln\tan\left(\frac{\pi}{4}-\frac{\theta}{2}\right)}\right\}, \quad (1)$$

where $R$ is the radius of the Debye camera used, $r$ is sample radius, and $D$ is the distance from the sample to the point

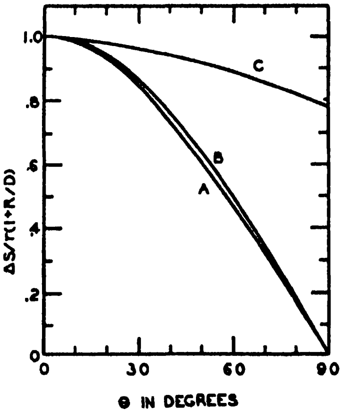

FIG. 1. Comparison of exact expression curve *A* with approximation curve *B*. Ratio of *A* to *B* is shown in *C*.

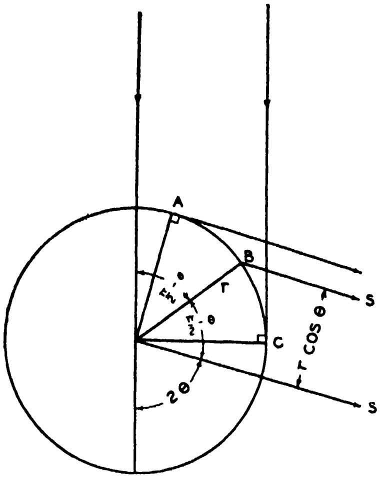

FIG. 2. Diffraction of a parallel x-ray beam from the surface of a highly absorbing cylindrical sample. By virtue of the above construction, *B*, the center of arc *ABC* lies on the bisector of the supplement of 2θ giving the above relationship among the angles.

from which the beam diverges. The purpose of this note is to point out that an approximation useful for general work is simply

$$\Delta S=(1+R/D)r\cos\theta. \quad (2)$$

This approximation is compared with Eq. (1) in Fig. 1. It can be noted that the approximation is best for small values of $\theta$. As $\theta$ increases, the magnitude of the departure increases at first, goes through a maximum, then decreases to zero at $\theta=90°$. The fractional departure however, increases steadily as can be gathered from curve *C* which is the ratio of (1) to (2), or simply the bracket in (1). At $\theta=90°$, curve *C* attains the value $\pi/4$.

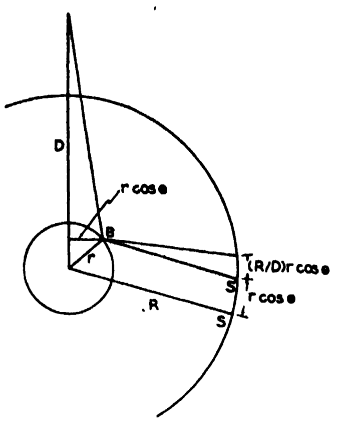

FIG. 3. Additional displacement caused by beam divergence.

A physical interpretation of the approximation (2) can be obtained with the aid of Fig. 2. First consider a parallel incident beam. For the right half of the sample, only the surface generated by moving *ABC* parallel to the sample axis is capable of contributing to the diffraction corresponding to $\theta$. *Assuming* that the center of gravity of the diffracted beam coincides with the ray diffracted from *B* the center of arc *ABC*, we find that *S'* is displaced parallel to the ideal position *S* by an amount $r\cos\theta$.

If the beam diverges from a point distant *D* from the sample (see Fig. 3), the angle of divergence of the ray to *B* is very nearly $(r/D)\cos\theta$. Therefore at the film, the ray diffracted from *B* is deviated by an amount $R(r/D)\cos\theta$, in addition to the quantity $r\cos\theta$ for the parallel case; the sum of the two effects is Eq. (2).

# Here and There

### New Appointments

J. H. Dillon, formerly with the Firestone Tire and Rubber Company, is now director of research of the Textile Research Institute, Inc., and of The Textile Foundation.

Frank M. Clark, insulation expert at the Pittsfield Works of the General Electric Company's Apparatus Department and assistant engineer of the Works Laboratory there, has been named technical consultant on insulation of the entire Apparatus Department.

W. Ewart Williams, English scientist now residing in the United States, has been appointed a consulting physicist on the research and engineering staff of Bausch and Lomb Optical Company.

### Awards

The Medal of Freedom, the nation's second highest decoration for civilian achievement in wartime, was awarded recently to two members of the staff of the National Bureau of Standards: Lauriston S. Taylor, chief of the X-Ray Section, and Fred L. Mohler, chief of the Atomic Physics Section. Mr. Taylor was also awarded the Bronze Star Medal.

### Electron Jubilee Celebrations

The fiftieth anniversary of the discovery of the electron by the British physicist, Sir Joseph Thomson, will occur this year. To mark this jubilee and to demonstrate the tremendous influence such an advance in pure physics may have on the life of the community, the Institute of Physics and the Physical Society are jointly arranging a series of meetings and other functions to take place on September 25 and 26, 1947, in London. A special exhibition which will remain open to the public for several weeks will be held at the Science Museum, South Kensington, and will show the development of the vast range of modern industrial equipment from its earliest experimental origins.

### Radio Engineering Show in March

The Annual Radio Engineering Show, a part of the 1947 National Convention of The Institute of Radio Engineers, will be held in Grand Central Palace, New York, March 3–6, 1947. The displays will be strictly of an engineering nature—transmitter equipment, instruments, component parts, and radio direction and location devices.

### Commemoration Program at Argonne National Laboratory

Major General Leslie R. Groves and Enrico Fermi were the principal speakers at the anniversary program held December 2 at the Museum of Science and Industry in Chicago, commemorating the initial operation of the first self-sustaining nuclear chain reaction.

### Research Physicists and Engineers Needed by NACA

The following statement was issued recently by the National Advisory Committee for Aeronautics:

"Physicists and engineers with research experience in problems related to aeronautics are needed by the National Advisory Committee for Aeronautics. Areas of research include the following: electronics, electrical measurements, servomechanisms, optics, interferometry, spectroscopy, electron or x-ray diffraction, mechanics of static or moving bodies, thermodynamics, aerodynamics, hydrodynamics, gas dynamics, metallurgy, lubrication, heat engines, mathematics, and other fields.

"The work of the NACA is to solve the fundamental problems of flight. This work is accomplished by means of basic research, consisting of experimental investigations and the development of theories needed for the prediction and explanation of aeronautical phenomena. The information obtained from this basic research is disseminated through publications to the field of aeronautics, where its application leads finally to the design and development of the nation's aircraft.

"This work is carried forward at three laboratories. The Langley Memorial Aeronautical Laboratory, Langley Field, Virginia, and the Ames Aeronautical Laboratory, Moffett Field, California, were constructed for, and are principally devoted to aerodynamic studies of the problems of flight and aircraft structures. Both are devoting a major portion of their work to fundamental problems of transonic and supersonic flight. Langley is also doing advanced research on the problems of guided missiles.

"The Aircraft Engine Research Laboratory, Cleveland, Ohio, is specifically designed for aircraft propulsion research. At the present time, the Cleveland facilities are primarily devoted to research investigations of the turbo jet, turbo propeller, ram jet, and rocket type power plants.

"Applications for positions or requests for further information should be addressed to the personnel officer of one of the laboratories."

# Ordnance Research Laboratory

By Eric A. Walker*
The Pennsylvania State College, State College, Pennsylvania

THE purpose of the Ordnance Research Laboratory at The Pennsylvania State College is to provide the Navy with an organization which can do research and development in an academic atmosphere. It differs from the Naval Ordnance Laboratory at White Oak, Maryland, and the Naval Research Laboratory in one important respect, namely, that this organization is completely under civilian control and has no Naval officers on its scientific or administrative staff. The organization of such laboratories as the Naval Ordnance Laboratory is too well known to demand further discussion at this time. It is recognized that such an organization cannot be perfect in all respects, and this new Laboratory represents an attempt to meet the problem of providing research for the Navy in a slightly different way.

Although the Laboratory was officially founded on January 1, 1945, it did not start work in its new building until October 1, 1945. However, the organization is much older than this. Many of the members of the staff were recruited from the Harvard Underwater Sound Laboratory, which itself was founded in 1941 and devoted most of its energies to submarine detection problems. Because of the caliber of some of the scientists, the Harvard Underwater Sound Laboratory was asked to undertake an ordnance problem which eventually grew into many and much larger problems, so that by 1943 the Ordnance Division of HUSL was firmly established. The major portion of this group was moved to the Ordnance Research Laboratory during the summer of 1945.

The Laboratory itself is housed in a two-story brick structure built especially for this purpose during the summer of 1945. This building affords approximately 30,000 square feet of space laid out in offices, laboratories, and shops in accordance with the needs. The Laboratory also operates two field groups, one at Newport, Rhode Island, and another at Fort Lauderdale, Florida.

FIG. 1. Exterior of Ordnance Research Laboratory. This Laboratory was designed by Paul Philippe Cret, well-known architect. It is laid out to be both functional and architecturally attractive.

---

* Director, Ordnance Research Laboratory.

FIG. 2. A view of the Black Moshannon Calibration Station for underwater sound devices. This calibration station is set on piles over a lake in a state forest. The general appearance is that of a Swiss chalet, and it was designed specifically to harmonize with its rural surroundings.

The one at Fort Lauderdale, Florida, will shortly be moved to a new laboratory structure at Key West. Both of these laboratories are modern buildings with office space, laboratory, and shops, but their work primarily is that of field testing the finished product or of obtaining fundamental determinations on which working designs can be based. At each of the field stations there exists a small core of four or five men who are on a permanent basis. The remainder of the staff is composed of scientists who are sent to the field stations for periods of from a few days to several months in order to test their designs.

The relationship between the Laboratory and the College is relatively simple. The Laboratory is established as a department of the School of Engineering in exactly the same way as any other department, such as Aeronautical, Civil, Electrical Engineering, etc. All members of the Laboratory staff are regular employees of the College. The scientists are given the academic titles of Professor, including the usual Associate and Assistant Professorships, or of Research Assistant, which in the usual academic scale corresponds to Instructor. Technicians hired as specialists in a particular field are usually classed as Assistants. The remainder of the staff, including machinists, clerks, and secretaries, carries appropriate designation. The direct line of responsibility between the Laboratory and the remainder of the College is through the Director and the Dean of the School of Engineering.

The relationship with the Navy is a much more tenuous one than that existing with the College, since there is only one Naval officer attached to the Laboratory. In fact, the Navy, by a contract between the College and the Bureau of Ordnance, sets aside a certain fund for the Laboratory to use in doing research and development on underwater ordnance. The Naval Ordnance Officer is expected to be cognizant of all the activities of the Laboratory and must approve certain business transactions which, because of their financial magnitude, seem to require prior Navy approval. The scientific tie between the Laboratory and the Navy is almost placed on a personal basis. The Navy does not write a directive on which the Laboratory must act, but most research programs undertaken by the Laboratory originate with the scientific staff of the Laboratory and are then submitted to the appropriate Naval officers for their approval. Because liaison between Naval officers and the scientific staff is a rather close and cordial one, usually there are a number of discussions preceding any formal proposal, and to date things are so well prepared that no proposal has been made which has not been accepted. This method of problem approval is a valuable one from the Laboratory's viewpoint because it serves as an automatic check on the work of the Laboratory and insures against scientists going off on unprecedented problems, while allowing the staff to judge the worth of the investigation and, to a great extent, to follow their own interests.

The internal organization of the Laboratory is not particularly novel, but it must stress certain factors which have to do with the product of the Laboratory, namely, scientific research. The Laboratory is headed by a Director and several Assistant Directors, but the weekly review of the working operations comes under the cognizance of a Council. This Council consists of the Directors of the Laboratory, including the Business Manager and Personnel Director, the leaders of all the sections, and the project engineers in charge of the major projects of the Laboratory. The scientific staff is organized both horizontally and vertically. There are five major scientific sections: Acoustics, Electronics, Applied Mechanics, Hydro- and Aerodynamics, and Mathematics. These may be further subdivided.

For instance, the Electronics Section is divided into a research division, a development division, and a production division, which undertake the particular functions indicated.

The Applied Mechanics Section is divided in a different manner, since it must fill a service function for the remainder of the Laboratory. It includes a design division which is expected to carry on all mechanical design through the blueprint stage, and the shops, which are expected to produce the mechanisms. This section also employs a number of mechanical designers or engineers who are expected to carry on any research projects which fall into this classification and to serve as representatives of this section in a manner which will be outlined later.

The Acoustics Section has research, development, and construction functions, and also test responsibilities which include the test of any acoustical device which is produced in this Laboratory or a device on which tests may be requested by other organizations.

The Hydro- and Aerodynamics Section is currently being organized. It will consist of two major divisions, the first concerned with the mathematical aspects of aero- and hydrodynamics with special emphasis on body shapes, propellers, and cavitation. The other division will be concerned with operations for the test of these devices either at sea or in the water tunnel.

The Mathematics Section, because of the peculiar nature of its work, has little or no formal organization.

The work of the Laboratory is usually concentrated in a small number of major projects. These projects are almost entirely development work, and therefore they come under the cognizance of a project engineer. In assembling a staff for any particular project, the project engineer may feel that he needs the services of engineers or scientists skilled in particular scientific fields, so he may request the proper section leader to assign to him a scientist who is familiar with the type of problem which he expects to meet. Conversely, the section leader, knowing a project is to be undertaken, may decide that this particular project has a number of features in which his group will be interested. He may then request representation and assign to the group a scientist who will pass on all of the designs which come in his field and who will keep the section leader informed of the progress of the work.

The work in a project usually divides itself into a construction phase which is undertaken at the main laboratory and a test phase which is undertaken at one of the field stations. One of the inviolable principles of operation is that the group which tests a device must be the same group which designed and supervised its assembly at the home laboratory. This serves to preserve continuity of knowledge which exists in unwritten form and which may be of considerable importance in the design and final operation of the device. Some difficulties arise from time to time when an engineer is asked to serve both the project engineer and the section leader. This matter is usually resolved by a ruling that in the field the project engineer is in complete charge, while in the laboratory he must confer with the section leaders.

Every attempt is made to insure complete dissemination of all information about all projects. This is possible because they cover a narrow range of scientific activity. First, a weekly organization report is issued. The material is collected as painlessly as possible by the group secretaries, who visit the various individuals at their work places and ask for their weekly reports. In it each scientific worker in the Laboratory may have his say. Frankness is encouraged, and because the organization report

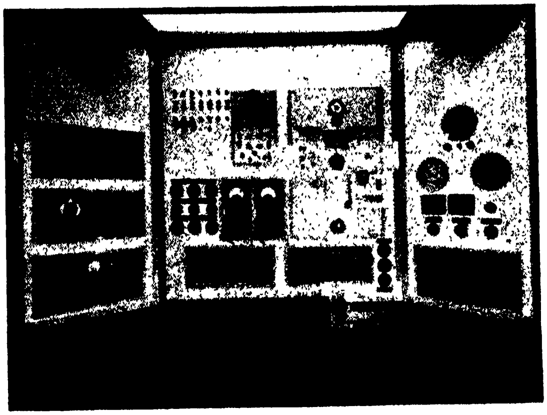

FIG. 3. Front view, Black Moshannon console. A close-up view of the console from which all of the underwater acoustic measurements are made. This panel is so laid out that all measurements can be made from this point and recorded automatically without the operator's leaving the control position.

FIG. 4. This is a view of one of the general shops. This particular shop is devoted to light machine work for the construction of models and test equipment.

never leaves the confines of the Laboratory, no editing is encouraged or attempted. The notes published in this organization report may be lengthy or brief, depending on the scientist's mood and on the amount of work he has done during the past week. At times these reports may be deadly reading, but they give every member of the Laboratory a chance to be heard on any subject, scientific, administrative, or otherwise.

The second method is to encourage the frequent writing of internal memoranda. Each member of the staff is told that when he reaches a suitable stopping point in his work, he should write a memorandum addressed to his immediate superior and sent to anyone else in the Laboratory who he feels might be interested in his work. As is expected, these memoranda provoke considerable comment and much constructive criticism.

The third method is by conferences. These are almost never scheduled on a calendar basis but are assembled on short notice by the project engineers when they feel that some clarification is needed.

The reports of the Laboratory take two forms: a monthly report which tells of the progress of all research programs, and reports on a single program which are issued when a suitable tying-off point is reached. Ultimately, the product of the Laboratory will be gadgets or weapons, together with complete sets of prints by which they may be constructed, and the maintenance and instruction manuals which are necessary for their use. Completion reports will include an evaluation of the device which sums up the matter by either saying that the gadget is no good and should be forgotten, or that it is useful and should go to the Fleet for training purposes.

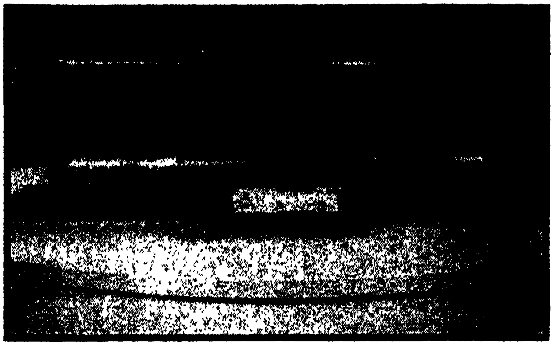

FIG. 5. Scale model of the 48-inch water tunnel which will be built at Penn State in the near future. The large section of the tunnel has a diameter of 12 feet and it is over 100 feet long. The picture shows a full-size railway box car to the same scale.

An attempt is made to provide every useful mechanical aid for the scientists, since they, at the present time, are by far the scarcest commodity. Computers are provided to make routine calculations and to plot curves. Draftsmen are provided to put sketches into publishable form, and a library and staff keep the master files and all available useful information. Because these files become quite voluminous it has been found desirable to keep a microfilm file of all documents which are six months old or older. Most of these documents are on the general theme of underwater ordnance and include reports of this and other laboratories, as well as technical accounts of the ordnance used by foreign governments.

In the administration of any such organization, certain aids and methods of operation appear which are peculiar to the personnel employed and which may work in a laboratory of one size and nature and not in another. Experience at ORL has shown that it is desirable to provide almost complete segregation between the business and the scientific functions of the Laboratory. No scientist should be asked or even allowed to waste his time on matters which belong in a purchasing office. He should not be allowed to hire personnel because he may make commitments which cannot be honored. He should not be asked to waste his time securing tickets or hotel reservations if it can better be done by someone attached to the Business Office. One other peculiarity arises from the fact that in a research organization very often only one item of a kind is made. Many scientists feel that such an item can best be designed "on the lathe." It is quite obvious that no machine shop of any size can be run in this manner, so at ORL the stipulation is made that all machine shop work is done either to blueprint or to approved sketches. This still leaves the possibility that in some cases the scientist's contention may be correct, and it is not worth the time to make detailed drawings or elaborate sketches before construction is started. For this reason, a small and well-equipped machine shop is provided in which any scientist can do his own work. For the safety of both the scientist and the machines, an expert machinist is always in attendance who may actually do the job or, if necessary, guide the scientist while the job is being done. Such an arrangement, although a rather elaborate one, seems to remove many causes of irritation and friction.

Every attempt is made to get publications into the scientific press, and for this purpose an Editorial Office exists and may be called upon to give assistance if the author wishes or requires it.

# Here and There

### New Appointments

G. Howard Carragan has been appointed head of the Department of Physics at Rensselaer Polytechnic Institute. He succeeds Robert A. Patterson, who recently left to serve as an assistant director of Brookhaven National Laboratory, atomic research center at Camp Upton, Long Island.

### Walter Evans Receives Army Award

The War Department has announced the award of the Army Certificate of Appreciation to Walter Evans, vice president in charge of all radio activities for the Westinghouse Electric Corporation, for "his contribution to the Signal Corps in connection with the development and production of radio and radar equipment during World War II."

### Duane Roller Receives Oersted Medal

The American Association of Physics Teachers has awarded the Oersted Medal to Duane Roller, professor and head of the Department of Physics of Wabash College, Crawfordsville, Indiana. The award is made annually "for notable contributions to the teaching of physics."

Through the *American Journal of Physics*, which he has edited since it was founded in 1933, Dr. Roller had made probably the most notable contribution to the teaching of physics at the college and university levels since the subject was introduced into our educational system. If the *Journal* were his sole contribution (which it is not), Dr. Roller would richly deserve this signal honor.

He attended Culver Military Academy and did his undergraduate work at the University of Oklahoma. He also received the Master's degree at Oklahoma and taught there for thirteen years partly before and partly after his work for the Doctorate at California Institute of Technology, which he received in 1929. Subsequently he was a research associate at Columbia and an associate professor at Hunter College. During the first world war he was a pilot and during the recent war he was Chief Technical Aide of the National Defense Research Committee.

Former recipients of the Oersted Medal, which has been awarded every year since 1936, include W. S. Franklin of Lehigh, M.I.T., and Rollings; R. A. Millikan of Columbia, Chicago and Caltech; Henry Crew of Northwestern, and G. W. Stewart of Iowa. Last year's award was to R. L. Edwards of Miami University.

The formal award was made at the January 31 session of the annual meeting of the American Association of Physics Teachers, which occurred at Columbia University. In his address of acceptance Dr. Roller discussed one of his chief professional interests, physical terminology, another field in which he has made notable contributions, both to the teaching of physics and to the science itself.

### Chicago I.R.E. Conference

The second Chicago Conference of the Institute of Radio Engineers will be held on Saturday, April 19, at Northwestern Technological Institute. It will feature an all-day series of technical sessions and discussions on the practical side of electronic engineering, with emphasis on applied electronics.

### The Bulletin of Mathematical Biophysics

Following is the table of contents of the March 1947 issue of *The Bulletin of Mathematical Biophysics:*

**Suggestions for a Mathematical Biophysics of Some Psychoses**—N. RASHEVSKY

**A Problem in Mathematical Biophysics of Interaction of Two or More Individuals Which May Be of Interest in Mathematical Sociology**—N. RASHEVSKY

**Mathematic Theory of Motivation Interactions of Two Individuals: I.—**
**ANATOL RAPOPORT**
**The Mechanism of the Middle Ear: I. The Two Piston Problem—**
**MARTINUS H. M. ESSER**

The University of Chicago Press, Chicago, Illinois, Volume 9, Number 1.

### New Physics Laboratory at Carnegie Tech

The Buhl Foundation of Pittsburgh has made a grant of $300,000 to Carnegie Institute of Technology for the partial support of a plan to build a 200-million-volt synchrocyclotron and nuclear physics laboratory. A condition of the grant provides that at least $250,000 shall be subscribed by others for the same purpose. Dr. Charles F. Lewis, Director of The Buhl Foundation, said of the grant, "It is confidently expected that this program will notably strengthen Pittsburgh's position as one of the nation's outstanding centers in scientific research."

### Institute of Navigation

The Institute of Navigation held its eastern regional meeting on February 13 and 14 in New York City. The Institute was founded during the war by members of the Armed Services and by civilians as a non-profit scientific and technical society devoted to the modern science of navigation in the air and on the sea. The membership is composed chiefly of astronomers, mathematicians, navigators, aviators, physicists, and engineers. The president of the Institute is Commander Gordon A. Atwater, Director of the Hayden Planetarium, New York City.

### Frontiers in Chemistry Lectures

The sixth annual series of Frontiers in Chemistry lectures at Western Reserve University, Cleveland, Ohio, will occur in February, March, and April. Among the twelve scientists to appear in the series are Dr. Glenn T. Seaborg, Dr. Harold C. Urey, and Dr. K. C. D. Hickman. The lectures will be divided into two sections. The first will deal with recent advances in physical and inorganic chemistry, and the second with modern theories of organic chemistry. The course is designed chiefly for graduate chemists and physicists.

### Physics Research at Northwestern

In January it was announced that Northwestern University would begin immediately a $500,000 three-year program of fundamental research in physics that is expected to lead to new and improved communication devices. Financed by the Navy, the program will be directed by Professors Walter S. Huxford and Robert J. Cashman of the Department of Physics. It is an extension of wartime research in which they developed a new invisible-ray telephone and many new types of photoelectric cells used in the phone and in various Army and Navy secret weapons.

### Hugh L. Dryden Elected to International Committee

Hugh L. Dryden, associate director of the National Bureau of Standards, was elected a U. S. representative to the International Committee at the Sixth International Congress for Applied Mechanics held at the Sorbonne, Paris, September 1946. The Congress brought together for the first time since the war those scientists from each major country interested in theoretical and experimental work on the elastic and plastic properties of materials and structures, fluid mechanics, vibration, sound, friction and lubrication, thermodynamics, combustion, and heat transfer. The International Committee, consisting of outstanding scientists from member nations in the field of applied mechanics, is the managing body of the Congress, which is concerned with the international cooperation, advancement and standardization of the sciences of applied mechanics.

### General Electric Fellowships at Case School

Case School of Applied Science will offer fifty fellowships to high school teachers of physics for a six-weeks program of study during the summer of 1947. Recognizing the fact that industrial research and progress stem largely from a knowledge of physics, The General Electric Company has provided these fellowships for high school and preparatory school teachers of physics. The program is designed to acquaint teachers with recent scientific developments. The fellowships include all tuition fees, room and board, and travel expenses. High school and preparatory school teachers of physics from the following states are eligible to apply: Ohio, Michigan, Western Pennsylvania, West Virginia, Kentucky, Indiana, Illinois, Wisconsin, and Maryland.

### Research in Mineral Flotation at MIT

Armour and Company has established a fund of $12,000 for a graduate research program in the fundamentals of mineral flotation at the Massachusetts Institute of Technology. This program, which provides for grants-in-aid for several assistantships and fellowships, will concentrate on the operation of cationic collectors, particularly the organic compounds known as amines and amine salts.

### Harvey L. Curtis Retires from Bureau of Standards

Dr. Harvey L. Curtis, physicist at the National Bureau of Standards since 1907, has retired. His major scientific achievement has been in the field of absolute electrical measurements. He has written the standard textbook on the subject, and his conclusions will form the basis for United States proposals in establishing a fixed relationship between the absolute and international electrical measurement units at the next International Electrical Congress. During World War II he assumed responsibility for interior ballistics research at the Bureau.

### Journal of Mathematics and Physics

The Journal of Mathematics and Physics is published by the Massachusetts Institute of Technology in annual volumes of four numbers. Papers which appear in this journal deal with mathematical problems from the fields of engineering and applied physics and with mathematical methods of interest for the applications.

Individual members of the American Institute of Physics may subscribe to the Journal at the special rate of $3 per year. The regular subscription price is $4 per year. Subscription orders and other correspondence may be sent to the Journal of Mathematics and Physics, Massachusetts Institute of Technology, Boston 39, Massachusetts.

### Reinforced Concrete Research at Bureau of Standards

The American Iron and Steel Institute is supporting a research program on reinforced concrete now under way at the National Bureau of Standards. The prime objectives are improved design of concrete reinforcing bars and engineering data that will enable engineers and builders to make more effective use of reinforced concrete.

### Awards

Two members of the staff of the Naval Research Laboratory recently received the Distinguished Civilian Service Award from the Secretary of the Navy for their contributions to the war effort: George R. Irwin, director of the ballistics section, and Wayne C. Hall, head of the electrical division.

The War Department has awarded the Bronze Star Medal to Harold O. Wyckoff, associate physicist in the X-Ray Section, National Bureau of Standards. Dr. Wyckoff served in the European Theater as assistant chief of the Operational Research Section of the Ninth Air Force.

### Radio Engineering Meeting

On May 3 in Cambridge, Massachusetts, there will be an all-day New England Radio Engineering Meeting under the sponsorship of the North Atlantic Region of the Institute of Radio Engineers. All persons interested in radio and electronic engineering are cordially invited to attend. There will be six technical sessions, none held concurrently, exhibits by the leading manufacturers in New England, a luncheon and a banquet. The entire program will be held at the Continental Hotel in Cambridge. A complete program announcement will be made later.

### German Physical Society

A conference of German physicists was held October 4–6, 1946, at Göttingen, Germany, in the British Zone of Occupation. About three hundred physicists were present. A German Physical Society was organized for the British Zone. Following are the titles of papers presented: "Theory of the diffraction of electro-magnetic waves on a circular disk," "Measurements on the slowing-down of neutrons," "On neutron processes in beryllium, aluminum and lithium," "Experiments on photographing by means of neutrons," "Changes of sensitivity on light counter tubes," "On a method for the determination of energy and energy distribution of ionizing particles," "On the age of the world," "On the isotope displacement effect in the *E I*-Spectrum," "Experimental detection of the von Schmidt headwave in optics," "Collision discharge in highest pressure mercury lamps," "The accommodation time of the electron temperature in a stationary electric discharge," "Determination of the altitude of the sodium layer shining in the night sky," "Oxide layers on metals," "The optical and electrical qualities of synthetic Greenockite," "Density of sublimed salt layers," "Thermal dissociation in the radiation black body cavity," "Deformation of electron clouds by the collision of gas molecules," "Intuitive models for the theory of super-conductivity," "Superconductivity and the periodic system of elements," "Electron theory of superconductivity," "Sublimation, condensation, saturation pressure and critical point in a model experiment," "Does the lattice constant change for very small particles?" "Optical analyses on electrolytic solutions. Measurements on absorption coefficients," "Thermal effects of gliding friction," "Equation of state of water at high densities," "Exact viscosity measurements up to 2000 atm." "Hydrogen bonding, resonance and the formation of molecular chains," "Remarks on the statistical theory of turbulence."

Dr. Max von Laue was elected Chairman of the Society. The question of journals was discussed but no action was taken.

The following note at the end of the program is significant. "This program may at the same time be regarded as a ticket. . . . Ration cards, including those for potatoes, are necessary."

### Necrology

George A. Scott, assistant professor of physics at the University of Pittsburgh, passed away suddenly following a heart attack in January.

---

## PROCEEDINGS OF THE ELECTRON MICROSCOPE SOCIETY OF AMERICA

THE annual meeting of the Electron Microscope Society of America was held at the Mellon Institute in Pittsburgh, Pennsylvania, December 5–7.

Titles and abstracts of the papers presented are given below:

**1. Trends in X-Ray Diffraction Work.** DAVID HARKER, *General Electric Company, Schenectady, New York.*

**2. Trends in the Use of the Electron Microscope in the Study of Fine Structure.** JAMES HILLIER, *Radio Corporation of America, Princeton, New Jersey.*

**3. The Application of Electron Diffraction Methods in the Study of Fine Structure.** ROBERT HEIDENREICH, *Bell Telephone Laboratories, Murray Hill, New Jersey.*

**4. First-Order Theory of the Three-Electrode Electron Gun with Plane Electrodes.** S. G. ELLIS, *University of Toronto, Canada.*—On the simplifying assumption of linear potential variations within the electron gun it is possible to deduce the position of the image of the cathode, the magnification and the angular aperture of the beam external to the gun. The results are compared with those of Johannson. The area of the specimen illuminated in the electron microscope is discussed. It is shown that in general an electron gun can be operated either with or without the production of a cross-over.

**5. Some Observations on the Shadow Cast Formvar Replica Technique.** BEATRICE M. DEACON, S. G. ELLIS, AND W. G. CROSS, *University of Toronto, Canada.*—Formvar replicas of polished glass surfaces containing sleeks were examined in the electron microscope both with and without shadow casting. In another experiment several replicas from the same region of a glass surface were examined. The nature of the replicas and the limitations of the method are discussed.

**6. Electron Microscopy of Colloid Systems.** JOHN TURKEVICH, *Princeton University* AND JAMES HILLIER, *Radio Corporation of America, Princeton, New Jersey.*—Typical colloidal systems such as gold, silver, platinum, alumina, ferric oxide, tungsten oxide, vanadium pentoxide, cadmium sulfide, arsenic sulfide, etc., were examined under high resolution with the electron microscope. The form of the colloidal particle and its size were determined as a function of the variables used in the preparation. A method will be described for obtaining gold particles of very uniform size and suitable for calibration standards. The behavior of particles of alumina on steam treatment will be illustrated with electron microphotographs.

**7. Electron Microscope Examination of the Microphysical Properties of the Polymer Cuprene.** JOHN H. L. WATSON, *Shawinigan Chemicals Limited, Shawinigan Falls, Quebec.*—The microphysical structure of cuprene is described from electron micrographs and suggestions are made from them concerning the mechanism of the formation and catalysis of this material. Copper is detected in the electron diffraction pattern. Cuprene samples prepared by polymerization of acetylene in the presence of finely divided cuprous oxide are shown as hollow fibers characterized by both longitudinal and transverse structure and a very thin skin. The striking appearance of this type of cuprene serves to identify it in clogging deposits taken from acetylene lines. This is illustrated by a deposit taken from a reactor used in the process of hydrogenation of acetylene to ethylene. "Cuprene" specimens formed by alpha-ray bombardment of acetylene gas are shown as round particles joined by short necks about 500 to 1000A in length. An oxidized sample has round particles of mean diameter 4900A and unoxidized sample of mean diameter 3800A. The alpha-ray cuprene is quite unlike the catalyzed solid material in appearance and in addition possesses characteristics of a very viscous liquid in the electron micrographs.

**8. An Effect of Electron Bombardment upon Carbon Black.** JOHN H. L. WATSON, *Shawinigan Chemicals Limited, Shawinigan Falls, Quebec.*—A significant change is reported in mean particle size and shape characteristics of carbon black due to specimen contamination while under examination in electron microscopes. The effect is described for a number of well-known commercial blacks and examples are given in micrograph, graphical and tabular form to illustrate expected variations in mean particle size with continued bombardment. At normal focusing intensities, the particle size usually will have changed more than 5 percent in 30, or sometimes in as little as 15 seconds. The change is detected with other materials but is more pronounced with carbon black. Chromium shadow cast specimens seem to change to a less degree than uncoated samples. The contamination is explained as arising from the well-known polymerization and condensation processes which occur when organic vapors and gases are bombarded by charged particles. Suggestions are made for minimizing the effect.

**9. The Electron Microscope Examination of Greases.** S. G. ELLIS, *University of Toronto, Canada.*—A method is described for examining the soap component of lubricating greases with the electron microscope. The soap component is mounted on Formvar films from a dispersion in ether. The specimen is shadow cast by the method of Williams and Wyckoff. The deduction of the shape of the soap particles is discussed.

**10. Artifacts Produced by Poor Resolution.** L. H. WILLISFORD, *Goodyear Tire and Rubber Company, Akron, Ohio.*—A micrograph of round objects may show the following two opposite conditions: (1) the individual objects of a group will have a tie or rod connection with each adjacent individual of that group and (2) isolated individual objects will have smooth profiles with no evidence of any portion of a tie or rod. This condition of rod connection is caused by imperfect resolution. A simple set-up has been devised for casting shadows which simulate continuous changes from good to poor resolution. When two disks under conditions of poor resolution approach each other, the space between them remains clear until the distance is just less than the limit of resolution, at which distance a misty connection appears. With closer and closer approach, the connection darkens; and before the disks are in contact the connection has the appearance of reality. When slightly overlapped, the disks have a pronounced dumbbell effect. This artifact rod has been confirmed by destroying the resolution of a standard micro-tessar lens; in fact, the "rod" effect is quite universal, and an audience participation demonstration will be given which will duplicate the clues of poor resolution to be looked for in regular and stereo micrographs of round objects.

**Some structural patterns in biological systems.** FRANCIS O. SCHMITT, *Massachusetts Institute of Technology, Cambridge, Massachusetts.*

**11. Remarks on the Borderline of Physics, Chemistry, and Biology.** L. MARTON.—A dual conception of life phenomena is proposed in a manner somewhat similar to the dual conception of wave mechanics. The probability of "creation of order from order" depends on the size of the elementary unit of a chemical compound and on the *non-periodic* complexity of its components. "Life" is therefore not restricted to the group of so called "living organisms," the probability function has a finite value for the simplest chemical compounds, although its value may be immeasurably small. For large chemical compounds, which are considered often on the border line between chemistry and biology, it depends on the experiment whether the "chemical" or the "life" character will be predominant. These considerations necessitate also a critical survey of the molecular concept. A more statistical definition of the molecule is attempted and experiments are proposed to prove the conclusions of the paper.

**12. Applications of the Phase Microscope in Electron Microscopy.** OSCAR W. RICHARDS, *American Optical Company, Buffalo, New York.*—The Spencer Phase Microscope controls light passing through it so that invisible phase differences arising from optical path differences in the specimen are converted into visible amplitude or intensity differences. In phase microscopy the contrast in the image may be increased, decreased or reversed, and either increased or decreased. The instrument and its use will be described. The Phase Microscope, within its limits of resolution, is useful for the examination of transparent specimens (e.g., replicas). The relation of phase and electron microscopy will be discussed.

**13. Preparation of Tissue for High Speed Sectioning.** MARY C. SCHUSTER AND CLIFFERD E. GRAY, *Interchemical Corporation, New York, New York.*—The standard techniques of tissue preparation for light microscopy produce distortions that become apparent with the increased resolution of the electron microscope. An adaptation of standard technique is made in the following manner: the tissue is washed free of soluble proteins using isotonic saline solution; fixation is started at very great dilution, and the concentration of fixative is increased slowly to the desired level; when fixation is complete, dehydration and embedding are performed with similar care. Preparation of various tissues with various reagents is discussed and illustrated. It is believed that the procedures described will add to the effectiveness of the joint techniques of high speed sectioning and electron microscopy.

**14. Electron Microscope Studies on the Structure of Chlorophyll "Crystals," "Crystalline Alpha Carotene," "Crystalline Beta Carotene" and "Crystalline Vitamin A."** EDITH A. ROBERTS, *Vassar College, Poughkeepsie, New York.*—Electron microscope studies of the above show that they are composed of structural units less than 100 ängströms, some of units close to 10 ängströms. These units appear to be protoplasmic entities comparable to those present in plastids rather than "crystals."

**15. Further Electron Microscope Studies of the Structure of the Starch Grain.** MILDRED D. SOUTHWICK, *Vassar College, Poughkeepsie, New York.*—Electron microscope studies of the structural organization of starch grains, either fresh or commercially prepared from the seeds, roots, stems, or leaves from different genera of plants belonging to the *Bryophyta*, *Pteridophyta*, and *Spermatophyta* indicate the same essential morphology of all starch grains. All show the presence of structural units, comparable to those in the chloroplast—the larger units, plastidules, and the smaller units, plastid granules, as well as the units of a still smaller size which would approach the smallest functional protoplasmic units known.

**16. The Mounting of Bacteria for Electron Microscope Examination.** JAMES HILLIER AND R. F. BAKER, *Radio Corporation of America, Princeton, New Jersey.*—In the case of some bacteria grown on solid media it is possible to remove a young culture from the medium intact. In other cases a modification of the light microscopists impression technique is found to be very satisfactory.

**17. A Study, with the High Voltage Electron Microscope, of the Endospore and the Life Cycle of Bacillus Mycoides.** GEORGE KNAYSI, *Cornell University, Ithaca, New York* AND R. F. BAKER AND JAMES HILLIER, *Radio Corporation of America, Princeton, New Jersey.*—A study of strain $C_2$ of *bacillus mycoides* at 150 kv shows that the endospores obtained from old agar-slant cultures present considerable differences in appearance. Most common are those which are uniformly opaque, those which show a black outline and a shrunken content, and those with transparent lateral areas and thick folds. The exine is thick and surrounded by a thin, elastic pellicle. The intine can sometimes be seen. Germination is initiated by an increased transparency to the electrons and by lateral bulging. This is followed by cracking of the exine, the two halves of which usually remain attached but occasionally are totally severed. In ordinary media, the germ cell and subsequent generations are semi-transparent but show no differentiation in their protoplasm until the fatty inclusions which usually appear before sporulation are formed. We were unable to observe these granules at 50 kv. The forespore appears homogeneous. The mature spore often shows a dark outline and a slightly shrunken protoplasm within the mother cell. High voltage is of distinct advantage in the study of this problem.

**18. Demonstration, with the Electron Microscope, of Nucleus-like Bodies in Cells of *Bacillus Mycoides* Grown in Nitrogen-Free Media.** GEORGE KNAYSI, *Cornell University, Ithaca, New York* AND R. F. BAKER, *Radio Corporation of America, Princeton, New Jersey.*—The endospore of *bacillus mycoides* contains a relatively considerable quantity of ribonucleic acid which is an excellent source of nitrogen but a very poor source of energy. In ordinary nutrient media, this material is also readily formed by the vegetative cell and is diffuse throughout the protoplasm in an apparently combined form. It is the reason why such cells stain homogeneously and are opaque to electrons. When the endospore germinates in a medium without a nitrogen source, the ribonucleic acid is used up and the subsequent generations of vegetative cells become poorly stainable and transparent to electrons even at 30 kv. In such cells one observes one to several opaque bodies which appear to divide and which are finally enclosed in the forespore; this behavior indicates their nuclear nature. There is also a variable number of smaller bodies of unknown significance. The best results were obtained with a medium consisting of 0.2 g of glucose+0.2 g of Na acetate+100 ml of distilled water.

**19. Observation on Actin and Myosin Extracted from Muscle.** M. A. Jakus and C. E. Hall, *Massachusetts Institute of Technology Cambridge, Massachusetts.*—Actin has been extracted from striated muscle according to the method of Straub. The addition of neutral salts or hydrogen ions to an aqueous solution of actin brings about a reversible transformation of the globular protein into a fibrous form. Electron micrographs of actin at different stages of linear aggregation will be shown. A water-soluble muscle component designated as "myosin" by Szent-Györgyi has also been prepared and examined. Micrographs of this protein will be presented and compared with those of myosin extracted in alkaline salt solution after the method of Greenstein and Edsall.

**20. Size Distribution of Tobacco Mosaic in the Early Stages of Infection.** Gerald Oster, *The Rockefeller Institute for Medical Research, Princeton, New Jersey.*—A method is described whereby the contents of the hair cells from leaves of Turkish tobacco plants diseased with tobacco mosaic virus may be examined by means of the electron microscope. It was found that 68 percent of the rod-like particles present in the hair cells of plants infected for 25 days are about 280 mu in length. The contents of hair cells infected with the virus were also examined less than one day after innoculation, and particles less than 280 mu in length were found to be present. The size distribution of virus preparations subjected to sonic treatment was determined. The virus activity of the sample is proportional to the number of particles 280 mu in length that are present.

**21. Studies on the Newcastle Disease Virus (California Strain).** A. R. Taylor, *Duke University School of Medicine, Durham, North Carolina.*—The infectious agent responsible for Newcastle disease of fowls has been concentrated and purified by ultracentrifugation. Studies of the concentrates have been made by means of electron micrography, analytical ultracentrifugation, and chemical analysis. The virus is a sperm-shaped particle with a head of about 70-mu width and 180-mu length and a thin tail of about 500-mu length. Well-defined internal structure was observed in the head-piece. The virus consists of protein and lipid in association with a small amount of mucleic acid. The results of elementary and component analyses will be given in detail.

**22. An Electron Microscope Study of the Structures of Some Virus Protein Crystals.** R. W. G. Wyckoff, *National Insitute of Health, Bethesda, Maryland.*—This is a discussion, illustrated with electron micrographs, of the kinds of regularity of particle arrangement obtained when suspensions of several crystallizable macro molecules are desiccated in the presence and in the absence of salts. These kinds of order are compared with that observed by electron microscopy in preformed crystals of these substances.

**23. Immunochemical Aspects of Sonic Treated Tobacco Mosaic Virus.** Saul Malkiel, *The Rockefeller Institute for Medical Research, Princeton, New Jersey.*—In preparing tobacco mosaic virus from the juice of infected plants, Sigurgeirsson and Stanley found small non-infectious particles about ⅓ of the usual length of the tobacco mosaic virus particles in the supernatant liquids after centrifugation of the normal virus particles. Preparations of this small particle were compared quantitatively with the $280\times15$-mu sized rod by means of the precipitin reaction. More antibody was precipitated by the rod of normal size. A solution of freshly prepared tobacco mosaic virus was subjected to sonic vibrations in order to yield small particles. By fractional centrifugation, the normal sized tobacco mosaic virus particles were removed, leaving a supernatant liquid containing a preponderance of smaller particles as checked by distribution measurements of electron micrographs. In order to investigate and compare more fully the immunochemical behavior of these particles with normal tobacco mosaic virus, the stoichiometric relationship of antigen to antibody in specific precipitates was determined by means of the quantitative precipitin reaction. Both heterlogous and homologous antisera were used for this investigation. These findings and the possible theoretical considerations are presented.

**24. Specimen Preparation for Electron Micrographs and Diffraction Patterns.** Leland L. Antes, *University of Texas, Austin, Texas.*—Several simple and effective methods of dispersing fine powders which have a tendency to agglomerate when in suspension are outlined. As applied to such materials as carbon black, metallic oxide pigments and catalysts, these methods may be roughly classified into dry smear and surface film techniques. The results of these methods are compared with others which are generally used. Methods of preparing water-soluble salts for diffraction patterns are discussed, and the advantages of electron diffraction methods in determining crystal structure are pointed out. A means of directly comparing the intensities of diffraction pattern spots or rings is suggested.

**25. Alterations and Additional Equipment for an R.C.A. Console Electron Microscope.** Henry C. Froula, *Armour Research Foundation, Chicago, Illinois.*—Alterations and additional equipment were made for an R.C.A. console electron microscope to simplify maintenance and operation and to improve performance. The items involved include: (1) controls for more positive gun-alignment, (2) equipment for testing the vacuum system for leaks, (3) panel control of illumination, (4) calibration of intensity and focus controls, (5) functionally improved control dials, (6) cassette markings for more certain identification of exposures, and (7) simple holder for storage of specimens. The usefulness of these items will be discussed.

**26. Spherical Aberration of Compound Magnetic Lenses.** L. MARTON AND K. BOL, *Stanford University, Palo Alto, California.*

**27. Further Studies on the Magnetic Electron Microscope Objective.** J. HILLIER AND E. G. RAMBERG, *Radio Corporation of America, Princeton, New Jersey.*—Fresnel diffraction fringes observed in through-focus series are shown to be a sensitive criterion for the existence of asymmetries in the electron microscope objective. It is shown that sufficiently accurate symmetry in the objective field can be attained by empirical compensation. The method of compensating the objective is described in detail and some of the results in which resolving powers of 10A were obtained are shown. Further experiments with a new high contrast objective are described.

**28. Bias Focused Electron Gun.** JOHN H. REISNER, *Radio Corporation of America, Camden, New Jersey.*—History of the gun—A qualitative description of the action of the gun; field plots to be given; effect of circuits on the operation; physical parameters affecting spot sizes and intensities; desirable uses of the gun; effect on alignment; effect of vacuum; filament shapes; constructional materials.

**29. Photographic Plates for Use in Electron Microscopy and Electron Diffraction.** ROBERT G. PICARD AND W. F SWANN, *Radio Corporation of America, Camden, New Jersey.*—A summary of work carried out jointly by Eastman Kodak and R.C.A., to provide a plate especially suited to the requirements of electron microscopy. After many attempts, an emulsion having long scale, medium contrast, fine grain and adequate speed has been developed. Special, practically grainless plates admirably suited for electron diffraction and subsequent microphotometry have also been tested and will be described.

**30. Calculated Magnitude of Fresnel Diffraction in Shadow Casting.** C. E. HALL, *Massachusetts Institute of Technology, Cambridge, Massachusetts.*—The intensity curve of the diffraction pattern near the edge of a shadow cast by an evaporated beam is calculated for a Maxwellian distribution of velocities in the beam. Effects other than diffraction which may contribute to unsharpness of the edge are neglected. The results indicate that when heights of the order of 100A are to be measured accurately by the shadow-casting technique, the width of the shadow edge may be appreciable in comparison to the total length of the shadow.

**31. Electron Microscope Goniometry.** A. F. KIRKPATRICK, EVELYN GAGNON, AND T. G. RECHOW, *Stamford Research Laboratories, American Cyanamid Company, Stamford, Connecticut.*—The frequent occurrence of crystals in electron micrographs presents the problem of their identification. The silhouette angles observed on the photographic plate are functions of the true interfacial angles of these crystals. The interfacial angles of a suspected compound, available in the literature, can be used to calculate the angles that would be formed by the orthographic projection of the crystal edges upon the plane of the photographic plate. A comparison of the calculated angles with those measured on the electron micrograph serves to identify the crystals. Thus a measurement of a physical constant can be made with the electron microscope. The calculations can be made by geometrical construction with the use of stereographic projections. Examples of the use of electron microscope crystallography in the identification of crystals will be presented.

**32. Preparation and Uses of Silica Replicas in Electron Microscopy.** C. H. GEROULD, *The Dow Chemical Company, Midland, Michigan.*—A detailed description of the preparation of silica replicas and substrates and their many and varied uses is presented with photographs and electron micrographs. The question of "up and down" in stereo pictures of silica replicas is definitely settled by adding a metal oxide smoke (MgO) to the polystyrene replica before the silica evaporation. A successful powder dispersing technique consists of dispersing the powder in an ethyl cellulose lacquer and depositing upon a silica substrate. A method of preparing silica replicas of specimens which cannot be subjected to the temperatures and pressures of the ordinary technique is described. It consists of applying a polystyrene lacquer to the specimen surface in place of the conventional molding. Several other techniques are also included.

**33. Procedure for Preparing Latex Samples for Electron Micrographs.** WALTER E. BROWN, *The B. F. Goodrich Company.*—It is difficult to obtain good electron micrographs of latices consisting of soft particles such as natural and synthetic rubbers because the particles tend to flatten and merge. These particles can be hardened by bromination to give good micrographs. For GR-S and Hycar OR 15 this treatment results in a swelling of about 9 percent of the diameter. There is no other apparent change that might cause difficulty in interpreting the results. The reliability of the method is shown by: (1) comparison with a vulcanized GR-S latex; (2) by combining two latices of different particle sizes and obtaining the size distribution for the mixture; and (3) observing a particle in random orientation. The complete technique for making such samples is discussed. It is especially important that all of the materials used be very clean and this involves the use of freshly distilled water and solvents. Generally, it is necessary to wash the sample after drying.

## Theory of Radar Reflection from Wires or Thin Metallic Strips*

J. H. VAN VLECK,** F. BLOCH,† AND M. HAMERMESH††
*Radio Research Laboratory, Harvard University, Cambridge, Massachusetts*

(Received September 3, 1946)

Knowledge of the radar response of wires or thin metallic strips, as a function of their length and thickness, and of the radar frequency is important in the design of reflectors for radar. In view of the difficulty of this theoretical problem and the necessity of making approximations, as well as the dearth of adequate experimental data, two independent procedures for solution are presented. Detailed quantitative results are obtained for the angular dependence of the cross section, and also for the mean cross section, of randomly-oriented wires or, more generally, of metallic strips, which behave electromagnetically like cylindrical wires of a certain "equivalent radius." When expressed in terms of a unit of area equal to the square of the wave-length, these cross sections depend on the dimensions of the wire only through the two ratios

$$\frac{2l}{a}=\frac{\text{length of wire}}{\text{equivalent radius of wire}},\quad \frac{2l}{\lambda}=\frac{\text{length of wire}}{\text{wave-length}}.$$

The mean cross section is shown to take on maximum values when $4l/\lambda$ is slightly less than an integer ($n=1$, 2, etc.). The shift of these "resonances" from integral values depends on the ratio $2l/a$, becoming greater as $2l/a$ decreases. The value of $\bar{\sigma}/\lambda^2$ at resonance increases slowly with the order $n$ of the resonance; it depends only very slightly on the ratio $2l/a$, increasing as $2l/a$ decreases. For values of $4l/\lambda$ away from resonance, $\bar{\sigma}/\lambda^2$ decreases rapidly, reaching minimum values near $4l/\lambda=3/2$, 5/2, etc. The value of $\bar{\sigma}/\lambda^2$ at these minima is strongly dependent on $2l/a$, increasing as $2l/a$ decreases. Also as $4l/\lambda$ increases, the heights of the minima increase and approach the height of the resonance peaks. A brief comparison with preliminary experimental results is given.

### I. DESCRIPTIVE SURVEY

*INTRODUCTION:* In the use of radar, an electromagnetic wave is sent out from a transmitter; the wave impinges on a target and some of the energy is scattered back in the direction of the radar. There it is received and presented on a screen. The strength of the return signal (echo) will depend, among other factors, on the scattering properties of the target. These can be described completely, for our purposes, by introducing the concept of "radar cross section" $\sigma$ defined as $4\pi$ times the quotient of power returned per unit solid angle in the direction of the radar to the power density incident upon the target.

The customary targets for radar observation are aircraft, ships, and topographical features. Since these objects have not generally been constructed from the point of view of their use as radar reflectors, one finds that they are rather inefficient in this respect—one can obtain radar responses comparable to those of an aircraft or ship by using properly designed reflectors of much smaller dimensions. These reflectors can perform several functions.

They may be used to present echoes to a radar for purposes of identification of a target, or for marking a geographical location, thus replacing complicated beacons.

For military purposes they can be used to present "false" echoes to a radar operator for purposes of deception or confusion.

Useful types of reflectors for these purposes are flat sheets, spheres, corner reflectors, and metallic wires or strips. Reflectors for use by aircraft require special consideration as regards weight, size, and ease of handling. The most convenient type of reflector in this case is the bundle of strips, known as window, which, when dropped from the aircraft, will produce the required radar signal. Though strips are most convenient for

†† Now at New York University, University Heights, New York, New York.

practical use, we shall refer to the reflectors as "wires," and assume that they are circular cylinders. This assumption involves no loss of generality since, as shown in another paper by F. Bloch and M. Hamermesh,[1] a thin antenna of arbitrary cross-sectional shape has the same electrical characteristics as a circular cylinder of the same length and having an equivalent radius $a$. For a flat strip the equivalent radius is one-fourth the width of the strip.

In designing these reflectors it is of importance to know the radar response of the wire as a function of its length and thickness, and the wave-length used by the radar. There will be an optimum length for producing echoes at a given radar wave-length; the band of wave-lengths to which the wire responds strongly will depend on its thickness. Wires cut for one wave-length may produce undesirable responses at other wave-lengths (effect of "harmonics").

The calculation of the radar response of wires is also of interest from the point of view of general antenna theory. The problem presents most of the pertinent features of the receiving or transmitting antenna; at the same time it does not involve the complication presented by the gap at the center in such instruments. Thus it represents our best opportunity for comparing theoretical predictions with experiment.

The problem of radar reflection from a wire can be formulated as follows: A transmitter emits a linearly polarized wave which impinges upon a wire, the direction of incidence being at an angle $\theta$ to the axis of the wire. The wave scattered back along this same direction is picked up by a receiver ordinarily polarized parallel to the transmitter. We wish to calculate the power returned to this receiver as a function of the angle of incidence $\theta$, the direction of polarization, the wave-length, and the length and radius of the wire.

*Notation:* We shall use the following symbols:

$\lambda$ = wave-length.

$\beta = 2\pi/\lambda$; $\omega = 2\pi c/\lambda$; $c$ = velocity of light.

$2l$ = length of wire.

$a$ = equivalent radius of wire.

$E_0$ = amplitude of the electric field of the incident wave.

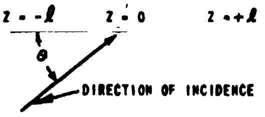

FIG. 1.

$\varphi$ = angle between the electric field of the incident wave and the plane of Fig. 1.

$q = \beta \cos\theta$.

$I(z)$ = current in the wire at $z$, the coordinate giving position along the wire (Fig. 1).

log = logarithm to base $e$.

The cross section $\sigma$ is defined as:

$$\sigma = 4\pi \frac{\text{Power reflected backwards (per unit solid angle)}}{\text{Power density incident upon the target}}$$

$\bar{\sigma}$ is the "average cross section" which will be observed when the signal is reflected from a bundle of randomly oriented wires. It can be computed from $\sigma$ by averaging:

$$\bar{\sigma} = (1/4\pi) \int\int \sigma \sin\theta d\theta d\varphi.$$

$\sigma(\theta) = (1/2\pi) \int \sigma d\varphi$ is the average return signal for fixed direction of incidence and random polarization. The average power returned to a rotating dipole antenna from a wire in fixed orientation would be given by $\sigma(\theta)$.

*Methods of Solution:* The first step in the solution of our problem is to calculate the current induced in the wire. (This is essentially the problem of the receiving antenna.)

A simple method, which has been used in similar problems is that of Siegel and Labus.[2] This method starts from a reasonable assumption concerning the form of the expression for the current, and evaluates the numerical magnitudes in this expression by applying the requirement of conservation of energy (e.m.f. method). Rigoristically speaking, it is not a method for deducing the solution to the antenna problem. A second, more satisfactory procedure, is to try to satisfy the Maxwell equations and to fulfill the boundary conditions at the surface of the wire, using a method of successive approximations. The tangential component of the total electric field must vanish on the surface of the wire (assumed to be a perfect conductor). This

---

[2] E. Siegel and J. Labus, Hoch: tech. u. Elek: akus. 43, 166 (1934).

total field consists of the incident field plus the field produced by the induced current in the wire. For sufficiently thin wires the current at the ends may be set equal to zero. The mathematical equivalent of these statements is the integral equation[3]

$$\int_{-l}^{+l} d\xi I(\xi)\frac{e^{-i\beta r}}{r}=\frac{i\omega \cos\varphi E_0 e^{iqz}}{\beta^2 \sin\theta} + A_1 \cos\beta z + A_2 \sin\beta z \quad (1)$$

with

$$r=[(z-\xi)^2+a^2]^{\frac{1}{2}}, \quad I(\pm l)=0.$$

These equations assume that the current is located at the center of the wire rather than residing on its surface, but it is well known in antenna theory that the resulting error is not serious (the reason being essentially that any infinitely long cylindrically symmetric charge distribution gives the same exterior potential as though concentrated at the center).

King and Harrison[3] solved the integral Eq. (1) for the receiving antenna by a method of successive approximations due to E. Hallén.[4] In its original form, the Hallén method suffered from the defect that the convergence of the successive approximations becomes poorer as $l/\lambda$ increases. Even for $l=\lambda$, a reasonably accurate solution would require the use of complicated higher approximations.

This difficulty, however, is avoided by following procedures introduced by Miss Gray,[5] and especially by King and Middleton,[6] who start from the same integral equation but who choose different procedures of successive approximation. The Gray procedure was intended primarily for the transmitting antenna but, as explained more fully in the last part of the appendix, it is more suitable for the receiving antenna. It leads to difficulties when the wire is so very long that it contains a large number of wave-lengths (a case which does not usually arise in practice). The most refined scheme of approximation is that recently published by King and Middleton.

We have obtained solutions of the problem by two methods:

(A) A combination of a judicious guess based on the solution of King and Harrison (with some corrections à la Gray or King and Middleton), and the application of the principle of conservation of energy.

(B) An approximate solution of the integral equation for the receiving antenna. The procedure which we employed is one which we deemed at the time a modification of the Gray method, since it resembled the latter rather more than that of Hallén. After our investigations were completed, however, the paper of King and Middleton was published. It turns out that actually our scheme for approximating the integral equation involves the same kind of attack as that used by King and Middleton in the antenna problem, though the superficial language is rather different. The point is discussed more fully at the end of the appendix. The mathematical details of the approximate solutions by methods (A) and (B) will be described in Sections II and III, respectively.

In both methods (A) and (B) the current along the wire is assumed to be of the form

$$I(z)=C_1 \cos qz + C_2 \cos\beta z + C_3 \sin qz + C_4 \sin\beta z, \quad (2)$$

where $C_1$, $C_2$, $C_3$, $C_4$ are functions of the angles $\theta$, $\varphi$ and of $l$, $\lambda$, $a$. We shall refer to the terms in $\sin qz$ and $\sin\beta z$ (or $\cos qz$ and $\cos\beta z$) as the forced and resonant parts, respectively, of the solution, inasmuch as the phase of the impressed field along the wire is $qz$, and inasmuch as the amplitude $C_2$ (or $C_4$) is abnormally large, because of resonance, if $\beta l/\pi$ is a half-integer (or integer). The cosine and sine terms will be characterized as the even and odd members, respectively. In method (A) the values of $C_1$, $C_2$, $C_3$, $C_4$, are determined by the conservation of energy and a supplemental assumption concerning the form of the solution away from resonance. In (B) one calculates the $C_1$, $C_2$, $C_3$, $C_4$ in a more dynamical fashion from the integral equation. In (A) it is

[6] R. King and D. Middleton, Quart. App. Math. 3, 302 (1946). For an interesting critical comparison of the various schemes which have been proposed for approximate solution of the integral equation for the transmitting antenna, see D. Middleton and R. King, J. App. Phys. 17, 273 (1946). Our approximation is, we believe, comparable with what these authors call "first-order King-Middleton," as we do not essay the refined but rather lengthy calculation of the second order terms included in the articles of Bouwkamp and of King and Middleton.

assumed that

$$\frac{C_1}{C_2}=-\frac{\cos\beta l}{\cos ql};\quad \frac{C_3}{C_4}=-\frac{\sin\beta l}{\sin ql},\tag{3}$$

so that the boundary conditions $I(\pm l)=0$ are automatically satisfied. In (B) the ratios $C_1/C_2$, $C_3/C_4$ have somewhat different values than (3), especially near resonance. At first sight this fact may seem to imply that in (B) the boundary conditions are not satisfied, but this is not really the case, as in satisfying the latter in (B) certain extra terms are included which we have not written down in the expression (2) for $I(z)$. It is consistent to carry these higher order terms only in satisfying the boundary conditions,[7] but not in computing the radiation, since most of the radiation comes from parts of the wire not near the ends, whereas the correction terms are abnormally important at the ends, especially in the interesting resonance region where $\cos\beta l$ or $\sin\beta l$ is nearly zero. In (A) the amplitude of one of the forced terms drops to zero at resonance, since (3) shows that $C_1$ and $C_3$ vanish with $\cos\beta l$ and $\sin\beta l$, respectively. Actually, this is not correct, as the forced vibration is unaffected by resonance rather than suppressed by it. In consequence of the fact that (B) uses a more refined current expression than does (A) in satisfying the boundary condition, (B) is able to yield various effects and details which (A) is incapable of describing.

*Chu's Theory:* A simple and ingeneous, though crude, method for obtaining expressions for the radar response, was used by Chu (unpublished). (We shall not give the details of this method since, as shown in Sec. II, the results can be obtained as a special case of Method A.)

For resonant wires (length a multiple of $\lambda/2$) Chu proceeds as follows: The current is assumed to be a pure sine function vanishing at the ends of the wire. Then the magnitude of the current is determined by applying the law of conservation of energy (as in our method (A), which differs from Chu in the choice of current form). The expression for $\bar{\sigma}$ at resonance is

$$\bar{\sigma}=\frac{3\lambda^2}{16\pi}\,\frac{4\pi^2 l/\lambda-\frac{3}{2}+3\log(8\pi l\gamma/\lambda)-\log 2}{[\log(8\pi l\gamma/\lambda)]^2},\tag{4}$$

where $\gamma$ denotes Euler's constant 1.78. The variation of cross section with angle of incidence, i.e., $\sigma(\theta)$, may be obtained from the diagrams on page 788 of Terman's Handbook. One must, however, take the fourth power of the radial coordinate shown in his plots, as the cross section involves power rather than voltage, and as there is an extra square because on back-scattering the angular factor occurs both in incidence and reflection.

The other case treated by Chu is that of long wires. Here only forced terms are considered (i.e., $C_2=C_4=0$ in Eq. (2)) and he obtains

$$\sigma=\frac{4\pi l^2\sin^2\theta(\sin x/x)^2}{(\pi/2)^2+(\log\{\lambda/\gamma\pi a\sin\theta\})^2}\cos^4\varphi,\tag{5}$$

with the abbreviation $x=(4\pi l/\lambda)\cos\theta$. Averaging over all $\theta$ and $\varphi$, Chu finds

$$\bar{\sigma}=\tfrac{3}{8}l\lambda\frac{\pi/2-\lambda/8\pi l}{(\pi/2)^2+(\log\{\lambda/\gamma\pi a\})^2}.\tag{5a}$$

Chu's method has the advantage of extreme simplicity, but it suffers from several defects:

(a) It gives no information on the response in the intermediate region between the peaks corresponding to the resonant lengths, and the valleys corresponding more to the case of long wires.

(b) It does not predict any shifts in the resonance maxima from the values $\lambda=4l/m$, where $m$ is an integer. Actually, the experimentally observed maxima are somewhat on the long wave-length side.

(c) At resonance it neglects the effect of the forced oscillation, which is not negligible for broadside response or at the higher maxima (large values of $m$).

(d) It makes an error in the values of the height of the resonance peaks because the resonance shifts (effect $b$) alter the damping constant, and hence the amplitude.

(e) The heights of the valleys are furnished by the Chu theory only if one assumes that away

---

[7] The current can be made to vanish at the end even in the first approximation if one iterates in such a way that at each stage the solution at the end of the wire is subtracted from that at the middle. This is done, for instance, in the papers of Hallén and of King and Middleton. Such a difference in procedure from ours is, however, a rather superficial one. It amounts, so to speak, to merely a different system of book-keeping for the various terms which necessarily appear as the iteration progresses.

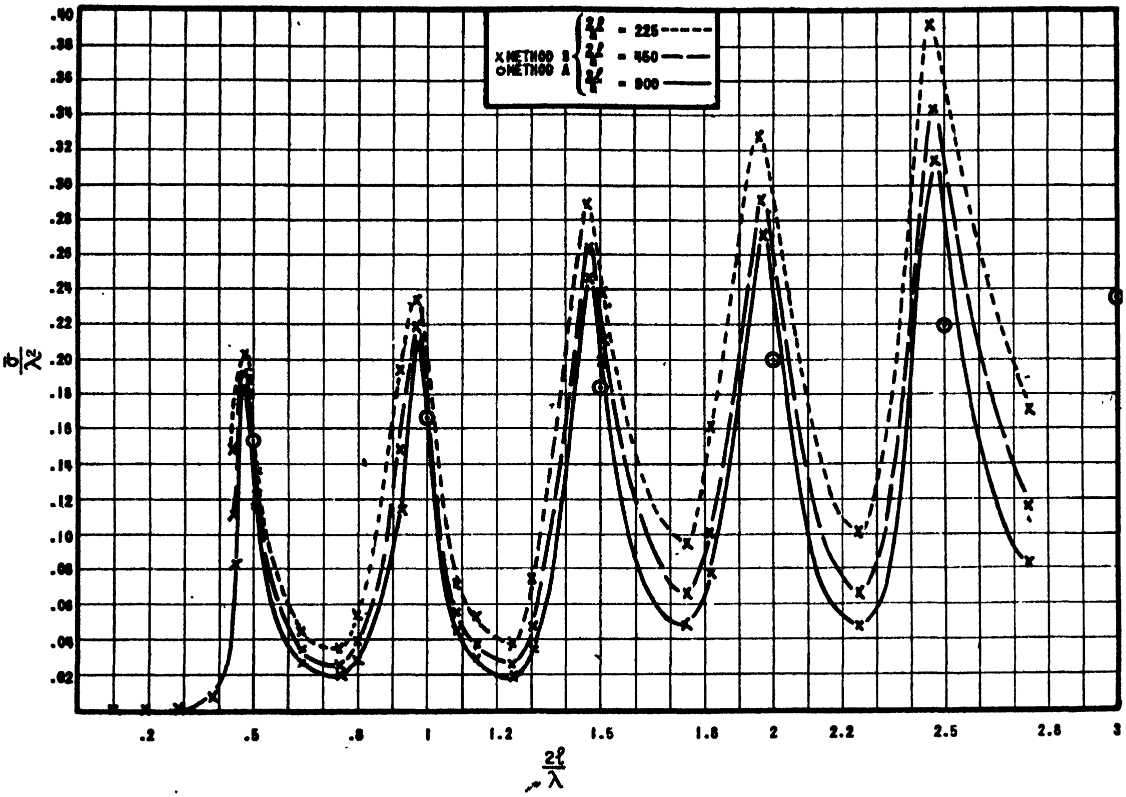

FIG. 2. Radar response of wires: average cross section.

from resonance practically all the response is caused by the forced rather than resonant terms, so that one can use his result (5a) for infinitely long wires. Actually, for wires of practical length the effect of the resonant members cannot be neglected even in the valleys.

*Relative Merits of Methods* (*A*) *and* (*B*)*:* The results of Chu may be roughly characterized as a zero-order theory, which suffers from the defects mentioned in items (a)–(e) inclusive. Method (A) gives formulas for all wave-lengths, thus removing difficulty (a), but it is open to the objections (b–c–d). It is more than just an interpolation scheme between the various Chu formulas as it does include the effect of the resonant terms away from the maxima, and so is not subject to the drawback (e). Hence (A) usually agrees quite closely with (B) in the valleys, but near the peaks (A) gives results which practically coincide with those given by the Chu resonance formula. Quite irrespective of the additional refinement connected with (b), (c), (d), method (B) has the advantage that it yields formulas that are much more tractable than those supplied by (A), as it gives closed expressions for the cross section averaged over all angles. Hence most of our comparison with experiment will be based on (B) and, because of the labor involved, only a few points will be computed by means of (A).

## Results

(1) *Variation of the Averaged Cross Section with Wave-Length:* It is perhaps well first to take a bird's-eye view of the response curves furnished by the theory for the cross section averaged over all angles, i.e., for a random distribution of wires. This is provided by Figs. 2 and 3. The curves are those furnished by method (B). Each curve of Fig. 2 refers to a different value of the ratio $2l/a$ of the wire length to radius. In Fig. 2, the cross section is plotted out to $l/\lambda=1.25$ (five peaks), while in Fig. 3 the curve is extended to the 20th peak for the special case $2l/a=900$. The points actually calculated by method (B) are indicated by crosses in Fig. 2, and it is seen that, except for a few selected instances, most of the points

beyond the second or third maximum have been calculated only for the peaks and valleys, i.e., for resonance and antiresonance. No monumental accuracy should be attached to the precise values of the coordinates in the transition region where the curves slope very steeply and cannot be determined precisely without calculating a very large number of points. In the additional region covered by Fig. 3, only the peaks and valleys have been calculated, except that the shape of the curve has been computed in some detail for the 19th peak in order to examine whether there are any important changes in the band width at the higher resonances. It is seen from Fig. 3 that, measured in frequency, the band width increases slowly as one passes to the higher resonances, and is over 3 times as great for the 19th as for the first peak. On the other hand, the percentage change in frequency required to detune from resonance is obviously much smaller at the higher peaks, simply because the frequency is higher. As one would expect, the peaks are sharper, the smaller the radius of the wire in comparison to its length. No attempt has been made to calculate a detailed curve by method (A). Instead, the points calculated with this method are indicated by circles in Figs. 2 and 3. As can be seen from the curves, the two methods agree quite well away from resonance. The circles at $2l/\lambda=\frac{1}{2}$, 1, $1\frac{1}{2}$, $2\cdots$ are the peak maxima for method (A), and have practically the same values as those given by the simple resonance theory of Chu.

It should be noted that the percentage difference between resonance and antiresonance diminishes as the length of the wire, measured in multiples of wave-length, increases. For instance, Fig. 3 shows that the first peak is ten times as high as the first valley, whereas the ninth peak has only three times the height of the ninth valley. For infinitely long wires the difference between the peaks and valleys would disappear entirely.

As we go from one valley to another the height of the valley floor does not increase uniformly, but rather increases in an alternating fashion. The first and second valleys, for instance, are approximately equal in elevation. Similar remarks apply to the third and fourth, which are both considerably higher than the first and second. This result is yielded by both (A) and (B), and is in accord with the experimental data.

(2) *Positions of the Maxima:* Both experimentally and theoretically (method (B)), the resonance maxima come at somewhat longer wave-lengths than in the usual approximate formula $4l/\lambda=m$. The displacements are greater the larger the radius of the wire; for an infinitely thin wire the resonance would be at exactly $4l/\lambda=m$. With finite radii, the expression for the resonance maxima furnished by method (B) is approximately

$$\begin{pmatrix}\cot\beta l\\ -\tan\beta l\end{pmatrix}=\tfrac{1}{4}\pi[2\log(\lambda/\pi a)+\tfrac{1}{2}\log(2\pi l/\lambda)-1.87]^{-1}. \quad (6)$$

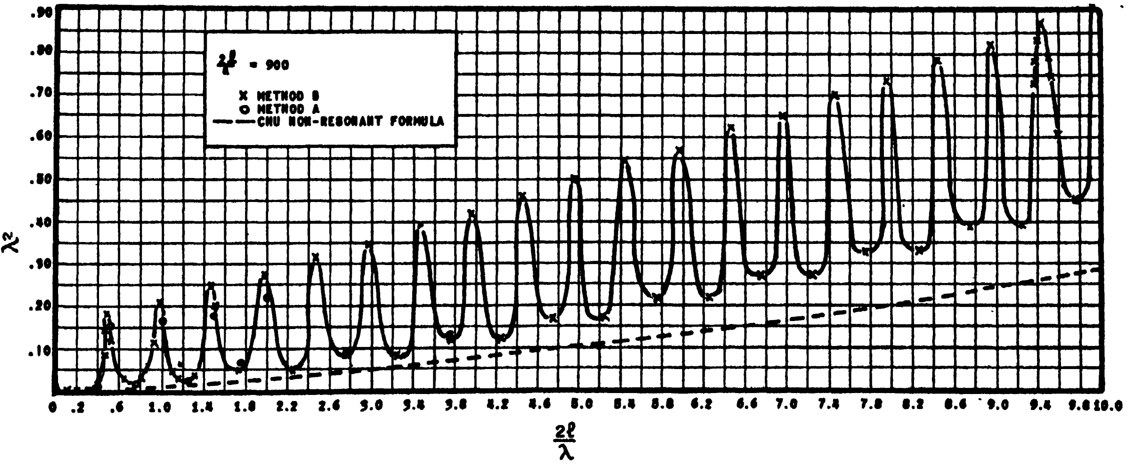

FIG. 3. Response of wires: average cross section.

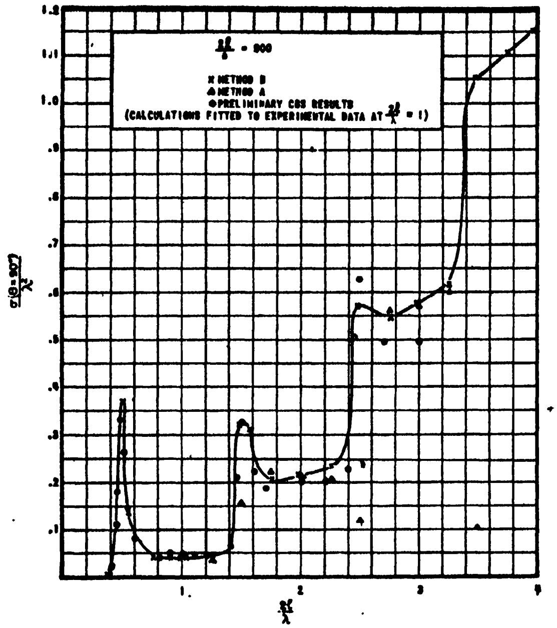

Fig. 4. Broadside response of wires.

(See Eq. (36) of Sec. III, where one will find a more complete discussion of expressions for the resonance maxima, including formulas (36′) and (36″) which are more accurate than (6) under certain conditions.) Here the cotangent applies to the resonances 1, 3, 5, etc., and the tangent to 2, 4, 6⋯.

The positions of the maxima furnished by method (B) are in quite good accord with experiment. For $2l/a=900$, it predicts that the successive maxima should come at $4l/\lambda=0.95$, 1.94, $2.93\underline{5}$, 3.93, $4.92\underline{5}$ whereas the observed values are $4l/\lambda=0.96$, 1.88, 2.94, 3.90, 4.92.

(3) *Influence of Forced Terms at Resonance-Broadside Response:* If we consider only the averaged cross section, the amplitude at resonance is determined almost entirely by the resonant term ($C_2$ or $C_4$ in Eq. (2)) and but little harm is done in omitting the "forced" members $C_1$ and $C_3$ in calculating the amplitudes of the first few peaks ($m=1$, 2, 3). When however, we do not average over all orientations of the target, but instead consider only the broadside response (at $\theta=90°$), this is no longer true. The theory is particularly simple for the broadside case, as the phase of the incident electric vector is the same for all parts of the wire. The curve furnished by method (B) for the cross section as a function of $2l/\lambda$ for broadside setting of the wire is shown in Fig. 4.[8] It is in quite good agreement with the experimental data indicated by circles. On the other hand, method (A) gives results not in accord with experiment at the odd resonances. (The even resonances have no particularly large broadside scattering.) The reason why the forced vibrations cannot be neglected, as in method (A), for broadside response at resonance, especially at the higher maxima, is the following:

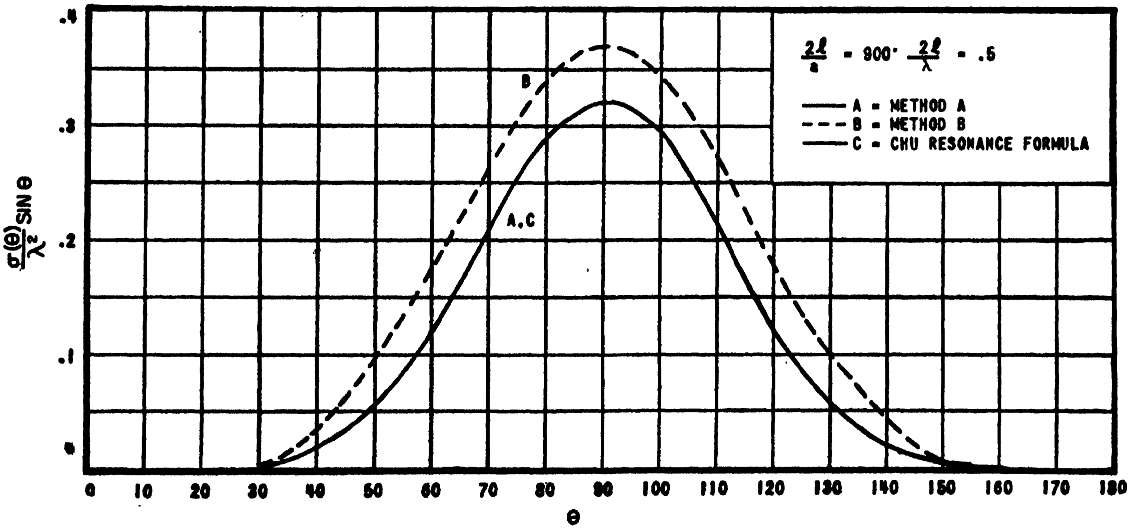

Fig. 5. Angular distribution of response of wire.

---

[8] The quantity plotted in Figs. 4–8 is $\sigma(\theta)$ which is connected with $\sigma$ by the relation $\sigma=(8/3)\cos^4\varphi\,\sigma(\theta)$.

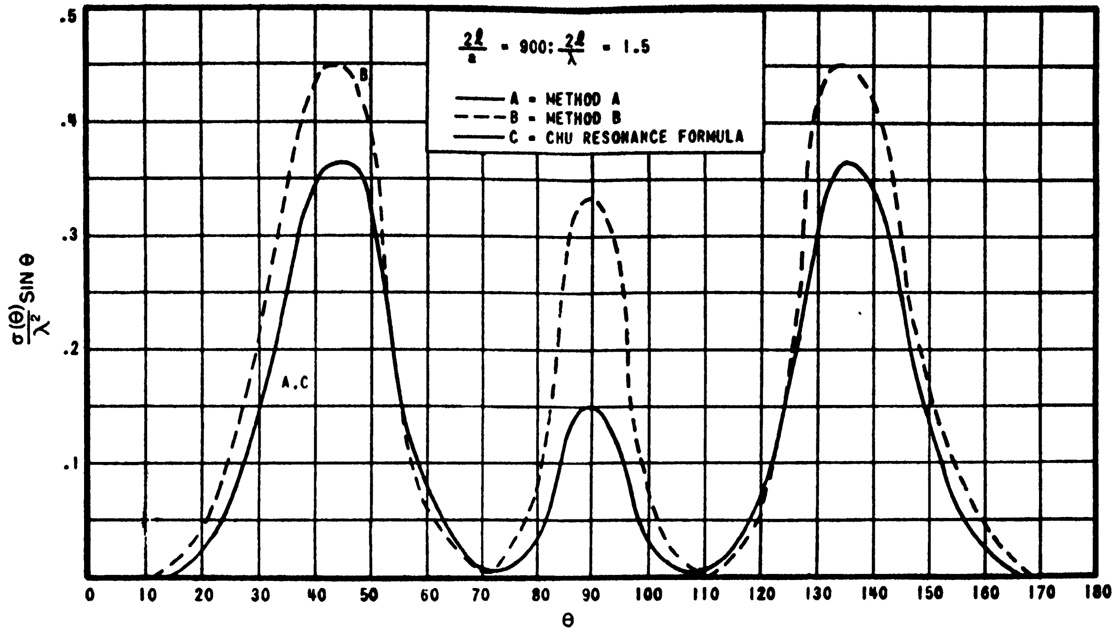

FIG. 6. Angular distribution of response of wire.

When we average over all orientations, the important term at resonance is usually that corresponding to resonant rather than forced oscillation (i.e., of structure $\sin\beta z$ or $\cos\beta z$ rather than $\sin qz$ or $\cos qz$ in Eq. (2)). In the broadside case, however, we are interested in scattering perpendicular to the wire (the equatorial zone). The forced oscillations $C_1$, $C_3$ in Eq. (2) give a particularly strong perpendicular scattering, whereas except for the first resonance or two, the major lobes due to the resonant vibrations $C_2$, $C_4$ are nearer the poles than the equator. For this reason the forced radiation is abnormally important in the broadside case, and at the higher resonances actually exceeds the resonant, despite the fact that the latter is associated with a far larger current amplitude. As an example we cite some numerical results obtained by method (B) for a wire having $2l/a=900$. Here at the first, third, fifth, seventh resonances, the contribution due to the resonant oscillations represents respectively 95, 54, 24, 11 percent of the total broadside cross section, the remainder being caused by the forced oscillations. It is because method (A) artificially suppresses the forced vibrations at resonance that it actually gives minima rather than maxima in the broadside response curves at resonance.

(4) *Height of the Maxima in the Averaged Cross Section:* The height of the resonance peaks as given by method (B) is higher than that given by method (A) or by the Chu formula. For instance, if $2l/a=900$, the maxima corresponding to $m=1$, 3, 5, 10, 20 are, respectively, 20, 32, 42, 66, 112 percent higher than given by Chu's expression. This difference, which would disappear for infinitely thin wires, is ascribable to two causes. One is the neglect of forced oscillations by (A), or by the Chu expression (our Eq. (4)), at resonance maxima. We have already discussed in paragraph (3) how this affects the results at broadside. For the first two or three maxima, the peaks of the averaged cross section are not affected appreciably by the forced oscillations. However, if, for example, $2l/a=900$, inclusion of the forced oscillations in method (B) makes the first, third, and tenth maxima ($m=1$, 3, 10), respectively, 6, 11, 29 percent greater than if the forced members are neglected (i.e., if $C_1$ and $C_3$ are taken equal to zero in Eq. (2)). The other effect which makes the maxima given by (B) higher than those given by (A) or by Chu is the fact that (B) takes into account the displacement of resonance to a slightly longer wave-length than that furnished by the ordinary expression $l/\lambda=m/4$. The theory of Part III shows that the

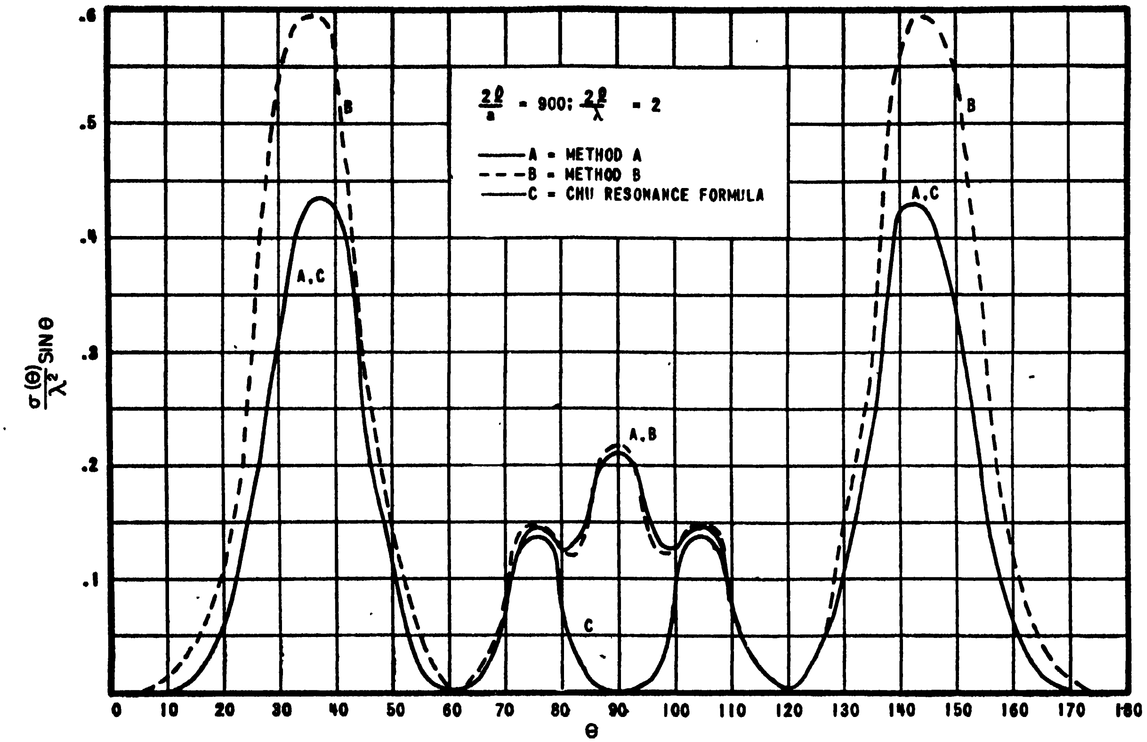

FIG. 7. Angular distribution of response of wire.

shift in the resonance decreases the damping and so increases the amplitude.[9] It is particularly noteworthy that this displacement effect makes the peak for $m=1$ higher than it would be otherwise, since this particular peak is often used for calibration. (Equation (4) shows that according to Chu the cross section at the first peak is $0.153\lambda^2$, regardless of the value of $l/a$. With method (B), on the other hand, it depends on the radius of the wire, and has the values of $0.184\lambda^2$, $0.194\lambda^2$, $0.204\lambda^2$ for $2l/a=900$, 450, 225, respectively.)

(5) *Height of the Valleys:* Here methods (A) and (B) agree quite well. The cross section furnished by the Chu non-resonant formula (Eq. (5a)), is indicated by the dotted line in Fig. 3. We see that even the deepest parts of the valleys are considerably higher than the dotted line. This means that even as far removed as possible from resonance, the effects of the resonant terms are not completely negligible. Stated in a different way, a finite wire, even when it is non-resonant, is far from behaving like an infinite wire. It should be noted that the valley floors depend on the radius much more than do the peaks.

(6) *Angular Distribution:* It is interesting to plot $\sigma(\theta)$ for a fixed wave-length. This has been done for the first, third, and fourth resonance maxima in Figs. 5–7. The types of angular variation predicted by methods (A) and (B) are not much different and are in general agreement with experiment. The angular patterns given by method (A) for the first few resonances are almost identical with those obtained by the simple theory of Chu. For higher maxima such as the 2 peak, however, the corrections to the simple theory are important, as shown by Fig. 7, especially at 90°.

As typical of an angular response well removed from resonance, the angular pattern for $2l/\lambda=1.25$ is given in Fig. 8, for which methods (A) and (B) give the same distribution.

(7) *Comparison with Experiment:* Unfortu-

---

[9] Mathematically, this is expressed in the fact that the "resonance denominators" $\Psi^2+\Xi^2$ appearing in the expressions for $G$ and $H$ in Eq. (35) are smaller in numerical magnitude for $\beta l<(m+\frac{1}{2})\pi$ and $\beta l<m\pi$, respectively, than for $\beta l=(m+\frac{1}{2})\pi$ and $\beta l=m\pi$.

nately, one will not find in the present paper elaborate curves comparing theory with experiment. This is because the existing data are, in our opinion, not yet satisfactory. In the absence of well-established experimental material, obviously more reliance must be placed on theory than would otherwise be the case, and this is one reason why we have developed the theory in detail in the two forms, (A) and (B); it is perhaps reassuring to have two independent theoretical approaches. Two results of the theory, for which significant comparison with experiment can be made at present have already been discussed, *viz.*, (a) shift in the positions of the resonance maxima from the "zero-order" positions $l=\frac{1}{4}m\lambda$; and (b) broadside response. Experiments on either of these features are easier than on the averaged cross section. Obviously (a) does not involve any intensity measurements, while (b) does not involve a variety of angular settings such as are needed in finding the averaged cross section. A more important feature of measurements of the broadside response is that they avoid polarization effects in the suspensions used to support the wires during laboratory measurements. The dielectric properties of the suspension may alter the charge distribution and hence the current in the wire. However, in the broadside case the current is a symmetrical function of the distance from the center of the wire, so that at the center we have $\partial I/\partial z=0$. Furthermore, the equation of continuity gives $\partial I/\partial z=i\omega\rho$, and hence there will be no charge near the center of the wire. Thus the polarization difficulties will not occur if the wire is supported at its center.

*Limitations of the Theory:* It is essential that the reader should appreciate that the antenna problem is so difficult that even these somewhat involved calculations apply only under the assumption that the wire is long compared to its radius. The calculations involve an expansion in descending powers of $\Omega=2\log(2l/a)$, where $l$ is the half-length of the wire, and $a$ is the radius of the equivalent wire. The fact that the expansion is in terms of reciprocal powers of $\log 2l/a$, rather than of $2l/a$, itself shows that under no conditions can the accuracy be monumental. For values of $2l/a$ of the order $10^3$ it is doubtless quite good (say within a few percent) and for $2l/a\sim 100$ it is probably adequate, but for very "fat" wires of the order $2l/a=10$ the calculations can at most be relied on only for orders of magnitude. Even when $l/a$ is very large, the theory may involve considerable percentage of error in its expression for the amplitude of the resonant vibrations, if the wire is so very long as to contain

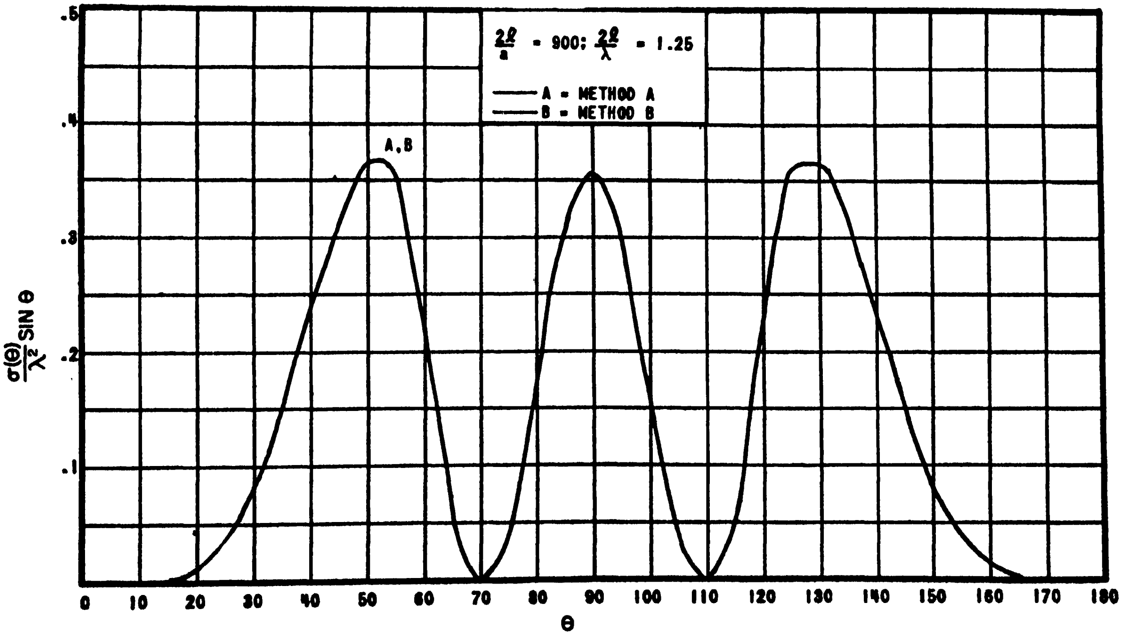

FIG. 8. Angular distribution of response of wire.

a large number of wave-lengths (see discussion in latter part of appendix). However, this difficulty is not serious, because for such exceedingly long wires the resonant vibrations are of minor importance compared to the forced ones.

## II. DETAILS OF METHOD A

The projection of the incident field on the antenna is $E_0 \sin\theta \cos\varphi e^{iqz}$. (We omit everywhere the time factor $e^{-i\omega t}$.) We choose our current in a form suggested by the solution of King and Harrison[3]:

$$I(z) = -\frac{i\omega E_0}{\beta^2 \sin\theta} \frac{\cos\varphi}{\Omega}\left[\frac{\cos qz \cos\beta l - \cos\beta z \cos ql}{\cos\beta l + (i/\Omega) f(l, q)} + i\frac{\sin qz \sin\beta l - \sin\beta z \sin ql}{\sin\beta l + (i/\Omega) g(l, q)}\right]; \tag{7}$$

$$\Omega = 2[\log(2/\gamma\beta a) + \mathrm{Ci}2\beta l]; \quad \gamma = 1.78; \quad \mathrm{Ci}x = -\int_x^\infty \frac{\cos t}{t} dt. \tag{8}$$

In Eq. (7) we shall refer to the first term in brackets as the even part and to the second as the odd part. To determine the functions $f$ and $g$ we use the procedure of calculating the work done on the antenna, and equate to the total energy flux radiated from the antenna; i.e., we set

$$\mathrm{Re}\int_{-l}^{+l} \mathbf{E} \cdot \mathbf{I}^* dz = \frac{c}{4\pi} \mathrm{Re} \int (\mathbf{E} \times \mathbf{H}^*) R^2 d\omega = \frac{c}{4\pi} \int |\mathbf{E}|^2 R^2 d\omega, \tag{9}$$

where $\mathbf{E}$, $\mathbf{H}$ are the fields produced by the induced currents in the antenna, $F^*$ is the conjugate complex of $F$, and Re denotes the real part. The first integral is taken over the antenna, while the second is taken over the surface of a large sphere of radius $R$.

On the antenna we have

$$\int_{-l}^{l} \mathbf{E} \cdot \mathbf{I}^* dz = -\frac{i\omega E_0{}^2 \cos^2\varphi}{\beta^2 \Omega}\left[\frac{\cos\beta l\{l + h(2q)\} - \cos ql\{h(q+\beta) + h(q-\beta)\}}{\cos\beta l - (i/\Omega) f(l, q)}\right.$$
$$\left. + \frac{\sin\beta l\{l - h(2q)\} - \sin ql\{h(q-\beta) - h(q+\beta)\}}{\sin\beta l - (i/\Omega) g(l, \beta)}\right] \tag{10}$$

with the abbreviation $h(x) = \sin xl/x$. Again we shall refer to the first term as the even part, and to the second as the odd part.

The field produced by the current $I$ at $\measuredangle\theta'$ and distance $R$ is

$$E = \frac{i\beta}{c} \frac{\sin\theta'}{R} \int_{-l}^{+l} I(z) e^{i\beta z \cos\theta'} dz. \tag{11}$$

The flux density is

$$\frac{c}{4\pi}|E|^2 = \frac{c}{4\pi} \frac{\beta^2}{c^2} \frac{\sin^2\theta'}{R^2} \int_{-l}^{+l} \int_{-l}^{+l} I(z) I^*(z') e^{i\beta(z-z') \cos\theta'} dz dz'. \tag{12}$$

The total flux is

$$\frac{c}{4\pi} \int_0^{2\pi} d\varphi' \int_0^\pi \sin\theta' d\theta' |\mathbf{E}|^2 R^2 = \frac{1}{\omega}\left\{ \int_{-l}^{+l}\int I^*(z') \frac{\sin\beta(z-z')}{z-z'}\left[\left(\beta^2 + \frac{d^2}{dz^2}\right) I(z)\right] dz dz'\right.$$
$$\left. - \int_{-l}^{+l} dz' I^*(z') \left( \frac{dI(z)}{dz} \frac{\sin\beta(z-z')}{z-z'} \Big|_{z=-l}^{z=+l} \right) \right\}. \tag{13}$$

We have written the current as the sum of an even and an odd function of $z$. As can be seen from Eq. (13), integrals involving products of even and odd parts of the current vanish; i.e., the total flux consists of two parts, one in which we choose for $I(z)$ only the even part of the current; the other in which we use only the odd part.

We shall satisfy Eq. (9) (which is actually simply a statement of the law of conservation of energy) separately for the odd and even parts. Using only the even part of $I(z)$ from Eq. (7) in Eq. (13), and performing the integrations, we obtain for this part of the total flux the value

$$\frac{1}{\cos^2\beta l+f^2/\Omega^2}\,\frac{1}{\omega}\,\frac{\omega^2 E_0^2\cos^2\varphi}{\beta^4\sin^2\theta\,\Omega^2}\left[\beta\gamma(\beta)\cos^2 ql+K\sigma(q)-L\gamma(q)-M\cos^2\beta l\right], \tag{14}$$

where

$$K=(\beta^2-q^2)\{l+h(2q)\}\cos^2\beta l+2\cos\beta l\cos ql(q\sin ql\cos\beta l-\beta\cos ql\sin\beta l),$$

$$L=(\beta^2-q^2)\cos^2\beta l(\cos 2ql/2q)+q\cos^2\beta l\cos 2ql+\tfrac{1}{2}\beta\sin 2ql\sin 2\beta l,$$

$$M=(\beta+q)\sin^2(\beta-q)l+(\beta-q)\sin^2(\beta+q)l,\quad \sigma(q)=\mathrm{Si}2(\beta+q)l+\mathrm{Si}2(\beta-q)l,$$

$$\gamma(q)=\mathrm{Cin}2(\beta+q)l-\mathrm{Cin}2(\beta-q)l,\quad \mathrm{Si}x=\int_0^x\frac{\sin t}{t}dt;\quad \mathrm{Cin}x=\int_0^x\frac{1-\cos t}{t}dt=\log x+0.577-\mathrm{Ci}x.$$

Equating (14) to the even part of Eq. (10), and solving for $f(l, q)$, we obtain

$$f=\sigma(y)\cos x+A^{-1}\{\gamma(x)\cos^2 xy-\gamma(y)[\tfrac{1}{2}y^{-1}(1+y^2)\cos^2 x\cos 2xy+\tfrac{1}{2}\sin 2x\sin 2xy]$$
$$-\cos^2 x[(1+y)\sin^2 x(1-y)+(1-y)\sin^2 x(1+y)]\}, \tag{15}$$

where

$$x=\beta l;\quad y=\cos\theta=q/\beta;\quad \sigma(y)=\mathrm{Si}2x(1+y)+\mathrm{Si}2x(1-y);\quad \gamma(y)=\mathrm{Cin}2x(1+y)-\mathrm{Cin}2x(1-y);$$
$$\gamma(x)=\mathrm{Cin}4x;\quad A=(1-y^2)(x+\tfrac{1}{2}y^{-1}\sin 2xy)\cos x-\cos xy\{(1+y)\sin x(1-y)+(1-y)\sin x(1+y)\}.$$

By a similar procedure, using the odd part of the current, we obtain

$$g=\sigma(y)\sin x+B^{-1}\{\gamma(x)\sin^2 xy+\gamma(y)[\tfrac{1}{2}y^{-1}(1+y^2)\sin^2 x\cos 2xy-\tfrac{1}{2}\sin 2x\sin 2xy]$$
$$-\sin^2 x[(1+y)\sin^2 x(1-y)+(1-y)\sin^2 x(1+y)]\}, \tag{16}$$

where

$$B=(1-y^2)(x-\tfrac{1}{2}y^{-1}\sin 2xy)\sin x-\sin xy\{(1+y)\sin x(1-y)-(1-y)\sin x(1+y)\}.$$

Having determined the functions $f$ and $g$, we now calculate the scattering cross section in the backward direction $\theta$. The scattering cross section is defined as $\sigma=4\pi R^2|E|^2/|E_0|^2$ when $E$ is the scattered field in direction $\theta$, as given by Eq. (11). After performing the integration, we can write $E$ in terms of $x$ and $y$ as

$$E=\frac{E_0\cos\varphi}{\beta\Omega(1-y^2)}\left[\frac{A}{\cos x+if/\Omega}-\frac{B}{\sin x+ig/\Omega}\right], \tag{17}$$

$$|E|^2=\frac{E_0^2\cos^2\varphi}{\beta^2\Omega^2(1-y^2)^2}\left[\frac{A^2}{\cos^2 x+f^2/\Omega^2}+\frac{B^2}{\sin^2 x+g^2/\Omega^2}-\frac{2AB(\sin x\cos x+fg/\Omega^2)}{(\sin x\cos x+fg/\Omega^2)^2+\Omega^{-2}(g\cos x-f\sin x)^2}\right]. \tag{18}$$

We assume that both transmitter and receiver are polarized parallel to each other. This gives an extra factor $\cos^2\varphi$. The average over all polarizations give $\langle\cos^4\varphi\rangle_{\mathrm{Av}}=\tfrac{3}{8}$ (if the polarizations of receiver and transmitter were crossed, we would be concerned with $\langle\sin^2\varphi\cos^2\varphi\rangle_{\mathrm{Av}}=\tfrac{1}{8}$, making the cross section one-third as large). Thus we have

$$\frac{\sigma(\theta)}{\lambda^2}=\frac{3}{8\pi\Omega^2}\frac{1}{(1-y^2)^2}\left[\frac{A^2}{\cos^2 x+f^2/\Omega^2}+\frac{B^2}{\sin^2 x+g^2/\Omega^2}-\frac{2AB(\sin x\cos x+fg/\Omega^2)}{(\sin x\cos x+fg/\Omega^2)^2+\Omega^{-2}(g\cos x-f\sin x)^2}\right]. \tag{19}$$

TABLE I.

| $2l/\lambda$ | 1/4 | 1/2 | 3/4 | 1 | 5/4 | 3/2 | 7/4 | 2 | 15/4 |
|---|---|---|---|---|---|---|---|---|---|
| $\bar{\sigma}/\lambda^2$ | $6\times10^{-5}$ | .151 | .023 | .163 | .022 | .176 | .066 | .219 | .127 |

Assuming that the wires are randomly oriented in space, the average cross section, $\bar{\sigma}$, is

$$\bar{\sigma}=\int_0^{\pi/2} d\theta\,\sin\theta\,\sigma(\theta), \tag{20}$$

where $\sigma(\theta)$ is given by Eq. (19). The evaluation of $\bar{\sigma}/\lambda^2$ requires numerical integration of Eq. (20). For $2l/a=900$, the results are given in Table I.

The parameter $\Omega$ increases as the radius of the antenna decreases. The terms of Eq. (19) are of order $1/\Omega^2$, except when $\cos x$ or $\sin x$ become small; i.e., the cross section will be small ($\sim 1/\Omega^2$) except for values of $x$ nearly $\pi/2$, $3\pi/2$, etc. (odd resonances) and $\pi$, $2\pi$, etc. (even resonances). Figures 5 to 8 show plots of $\sigma(\theta)/\lambda^2$ as a function of $\theta$ as computed from Eq. (19).

The broadside cross section is of interest for comparison with experiment and with method (B). For this case $\theta=90°$, $y=0$. If we let $y$ approach zero, then $A\rightarrow 2x\cos x-\sin x$; $B\rightarrow 0$; $f\rightarrow 2\cos x\,\mathrm{Si}2x+\frac{1}{2}[\gamma(x)-\sin^2 2x](x\cos x-\sin x)^{-1}$; $g$ remains finite, so that the odd term gives no contribution broadside. This is easily seen physically. For an odd distribution of current, contributions to the field broadside will cancel in pairs.

Substituting in Eq. (19) we obtain

$$\frac{\sigma(\theta=90°)}{\lambda^2}=\frac{3}{2\pi}\,\frac{(x\cos x-\sin x)^2}{\Omega^2\cos^2 x+\{2\cos x\,\mathrm{Si}2x+\frac{1}{2}[\gamma(x)-\sin^2 2x][x\cos x-\sin x]^{-1}\}^2}. \tag{21}$$

For $\theta=90°$, $\sigma(\theta)/\lambda^2$ is plotted in Fig. 4, for $2l/a=900$. Equation (19) reduces, in limiting cases, to the results obtained by Chu. At odd resonances ($x=\pi/2$, $3\pi/2$, etc.) $\sin x=1$, $\cos x=0$. Then the contribution of the odd terms will be of order $1/\Omega^{-2}\times$ (even terms). If we neglect the odd terms then we find

$$\sigma(\theta)/\lambda^2=\tfrac{3}{8}\pi^{-1}[A/f(1-y^2)]^2,\quad\text{with}\quad f^2=\tfrac{1}{4}[\gamma(x)]^2;\quad A^2=4\cos^4 xy.$$

The corresponding averaged cross section is

$$\bar{\sigma}/\lambda^2=\tfrac{3}{2}\pi^{-1}\gamma(x)^{-2}[x(\mathrm{Si}4x-\tfrac{1}{2}\,\mathrm{Si}8x)+\tfrac{1}{2}\,\mathrm{Cin}4x-\tfrac{1}{8}\,\mathrm{Cin}8x]. \tag{22}$$

Using the asymptotic expansions $\mathrm{Si}z\sim\frac{1}{2}\pi-(\cos z/z)$; $\mathrm{Cin}z\sim\log\gamma z+\sin z/z$; we have

$$\frac{\bar{\sigma}^2}{\lambda^2}\simeq\frac{3}{16\pi}\,\frac{4\pi^2 l/\lambda-\frac{3}{2}+3\log(8\pi l\gamma/\lambda)-\log 2}{[\log(8\pi l\gamma/\lambda)]^2}, \tag{22a}$$

which is the expression obtained by Chu (Eq. (4)). A similar derivation for the even resonances yields the same final formulas (22) and (22a).

For long wires ($x\rightarrow\infty$), we have, provided we are not at resonance and so long as $y\neq 0$:

$$f\rightarrow\sigma(y)\cos x;\quad g\rightarrow\sigma(y)\sin x;\quad A\rightarrow x(1-y^2)\cos x;\quad B\rightarrow x(1-y^2)\sin x.$$

Substituting in Eq. (19) we find that the return cross section is zero (for $y\neq 0$); i.e., for long non-resonant wires the return signal is a sharp broadside lobe.

For large values of $x$, one finds from Eq. (21),

$$\frac{\sigma(\theta=90°)}{\lambda^2}\simeq\frac{3}{2\pi}\,\frac{x^2}{\Omega^2+\pi^2}=\frac{3\pi l^2}{2}\,\frac{1}{[\log(2/\gamma\beta a)]^2+\pi^2/4}, \tag{23}$$

which is identical with the expression obtained by Chu (cf. Eq. (5), with $\theta=90°$ and $\langle\cos^4\varphi\rangle_{Av}=\frac{3}{8}$).

## III. DETAILS OF METHOD B

The fundamental integral equation to be satisfied after removal of the time factor is that already given as our Eq. (1). The constants $A_1$ and $A_2$ are to be determined by the requirement that the current vanishes at the end of the wire.

We seek to satisfy Eq. (1) approximately by a solution of the form

$$I(z)=\alpha e^{iqz}+\gamma_1\cos\beta z+i\gamma_2\sin\beta z. \tag{24}$$

The coefficient $\alpha$ is determined so as to cancel the part of the right side of Eq. (1) which is proportional to $e^{iqz}$. As in the paper of Gray, we write

$$\int_{-l}^{+l} r^{-1}I(\xi)e^{-i\beta r}d\xi=I(z)\int r^{-1}\cos\beta r\,d\xi+\int r^{-1}[I(\xi)-I(z)]\cos\beta r\,d\xi-i\int r^{-1}I(\xi)\sin\beta r\,d\xi. \tag{25}$$

The limits of integration are to be understood throughout to be $\pm l$. In $\int r^{-1}\cos\beta r d\xi$ we must take into account the finite radius of the wire (otherwise the integral diverges), and following the usual procedure of antenna theory take the origin of $r$ as at the center of the wire. In the other members, on the other hand, the integrals converge at $r=0$ so that the wire here may be regarded as of negligible thickness. For a more thorough discussion of this point see Miss Gray's paper;[5] it will be assumed that the reader has some familiarity with the procedure used there.

With these approximations we have

$$\int_{-l}^{+l}\frac{\cos\beta r}{r}d\xi=Z(z),\quad\text{with}\quad Z(z)=\log\frac{[(l+z)^2+a^2]^{\frac{1}{2}}+(l+z)}{[(l-z)^2+a^2]^{\frac{1}{2}}-(l-z)}-\mathrm{Cin}\beta(l+z)-\mathrm{Cin}\beta(l-z), \tag{26}$$

$$\begin{aligned}\int r^{-1}e^{iq\xi}e^{-i\beta r}d\xi=\tfrac{1}{2}e^{iqz}\big[&2Z(z)+2\,\mathrm{Cin}\beta(l-z)+2\,\mathrm{Cin}\beta(l+z)-\mathrm{Cin}(\beta+q)(l-z)-\mathrm{Cin}(\beta-q)(l+z)\\&-\mathrm{Cin}(\beta-q)(l-z)-\mathrm{Cin}(\beta+q)(l+z)-i\,\mathrm{Si}(\beta+q)(l-z)-i\,\mathrm{Si}(\beta-q)(l+z)\\&-i\,\mathrm{Si}(\beta-q)(l-z)-i\,\mathrm{Si}(\beta+q)(l+z)\big]+\tfrac{1}{2}e^{iqz}\big[\mathrm{Cin}(\beta+q)(l-z)\\&+\mathrm{Cin}(\beta-q)(l+z)-\mathrm{Cin}(\beta+q)(l+z)-\mathrm{Cin}(\beta-q)(l-z)\\&+i\,\{\mathrm{Si}(\beta+q)(l-z)+\mathrm{Si}(\beta-q)(l+z)-\mathrm{Si}(\beta+q)(l+z)-\mathrm{Si}(\beta-q)(l-z)\}\big].\end{aligned} \tag{27}$$

The coefficients of $e^{iqz}$ in Eq. (27) are slowly varying functions of $z$, and we shall replace them by their mean values. Actually the deviations from the mean values are considerable near the very ends of the wire. Consequently, it may appear to the reader that a very sizable error is committed by using mean values in the current formulas when we apply the boundary conditions at the end of the wire. This point will be discussed more fully in the appendix, where it will be shown that the objection is not a serious one. The second of the two factors enclosed in $\big[\;\;\big]$ in Eq. (27) is an odd function of $z$, so that its mean value is zero. Furthermore

$$\begin{aligned}\langle Z(z)\rangle_{\mathrm{Av}}&=\tfrac{1}{2}l\int Z(z)dz=2[\log(2l/a)+\log 2-\mathrm{Cin}2\beta l-(\sin 2\beta l/2\beta l)]\sim 2[\log(\lambda/\pi a)-0.577],\\\langle\mathrm{Cin}k(l+z)\rangle_{\mathrm{Av}}&=\mathrm{Cin}2kl+(\sin 2kl/2kl)-1\sim\log 2kl+0.577-1,\\\langle\mathrm{Si}k(l+z)\rangle_{\mathrm{Av}}&=\mathrm{Si}2kl+(1/2kl)[\cos 2kl-1]\sim\tfrac{1}{2}\pi.\end{aligned} \tag{28}$$

The approximations following the wavy lines are contingent on $kl$ being somewhat large compared to unity, and may be considered adequate for our purposes except when the wire is less than a half wave long. Even with wires a half wave-length or so long, the error involved in using the asymptotic formulas is by no means negligible; if, for instance $(2l/a)=900$, the cross section at the first resonance is raised six percent when the asymptotic expansions are not made. Since the formulas based on these asymptotic expansions are much easier to compute with than are those involving the Si and Cin functions, and since we are usually interested in wires at least half a wave long, we shall carry through the calculations on the assumption that the use of asymptotic approximations is legitimate. However, we shall later give some of the more complicated final expressions which are obtained when these approximations are not made. The expression (27) now becomes $Ke^{iqz}$, where

$$K=2\{\log(\lambda/\pi a)-0.577\}+2\log(1/\sin\theta)-i\pi.$$

The appropriate value of the constant $\alpha$ in Eq. (24) is thus

$$\alpha=i\omega\cos\varphi E_0/K\beta^2\sin\theta. \tag{29}$$

We now proceed to determine the relation between $\gamma_1$, $\gamma_2$ and the constants $A_1$, $A_2$ of Eq. (1). Using the same type of approximation as in Eq. (27) we obtain

$$\int r^{-1}\cos\beta\xi e^{-i\beta r}d\xi=L\cos\beta z;\quad \int r^{-1}\sin\beta\xi e^{-i\beta r}d\xi=L\sin\beta z,$$

where

$$L=2[\log(\lambda/\pi a)-0.577]+\log 2\beta l+0.577-\log 2-i\pi/2-1.$$

Thus

$$\gamma_1=A_1/L;\quad i\gamma_2=A_2/L. \tag{30}$$

We must now determine the constants $A_1$ and $A_2$ so as to satisfy the boundary condition $I(\pm l)=0$. Here it is not sufficient merely to set the expression (24) equal to zero at $z=\pm l$, which would give $\gamma_1=-\alpha\cos ql/\cos\beta l$; $\gamma_2=-\alpha\sin ql/\sin\beta l$, in other words infinite current at resonance. Instead we can obtain a finite current at resonance and proper damping and radiation resistance only by demanding that the second, rather than first approximation to the current, vanish at the boundary. This second approximation is obtained by iterating once the first approximation to the current, or in other words using the first approximation to $I(\xi)$ and $I(z)$ in the second and third, but not the first term in the right side of (25). Clearly the first term is much more sensitive than the other two to the value of $I(z)$, as it involves an integral which would be infinite if the wire radius, $a$, were equal to zero, whereas the other integrals always remain finite even with $a=0$. The boundary conditions for determining $A_1$ and $A_2$ can thus be taken to be

$$\int r^{-1}[I(\xi)-I(\pm l)]\cos\beta r d\xi-i\int r^{-1}I(\xi)\sin\beta r d\xi=(i\omega\cos\varphi/\beta^2\sin\theta)E_0e^{\pm iql}$$
$$+A_1\cos(\pm\beta l)+A_2\sin(\pm\beta l); \tag{31}$$

as is seen by substituting (25) in (1) with $z=\pm l$, and with $I(\pm l)=0$ in the first right-hand member of (25). The approximation (24) may be used for $I(\xi)$ and $I(l)$ in evaluating the left side of (31), and $r$ has the value $|l\pm\xi|$.

The satisfaction of the boundary conditions at the two ends of the wire is equivalent to satisfying the condition at one end separately for the problem of an "even" impressed field $E_0\cos qz$ and an "odd" one $iE_0\sin qz$, rather than lumping both in the combination $e^{iqz}$. Instead of regarding the boundary conditions as determining $A_1$ and $A_2$, we can equally well regard them as specifying $\gamma_1$, $\gamma_2$ inasmuch as $\gamma_1$, $\gamma_2$ and $A_1$, $A_2$ are related by Eq. (30); it is more convenient to solve for $\gamma_1$, $\gamma_2$ than $A_1$, $A_2$, since the former enter directly into the expression (24) for the current distribution. When we utilize (29), (30), and (27) (approximated in the usual way for large $l$) we thus find that (24) yields the following expressions for determining $\gamma_1$, $\gamma_2$:

$$(i\omega\cos\varphi E_0/K\beta^2\sin\theta)\{[\log(1/\sin\theta)-\tfrac{1}{2}i\pi]\cos ql-\tfrac{1}{2}i\log[(1+\cos\theta)/(1-\cos\theta)]\sin ql\}$$
$$+\gamma_1\{\cos\beta l(\tfrac{1}{2}\log 2\beta l+0.288-\tfrac{1}{2}\log 2-\tfrac{1}{4}i\pi)-\tfrac{1}{2}i(\log 4\beta l+0.577)\sin\beta l+\tfrac{1}{4}\pi\sin\beta l\}$$
$$=(i\omega\cos\varphi E_0/\beta^2\sin\theta)\cos ql+\gamma_1L\cos\beta l, \tag{32}$$

$$(i\omega \cos\varphi E_0/K\beta^2 \sin\theta)\{[\log(1/\sin\theta)-i\pi/2]\sin ql+\tfrac{1}{2}i\log[(1+\cos\theta)/(1-\cos\theta)]\cos ql\}$$
$$+\gamma_2\{\sin\beta l(\tfrac{1}{2}\log 2\beta l+0.288-\tfrac{1}{2}\log 2-\tfrac{1}{4}i\pi)+\tfrac{1}{2}i(\log 4\beta l+0.577)\cos\beta l-\tfrac{1}{4}\pi\cos\beta l\}$$
$$=(i\omega\cos\varphi E_0/\beta^2\sin\theta)\sin ql+\gamma_2 L\sin\beta l. \quad (33)$$

We may, without too much error, replace $\log(1/\sin\theta)$ and $\log(1+\cos\theta)/(1-\cos\theta)$ by zero in these expressions. The justification for this is that the bulk of the scattering comes from $\theta>30°$, so that the omitted terms are unimportant, and their inclusion would excessively complicate the angular dependence and preclude our obtaining analytical expressions for the cross section averaged over angle. We shall also similarly neglect the term $\log(1/\sin\theta)$ in the quantity $K$ of Eq. (29). Of course, these minor angular terms could be included, but they yield nothing worth while. The expression for the current may now, in virtue of (24), (29), (32), (33) be written as

$$I(z)=(i\omega\cos\varphi E_0/\beta^2\sin\theta)[(F'+iF'')e^{iqz}+2(G'+iG'')\cos\beta z\cos ql+2i(H'+iH'')\sin\beta z\sin ql], \quad (34)$$

$$F'=\Omega'/(\Omega'^2+\pi^2),\quad F''=\pi/(\Omega'^2+\pi^2),\quad \Omega'=2\log(\lambda/\pi a)-1.154, \quad (34a)$$

$$\left.\begin{aligned}2G'&=\Psi(\beta l)[\Psi(\beta l)^2+\Xi(\beta l)^2]^{-1}-\pi\Omega'^{-1}G'',\quad 2G''=\Xi(\beta l)[\Psi(\beta l)^2+\Xi(\beta l)^2]^{-1},\\ 2H'&=\Psi(\beta l-\tfrac{1}{2}\pi)[\Psi(\beta l-\tfrac{1}{2}\pi)^2+\Xi(\beta l-\tfrac{1}{2}\pi)^2]^{-1}-\pi\Omega'^{-1}H'',\end{aligned}\right\} \quad (35)$$

$$2H''=\Xi(\beta l-\tfrac{1}{2}\pi)[\Psi(\beta l-\tfrac{1}{2}\pi)^2+\Xi(\beta l-\tfrac{1}{2}\pi)^2]^{-1},$$
$$\Psi(x)=-(\Omega'-\Delta)\cos x+\tfrac{1}{4}\pi\sin x,\quad \Xi(x)=\tfrac{1}{2}(\log 4\beta l+0.577)\sin x-\tfrac{1}{4}\pi\cos x,\quad \Delta=-\tfrac{1}{2}\log\beta l+0.712. \quad (35a)$$

The terms $-\pi G''/\Omega'$, $-\pi H''/\Omega'$ occurring at the very ends of our formulas for $G'$ and $H'$ are important only very near resonance, where $G''$ and $H''$ are abnormally large. In writing down these terms, we have neglected $\Delta$, etc., in comparison with $\Omega'$ so that their denominators are simply $\Omega'$. This approximation is allowable as the terms $-\pi G''/\Omega'$, $-\pi H''/\Omega'$ are never of dominant importance.

Resonance occurs when there is a peak in the cross section plotted against wave-length. If the wire is sufficiently thin, so that $2l/a$ is of the order $10^3$, the only important terms which vary acutely with wave-length are the $G$ terms at the resonances 1, 3, 5 ⋯ and the $H$ ones at 2, 4, 6. The problem of locating the resonance is that of finding the position of the maximum of $G'^2+G''^2$ or $H'^2+H''^2$, and resonance can be regarded as occurring when the denominator of the fractions in Eq. (35) is as small as possible. If the wire is not too long, or in other words if $\log\beta l$ can be regarded as very small compared to $2\log(2l/a)$, the resonance is located nearly at the point where the first of the two squared terms composing the denominator is equal to zero. Then the forced and resonant vibrations are 90° out of phase. With this approximation, resonance occurs when the factor $(\Omega'-\Delta)\cos\beta l-\frac{1}{4}\pi\sin\beta l$, or $(\Omega'-\Delta)\sin\beta l+\frac{1}{4}\pi\cos\beta l$ vanishes. The positions of the odd and even resonances are thus not given by $\cos\beta l=0$ or $\sin\beta l=0$, as commonly assumed, but rather by

$$\cot\beta l=\pi/4(\Omega'-\Delta)\quad\text{or}\quad -\tan\beta l=\pi/4(\Omega'-\Delta). \quad (36)$$

This relation is the same as Eq. (6) of Part I. If asymptotic expansions are not used, Eq. (36) is replaced by

$$\begin{pmatrix}\cot\beta l\\ -\tan\beta l\end{pmatrix}=\frac{\tfrac{1}{2}\,\mathrm{Si}4\beta l}{2[\log(2l/a)+\log 2-1]-\tfrac{1}{2}\,\mathrm{Cin}4\beta l-\mathrm{Cin}2\beta l-(\sin 4\beta l/4\beta l)+1}. \quad (36')$$

Substitution of (36′) for (36) alters the resonance frequency only negligibly except at the first maximum, and even here the change is slight, (e.g., 0.3 percent in $\beta l$ if $2l/a=900$). A more important refinement is the allowance for the fact that the minima of the denominators of $G$ or $H$ are not located exactly where their first terms vanish. Correction for this fact leads to the formula

$$\begin{pmatrix}\cot\beta l\\ -\tan\beta l\end{pmatrix}=\frac{\pi(1+\epsilon)}{4(\Omega'-\Delta)}\quad\text{with}\quad \epsilon=\frac{[\log(8\pi l/\lambda)+0.577]^2+2[\log(8\pi l/\lambda)+0.577][\Omega'-\Delta]}{[2(\Omega'-\Delta)]^2}. \quad (36'')$$

The difference between (36) and (36″) is particularly noticeable if the wire is long enough to contain several wave-lengths. For instance if $2l/a=900$, use of (36″) rather than (36) increases the shift of the first peak (measured from the Chu value) by only 10 percent, but the 10th peak by 28 percent. The numerical figures quoted in Sec. I are based on (36″) rather than (36), and in the first peak, avoidance of asymptotic expansions in the leading term is avoided by inserting the correction factor $1+\epsilon$ in (36′) rather than (36). It must be cautioned that if $2l/a$ is of the order $10^2$, so that the convergence of our method becomes slow due to the inadequate size of $\Omega$, none of the formulas (36), (36′), (36″) should be used for locating the maximum, as then the influence of the cross terms $FG$ or $FH$ becomes important and the resonance must be located by plotting the final expression (38) for the averaged cross section as a function of wave-length rather than merely maximizing $G'^2+G''^2$ or $H'^2+H''^2$. Thus if $2l/a=80$ it turns out that the shift given by (36″) is about 50 percent larger than what is obtained by locating the peak in the complete expression for the cross section.

The reflected field can be determined from $I(z)$ as given by Eq. (34) by following the same procedure as in Eqs. (11) and (12). We thus obtain

$$\begin{aligned}\sigma&=\frac{\cos^2\varphi(4\pi R^2)|E|^2}{|E_0|^2}\\&=4\pi\cos^4\varphi\left|\int_{-l}^{+l}dze^{iqz}[(F'+iF'')e^{iqz}+2(G'+iG'')\cos\beta z\cos ql+2i(H'+iH'')\sin\beta z\sin ql]\right|^2\\&=(4\lambda^2/\pi)\cos^4\varphi\{a_1^2(F'^2+F''^2)+(a_2+a_3)^2\cos^2 xy(G'^2+G''^2)+(a_2-a_3)^2\sin^2 xy(H'^2+H''^2)\\&\qquad+2(a_2^2-a_3^2)\sin xy\cos xy(G'H'+G''H'')+2a_1(a_2+a_3)\cos xy(F'G'+F''G'')\\&\qquad\qquad+2a_1(a_2-a_3)\sin xy(F'H'+F''H'')\},\end{aligned}\tag{37}$$

where

$$x=2\pi l/\lambda,\quad y=\cos\theta,\quad a_1=\tfrac{1}{2}y^{-1}\sin 2xy,\quad a_2=(1+y)^{-1}\sin[x(1+y)],\quad a_3=(1-y)^{-1}\sin[x(1-y)].$$

$\sigma(\theta)$ can be obtained from (37) by replacing $\cos^4\varphi$ by its mean value $\frac{3}{8}$. (For the case of crossed polarization see the remarks in Sec. II following Eq. (18).) To find the value of $\bar{\sigma}$, Eq. (37) should in addition be integrated from $y=0$ to $y=1$. (It must not be integrated from $-1$ to $+1$ as in evaluating the Si functions we have assumed their arguments positive, which requires $y>0$.)

The integrals are evaluable in terms of $\mathrm{Si}(x)$, $\mathrm{Ci}(x)$ and elementary functions.[10] It is convenient to make asymptotic expansions of $\mathrm{Si}(x)$ and $\mathrm{Ci}(x)$ after the integrals have been calculated. In some of the terms, however, it turns out that the factor multiplying $\mathrm{Si}(x)$ or $\mathrm{Ci}(x)$ contains a first power of $x$ explicitly rather than involving $x$ only through trigonometric functions, and in such terms it is not sufficient to use the approximations $\mathrm{Si}(x)\sim\frac{1}{2}\pi$, $\mathrm{Ci}(x)=0$, but rather we must employ the somewhat more accurate asymptotic developments $\mathrm{Si}(x)\sim\frac{1}{2}\pi-\cos x/x$, $\mathrm{Ci}(x)\sim\sin x/x$ in order to obtain answers correct to terms of the zeroth order in $x$. By proceding in this fashion it is found that the averaged cross section $\bar{\sigma}$ finally becomes

$$\begin{aligned}16\pi\bar{\sigma}/3\lambda^2=&(F'^2+F''^2)(2x\pi-1)+(G'^2+G''^2)[2x\pi-1+\log 4x+0.577+(4x\log 2+\pi)\sin 2x\\&\qquad+(\tfrac{1}{2}-2\{\log 4x+0.577\})\cos 2x-(\log 2)\cos 4x]\\&+(H'^2+H''^2)[2x\pi-1+\log 4x+0.577-(4x\log 2+\pi)\sin 2x\\&\qquad+(2\{\log 4x+0.577\}-\tfrac{1}{2})\cos 2x-(\log 2)\cos 4x]\\&+2(G'H'+G''H'')[4x(\log 2)\cos 2x-\tfrac{1}{2}\sin 2x]\\&+4(F'G'+F''G'')[(7\pi/4)\sin x-\tfrac{1}{2}(\log 4x+0.577)\cos x-\tfrac{1}{2}(\log 2)\cos 3x]\\&\qquad+4(F'H'+F''H'')[\tfrac{1}{2}\pi\cos x-\tfrac{1}{2}(\log 4x+0.577)\sin x+\tfrac{1}{2}(\log 2)\sin 3x].\end{aligned}\tag{38}$$

---

[10] For detailed evaluation of the integrals see report 411-103 of the Radio Research Laboratory, Harvard University (NDRC Div. 15). This report also contains more graphs of the angular cross sections than given in our Figs. 5–8.

*Short wires* in case the wire is not long enough compared to the wave-length to permit the use of asymptotic expansions, the preceding formulas must be modified as follows: Eq. (37) is still applicable, but the coefficients $F$, $G$, $H$, must be redefined. Equation (34a) is replaced by

$$F'=\Omega''/(\Omega''^2+\mathrm{X}^2),\quad F''=\mathrm{X}/(\Omega''^2+\mathrm{X}^2),\quad \mathrm{X}=2[\mathrm{Si}2\beta l+(2\beta l)^{-1}(\cos 2\beta l-1)],$$

$$\Omega''=2[\log(2l/a)+\log 2-\mathrm{Cin}2\beta l-(\sin 2\beta l/2\beta l)].$$

The formulas (35) for $G$ and $H$ are still valid if the coefficients $\pi\Omega'^{-1}$ in (35) are replaced by $2\Omega''^{-1}\mathrm{Si}2\beta l$, and if the definitions (35a) are modified to

$$\Psi(x)=-(\Omega''-\Delta'')\cos x+\tfrac{1}{2}\,\mathrm{Si}4\beta l\sin x,\quad \Xi(x)=\tfrac{1}{2}\,\mathrm{Cin}4\beta l\sin x-[\tfrac{1}{2}\mathrm{Si}4\beta l+(4\beta l)^{-1}(\cos 4\beta l-1)]\cos x,$$

$$\Omega''-\Delta''=2[\log(2l/a)+\log 2-1]-\tfrac{1}{2}\,\mathrm{Cin}4\beta l-\mathrm{Cin}2\beta l-(\sin 4\beta l/4\beta l)+1.$$

The explicit expression for the resulting averaged cross section is given in reference 10, and will not be reproduced here, as it is quite cumbersome.

For $2l/a=900$, the averaged cross section at the first resonance turns out to be six percent lower when asymptotic expansions are avoided. The lower values have been used in drawing the first peak in Figs. 2 and 3, but serious error would not have resulted had we used the asymptotic formulas. For the second and higher peaks, the results are not appreciably influenced by employing asymptotic expansions. On the other hand, when the frequency is lowered much below the first resonance, it is very essential to avoid using the asymptotic formulas.

When the frequency is quite small compared to the first resonant frequency, or in other words if the wire is cut much too short for resonance, it is very difficult to compute with the non-asymptotic formula that replaces (38). The cross section is expressed as a difference of terms which nearly cancel and which must hence be very accurately evaluated to obtain a significant answer.

However, for very short wires, simple formulas may be obtained by using for the coefficients the approximate values

$$F'=1/[2\log(2l/a)+2\log 2-1],\quad G'=-F'(1+x^2)/2,\quad H'=-F'/2x,$$

and developing the expression (34) for the current or the integrand of (37) as a Taylor's series in $x$ and retainining only the terms of lowest order. In this way one finds that before averaging the cross section is

$$\sigma=(\lambda^2x^6/9\pi)(\cos^4\varphi)(1-y^2)^2[\log(4l/a)-1]^{-2},\tag{39}$$

while the averaged cross section is

$$\bar{\sigma}=(\lambda^2x^6/45\pi)[\log(4l/a)-1]^{-2},\quad (x=2\pi l/\lambda).\tag{40}$$

Equations (39) and (40) can safely be used if the frequency is twenty percent or less of the first resonant frequency (i.e., $\lambda/l\geqq 20$). Equations (39) or (40) show that for wires very short compared to the wave-length, the cross section is proportional to the sixth power of the wire length, and inversely proportional to the fourth power of the wave-length. This behavior is reasonable, as in the low frequency limit the dimensions of the object and the wave-length also enter in the sixth and inverse fourth powers in the known formulas for other types of scatterers (e.g., spheres), as well as in the general Rayleigh theory of scattering by small particles.

We can, in fact derive (39) in a quite independent fashion by computing the Rayleigh scattering. It suffices to consider the case $\varphi=y=0$ where the wire axis $A$ is parallel to the incident vector $E_0$, as it is readily seen that for very long waves the cosine of the angle between $A$ and $E_0$ is involved to the fourth power, thus accounting for the factor $\cos^4\varphi(1-y^2)^2$ in (47). The broadside radiation of a dipole of moment $M$ has a Poynting vector $\frac{1}{4}\pi^{-1}c^{-3}R^{-2}(d^2M/dt^2)^2$. In the long wave-length limit we can safely take $d^2M/dt^2=-(2\pi\nu)^2a_0E_0$, where $a_0$ is the static polarizability of the wire. The cross section is then $a_0^2(2\pi/\lambda)^4 4\pi$. We now need only the value of $a_0$, and this we can take from the soluble problem[11] of a very prolate ellipsoid of revolution of semi-major axis and semi-minor axis $a$ in a static field parallel to the axis of symmetry. Since the wire is a conductor, we take the dielectric constant as $\infty$. The polarizability is then the volume of the ellipsoid divided by the demagnetizing factor $D$, and for the infinitely prolate case the value of $D$ is $(4\pi a^2/l^2)[\log(2l/a)-1]$. We thus obtain a formula identical with (39) except that $\log 2l/a$ occurs in place of $\log 4l/a$. The difference is of minor consequence since $2l/a$ is large, and is no doubt due either to the non-equivalence of an ellipsoid and cylinder, or to the fact that our replacement of $Z(z)$ by a constant $\langle Z\rangle_{\mathrm{Av}}$ as in (28) is of necessity an approximation.

The cross section falls off very rapidly as the frequency is lowered from the first resonance. Consequently in Fig. 2 or Fig. 3 the ordinate can be regarded as sensibly equal to zero when the abscissa is less than about half the value associated with the first resonance. Part of the drop of the curve as one approaches the origin is caused by the fact that $\bar{\sigma}/\lambda^2$ rather than $\bar{\sigma}$ is being plotted: $\lambda$ increases when the abscissa (proportional to frequency) is lowered. However, most of the decrease of $\bar{\sigma}/\lambda^2$ is caused by the $\bar{\sigma}$ rather than $1/\lambda^2$ factor. For instance, if $2l/a=900$, the value of $\bar{\sigma}/\lambda^2$ yielded by (40) at $x=0.3$ (frequency one-fifth that of the first resonance $x=1.5\sim\pi/2$) is 0.00000012, and the cross section $\bar{\sigma}$ is only one sixty-thousandth of its value at the first resonance. The values of $\bar{\sigma}/\lambda^2$ at frequencies forty, sixty, eighty, and one hundred percent of the first resonance ($x=0.6$, $x=0.9$, $x=1.2$, $x=1.50$) are 0.000043, 0.0014, 0.0071, 0.184, respectively, if $2l/a=900$.

## APPENDIX. SOME NOTES ON THE CONVERGENCE OF METHOD B

If we decompose the fundamental integral Eq. (1) into its forced and resonant parts, then the equation satisfied by either portion is mathematically of the type form

$$\int r^{-1} I_p(\xi) e^{-i\beta r} d\xi = D_p \cos kz, \tag{41}$$

where $I_p$ refers to only the forced or resonant part of the current ($p=f$, $r$, respectively) and where $k$ means $q=\beta\cos\theta$ for the forced and $\beta=2\pi/\lambda$ for the resonant case. For simplicity we consider only the portion of the solution which is even as regards reflection in the origin, as the convergence questions connected with the even and odd members are fundamentally similar. We seek to solve (41) by a trial function of the form $E_p \cos kx$. The left-hand side of (41) then turns out to be of the structure

$$E_p[f_p(z)\cos kz + g_p(z)\sin kz], \tag{42}$$

(Cf. Eq. (27)) where $f_p(z)$ is a slowly varying function of $z$, and $g_p(z)$ may be disregarded in the first approximation. We next replace $f_p$ by its mean value, and thus take

$$E_p = D_p/\bar{f}_p. \tag{43}$$

Against this procedure it may be objected by some readers that actually $f_p(z)$ does vary with $z$, and so should not be replaced by a constant in such a debonnaire fashion. In fact, at the ends of the wire $f(z)$ has approximately half its value at the center, which is also nearly its mean value, provided of course the wire length $l$ is large compared to its radius, as we assume throughout. Now for computation of the radiation from the wire, it seems fairly clear that the approximation $f_p=\bar{f}_p$ is not responsible for much error, since the ends of the wire contribute only a fraction of the total radiation. However, it may well seem at first sight that the use of (42) is a bad mistake in applying the boundary condition $I(\pm l)=0$, i.e., in satisfying Eq. (31), for it is at the ends of the wire that the difference between $f_p$ and $\bar{f}_p$ is largest. We shall now show that this objection is not as serious as it first seems. We may distinguish between two cases: (a) wires which contain at most a few wave-lengths, so that $\log(l/\lambda)$ is small compared with $\log(\lambda/a)$, and (b) wires which are so extended as to contain an enormous number of wave-lengths, so that $\log(l/\lambda)$ is comparable with, or greater than, $\log(\lambda/a)$.

First we shall dispose of case (a). Here as can be seen from the study of Eq. (27) the distinction between $f_p(z)$ and $\bar{f}_p$ is important only at distances from the ends of the wire which are comparable with the wire radius, and small compared

---

[11] E. C. Stoner, *Magnetism and Matter*, p. 39.

with the wave-length. However, because of the fact that the current vanishes at the ends of the wire, the substitution of $\bar{f}_p$ for $f_p$ leads to no serious error when we remember to include the sum of the resonant and forced terms rather than to consider them separately. Individually they would show abrupt discontinuities near the end of the wire if we assumed them inversely proportional to $f_p(z)$. Because $\log(l/\lambda)$ is by hypothesis small compared to $\log(\lambda/a)$ in case (a), the value of $f_p$ is roughly the same for the forced and resonant members, as can be seen from Eqs. (27) and (30). Hence for estimating the orders of errors, we can replace $f_f$, $f_r$ by a common expression $f$, and the point of our argument is that in the "end zone," i.e., the region a small fraction of a wave-length from the end of the wire, the difference between the expressions

$$f^{-1}(D_f \cos qz + D_r \cos\beta z)$$
and
$$\bar{f}^{-1}(D_f \cos qz + D_r \cos\beta z) \qquad (44)$$

is of minor importance. The reason for this statement is that at the ends of the wire the terms $D_f \cos qz$ and $D_r \cos\beta z$ nearly cancel. The cancellation, it was pointed out in Part I, is not complete, but still it is enough to insure that throughout the end zone either form of expression (44), and hence the difference between the two forms, is only of the order $I(0)/\Omega$ (with $\Omega \sim \log(\lambda/a)$). This is sufficient accuracy since our solution only pretends to be accurate to the order $I(0)$. Here $I(0)$ denotes the order of magnitude of the current down most of the wire (not necessarily at the center) and is of the order $\omega E/\beta^2\Omega$ away from resonance and $\omega E/\beta^2$ at resonance. This argument can be stated somewhat more exactly as follows: If we iterate (1) or (25) to obtain a second approximation to the current, the difference as compared with (24) is

$$\Delta I = f(z)^{-1}\Big\{ -\int r^{-1}[I_0(\xi) - I_0(z)] \cos\beta r d\xi$$
$$+ i\int r^{-1} I_0(\xi) \sin\beta r d\xi$$
$$+ (i\omega \cos\varphi/\beta^2 \sin\theta) E_0 e^{iqz}$$
$$+ A_1 \cos\beta z + A_2 \sin\beta z \Big\} - I_0(z), \qquad (45)$$

where $I_0(z)$ denotes the first approximation to the current, given by (24) and where the significant part of $f(z)$ is given by (26). Because of the boundary condition (31) one finds that $I_0(l)$ is of the order $1/\Omega$ compared with $I_0(0)$. The factor in braces in (45) vanishes at the ends of the wire, and reaches values of the order of $I_0(0)\bar{f}$ only when one moves a wave-length or so away from the ends. Except at the very ends of the wire, the distinction between $f$ and $\bar{f}$ disappears, so that the factor in braces in Eq. (45) is nearly the same as $f(z)I_0(z)$. Thus $\Delta I$ is everywhere of the order $I_0(0)/\Omega$. Similarly one can show that each successive approximation gives a contribution of the order $1/\Omega$ times the preceding one. Our procedure is hence convergent.

In case (b), however, the situation is a different one. The value of $f_p(z)$ is essentially different for the forced and resonant parts of the solution, as $f_f$ has the structure $A \log(\lambda/a) + B$, while $f_r$ has the form $C \log(\lambda/a) + D \log(l/\lambda) + E$ and so increases without limit when the wire contains more and more wave-lengths, whereas in (a) we assumed that $\log(l/\lambda)$ was small compared with $\log(\lambda/a)$. In the end zone the correction $\Delta I$ furnished by the second approximation still is of the order $I_0(0)/\Omega$, but becomes of the order $I_0(0)$ at distances from the end of the wire comparable with the wave-length, but large compared with the radius of the wire and small compared with its total length. Since the correction is comparable in order with the first approximation for part of the wire, it may seem that all semblance of convergence is lost. However, we believe that the resulting error is not serious. In the first place, the difficulty arises only in connection with the resonant rather than forced part of the solution, as the extra term $D \log(l/\lambda)$ occurs only in connection with the former, and in the latter most of the contribution comes from the "close-in" rather than the "far-away" portion since

$$\int_\epsilon^\infty \cos q\xi \frac{e^{-i\beta r}}{r} d\xi$$

converges. Hence our forced member is reasonably well determined, and for long wires this is the main effect. Furthermore, the fact that the integral varies only slowly with position on the wire, together with the fact that most of the radiation does not come from too near the end zone, means that the amplitude of even our resonant term is probably not in error by a factor 2 or so until $\log(l/\lambda)$ becomes large rather than merely comparable with $\log(\lambda/a)$. When $\log(l/\lambda)$ is large compared with $\log(\lambda/a)$, the resonant terms are unimportant compared with the forced, and so any quantitative percentage error in the resonant part of the theory in this region is inconsequential as long as it gives resonant terms which are small compared with the forced. In other words, our theory behave correctly in the limit of infinitely long wires, where it agrees with Chu. Before reaching the limit, but by the time $\log(l/\lambda)$ becomes comparable with $\log(\lambda/a)$, the difference between the heights of the peaks and valleys is small compared with the elevations of the valleys, so that accuracy in this difference is unimportant. We might add that practically we are not concerned, anyway, with wires so long that $\log(l/\lambda)$ is comparable with $\log(\lambda/a)$, so that case (b) is of rather academic interest.

In closing, it is perhaps well to make a few remarks comparing our procedure in method (B) to that of Hallén[4] (or King and Harrison[3]), of Gray,[5] and of King and Middleton.[6] In each instance one is concerned with obtaining a first approximation to an integral of the form $\int r^{-1}\cos k\xi e^{-i\beta r}d\xi$ with the singularity at the origin avoided by integrating down the center of the wire, so that $r^2=(\xi-z)^2+a^2$. Hallén approximates the integral by $\cos kz\int r^{-1}d\xi$. When the upper limit of integration is infinity, the integral $\int r^{-1}\cos k\xi e^{-i\beta r}d\xi$ converges when $k\neq\beta$, whereas $\int r^{-1}d\xi$ does not. Thus, it is clear that the Hallén procedure is not appropriate for long wires. This difficulty is avoided by Miss Gray, who approximates the integral by

$$\cos kz\int r^{-1}e^{-i\beta r}d\xi.$$

This is not an unreasonable step when $k\neq\beta$, as then both the original and substituted integrals are convergent. Hence the Gray scheme is a fairly suitable one for the forced part of the solution, as here $k\neq\beta$. In fact, for the broadside case $k=0$ which figures particularly prominently in the forced part of the scattering, the original form of the integral does not differ from that substituted by Miss Gray. In this particular case, there is no essential distinction between the Gray scheme of approximation and our own which resembles that of King and Middleton. (We might mention parenthetically, that the Gray procedure was not intended specifically for the problem of the receiving antenna, to the forced part of which it applies quite well, but rather for the resonant radiating antenna, to which the same difficulties apply as in the resonant portion which we now discuss. On the other hand, it was intended primarily for the half wave antenna, which is so short that the proper behavior, as $l$ approaches infinity, is irrelevant. Even for the half-wave case, the method of King and Middleton is somewhat more accurate than that of Miss Gray.) Certainly, the type of substitution employed by Miss Gray is not a happy choice for the resonant terms if the wire is so long as to contain a great number of wave-lengths. The difficulty is that the resonant part of the problem has $k=\beta$, so that $\int r^{-1}\cos k\xi e^{-i\beta r}d\xi$ diverges (through to half the Hallén value) when the limit is infinite, whereas the integral substituted by Gray converges. Correspondingly, the amplitude of the resonant member, which by (43) is inversely proportional to the substituted integral, remains finite if the Gray approximation is applied to an infinitely long wire, whereas actually it should go to zero. This difficulty is avoided in our type of procedure which is essentially the same as that of King and Middleton and consists in replacing $\int r^{-1}\cos k\xi e^{-i\beta r}d\xi$ by $\cos kz\int r^{-1}\cos k(z-\xi)e^{-i\beta r}d\xi$ in first approximation. (Cf. Eq. (27) or (42).) The factor multiplying $\cos kz$ is then an integral which converges for infinitely long wires for the forced part of the solution and diverges for the resonant part, whereas Hallén has divergence for both portions, and Gray has convergence. Correspondingly in the limit of very long wires, the forced amplitude remains finite, approaching the Chu value asymptotically, and the resonant member approaches zero as should be the case, whereas the first approximation of Hallén would make both amplitudes tend to zero, and that of Gray would make them both stay finite.

# X-Ray Scattering at Small Angles by Finely-Divided Solids. I. General Approximate Theory and Applications*

C. G. Shull** and L. C. Roess
*Beacon Research Laboratory of The Texas Company, Beacon, New York*

(Received August 29, 1946)

The general approximate theory of x-ray scattering at small angles by finely divided solids is reviewed. It is assumed that the x-ray scattering data can be interpreted in terms of a particle size distribution, with particle-to-particle scattering negligible. Scattered intensity curves for Maxwellian, Gaussian, and rectangular size distributions are calculated, and several procedures for obtaining a size distribution from the experimental scattering data are described. Details of the experimental technique are given, and evidence is presented to show that appreciable error can result if crystal-monochromated radiation is not used. General procedures are given for applying corrections to the experimental data for the slit geometry used. Scattering data, mass distribution curves, and average particle sizes are presented for amorphous silica gels and for crystalline oxides of alumina, nickel and iron. These data are shown to correlate well with the results of crystal size measurements by x-ray diffraction line broadening and with specific surface measurements. The average particle size values determined from the experimental data are shown to have considerable significance, at least for the type of materials considered here.

## INTRODUCTION

The usefulness of x-ray scattering at small angles in the study of finely-divided solids has been demonstrated by many investigators.[1] Carbon blacks have been studied by Warren and his collaborators,[1,2] by Guinier,[3] and by Krishnamurti,[1] cellulose in various forms by Kratky and his collaborators,[4] by Hosemann[5] and by Guinier,[3] while Guinier[3,6] has applied the method to ovalbumine, rubber, colloidal silver, ramie, and the hardening of alloys. Catalyst studies have been reported by Guinier,[3] Elkin, Shull, and Roess,[7] and Jellinek and Fankuchen.[8]

The interpretation of the x-ray intensity scattered at small angles is by no means unambiguous.[9] At least two specialized points of view have been emphasized in the literature: (1) the Guinier[1] and Hosemann[1] theory, which emphasizes particle form factor scattering and assumes that particle-to-particle scattering can be neglected, and (2) Kratky's view[4,10] that, at least for fibrous materials, such as cellulose, a statistical distribution of Bragg reflection planes is responsible for the observed scattering.

Basically it is the distribution of electron density which produces the scattering, and therefore nothing more than this distribution, if that much, can be obtained without ambiguity from the x-ray data. An average electron density, the Patterson distribution,[11] can be calculated, at least in principle, from the observed x-ray data. Such an average electron density having been determined, its interpretation in terms of more

directly useful physical pictures, such as particle size distributions, offers considerable difficulty, and requires that further assumptions be made.

The most useful method of interpreting the small angle x-ray data may well depend upon the nature of the materials being studied. It has seemed to us that the particle size (or mass) distributions resulting from Hosemann's theory, which assumes particle-to-particle scattering to be negligible, are of great value in forming physical pictures of the solid materials which we have studied (silica gels, silica-alumina catalysts, alumina gels, and alumina-base catalysts). We have, therefore, consistently used this method of interpreting the data, and have endeavored to find evidence supporting it from investigations of these materials by entirely independent means, such as physical adsorption and the broadening of ordinary x-ray diffraction lines.

Once this assumption of negligible particle-to-particle scattering is made, the procedure becomes straightforward. The angular distributions of x-ray intensity scattered at small angles by a series of particle mass distributions obtained by varying two parameters in several types of distribution functions have been calculated. The observed data are compared with the calculated curves, after taking into account any necessary corrections for the geometry of the apparatus, and the mass distribution giving the best fit is determined. Spherical particle shape is assumed in all of the work reported here, although calculations have been made[12] for randomly oriented spheroids also.

The justification for these assumptions can only be found in the usefulness of the particle size distributions obtained and in the agreement between predictions based on them and data obtained independently. We believe that on these grounds the assumptions have been shown to be justified for the materials we have studied.

It is possible to invert the x-ray data to give the mass distribution function directly.[13] This procedure was discovered too late for use in presenting our data. It is unlikely that significantly different results would be obtained for the materials studied here.

## GENERAL THEORY OF X-RAY SCATTERING BY A DISTRIBUTION OF RANDOMLY ARRANGED PARTICLES

For purposes of mathematical analysis we consider a scattering specimen which contains small particles arranged in a random fashion. The intensity of x-radiation scattered at a small angle $\epsilon$ by a single particle is given by

$$I(\xi)=I_e\rho_e^2V^2S(R,\xi), \tag{1}$$

where

$$\xi=(2\pi/\lambda)\epsilon, \tag{2}$$

$I_e$ is the Thomson scattering factor for a single electron and is essentially constant for the angles to be considered, $\rho_e$ is the electron density and $V$ the volume of the particle, and $S(R, \xi)$ is the scattering function characteristic of the particle size $R$ and its geometrical shape. The scattering function $S$ is related to the particle structure as the atomic form factor is related to the structure of an atom.

When many particles $N$ are present, as is always the case experimentally, and if their contributions to the scattered intensity are independent of each other, then obviously the scattered intensity is given by

$$I(\xi)=I_eN\rho_e^2V^2S(R,\xi). \tag{3}$$

This is the equation used by Guinier[3] in his early studies.

If a distribution of particle sizes is envisaged, as Hosemann[1] has suggested,

$$I(\xi)=I_e\rho_e^2\int_0^\infty N(R)V^2(R)S(R,\xi)dR \tag{4}$$

where $N(R)dR$ is the total number of particles having sizes in the range $R$, $dR$. This integral equation can be put into a somewhat more usable form by introduction of a mass distribution function and by expressing the particle volume in terms of the particle size. Thus

$$I(\xi)=KI_e\rho_e^2\int_0^\infty M(R)R^3S(R,\xi)dR, \tag{5}$$

with $M(R)dR$ representing the total mass of particles in the size range $R$, $dR$ and $K$ being a constant proportional to the total mass.

TABLE I. Relationship between average particle size and parameters in Maxwellian type of distribution.

| $n$ | 0 | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|
| $\bar{r}/r_0$ | 0.227 | 0.693 | 1.183 | 1.677 | 2.176 | 2.674 |

In proceeding further, it is necessary to assume a particular particle shape in order to permit evaluation of the scattering function $S$. The scattering function for the general case of spheroidal particles (which includes spherical, rod-shaped, and plate-shaped particles) has been evaluated in an exact form and will be discussed in the second paper[12] of this series. Guinier[3] has introduced an approximate scattering function

$$S_0(R,\xi)=\exp\left[-\frac{r^2}{3}\xi^2\right], \qquad (6)$$

which agrees exactly at very small angles with the exact scattering function for spherical particles. Deviations are obtained, however, at the larger angles and the effect of these on the interpretation of experimental data will also be discussed in the companion paper. In Eq. (6), Guinier has defined $r$ as the radius of gyration (defined as in the usual mechanical case) of the particle. However, the introduction of the radius of gyration is not of sufficient generality to make the Guinier function a good approximation for very asymmetrical particles, as Guinier[3] has shown.[14]

The integral Eq. (5) along with the Guinier scattering function has been used by Hosemann,[5] by Elkin, Shull, and Roess,[7] and by Jellinek, Solomon, and Fankuchen[8] in their studies. Since, in general, not very much is known in advance about the particle shape or whether there is a preferred shape, it would seem that the use of the Guinier scattering function would be as significant as any. A comparison of the results obtained by interpreting a typical set of experimental data with both the Guinier scattering function and the exact scattering function for spherical particles has shown agreement within about 20 percent for the calculated average particle size. In the present paper, the experimental data have all been interpreted by use of the approximate scattering function and the resultant particle size distributions described in terms of a particle diameter.

## Methods of Data Interpretation

In applying Eq. (5) to the interpretation of experimental data, it is necessary to perform a mathematical inversion of the data in order to obtain the desired particle size distribution. A direct inversion procedure making use of the exact scattering function for spheroidal particles has been introduced by Roess,[13] but as mentioned earlier this was discovered too late for application to the present experimental data. Several indirect methods are available, however, which provide a simple and easily-performed procedure for obtaining the particle size distribution, and these have been used in the present study. Basically these indirect methods involve a matching of the experimental scattering curve with either one or a suitable combination of standard scattering curves which have been calculated in advance for selected distributions of particle size. Three types of distributions have been studied: Maxwellian, Gaussian, and rectangular, and these will be considered individually.

### Maxwellian Type of Particle Size Distribution

Hosemann[1] has suggested that the particle size distribution might be represented by an expression of the type $r^n\exp[-(r/r_0)^2]$, where $n$ and $r_0$ are constants whose values are to be adjusted to the experimental data. Following this idea, we let

$$M(r)=\frac{2}{r_0^{n+1}\Gamma\left(\frac{n+1}{2}\right)}r^n\exp[-r^2/r_0^2], \qquad (7)$$

where the coefficient is that which gives a total mass of unity. The average particle size $\bar{r}$, which is defined as that size which divides the mass distribution in half, has been calculated for this distribution in terms of the parameters $r_0$ and $n$, and the resulting values are listed in Table I. It is interesting that $\bar{r}/r_0$ varies almost exactly linearly with $n$ for $n \geqslant 1$.

If Eq. (7) and the Guinier scattering function,

---

[14] See also section on Numerical Results in reference 12.

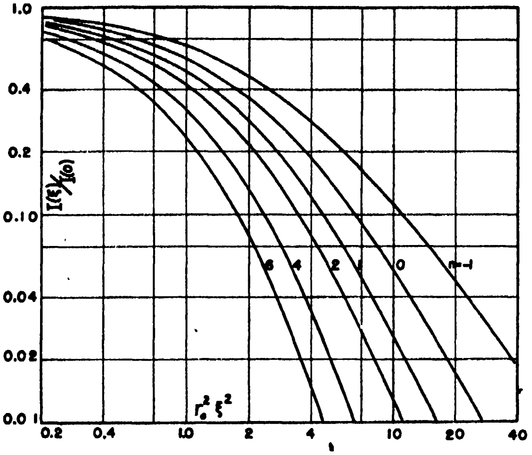

FIG. 1. Calculated scattering curves for Maxwellian type of particle size distribution.

Eq. (6), are inserted into Eq. (5), we obtain

$$I(\xi)=KI_e\rho_e^2\frac{2}{r_0^{n+1}\Gamma\left(\frac{n+1}{2}\right)}$$

$$\times\int_0^\infty r^{n+3}\exp[-(\tfrac{1}{3}\xi^2+r_0^{-2})r^2]dr, \quad (8)$$

and this integrates directly to

$$I(\xi)=\frac{2KI_e\rho_e^2\Gamma\left(\frac{n+4}{2}\right)r_0^3}{\Gamma\left(\frac{n+1}{2}\right)}$$

$$\times[\tfrac{1}{3}r_0^2\xi^2+1]^{-[(n+4)/2]}. \quad (9)$$

The requirement of finite total mass in the distributions of Eq. (7) restricts values of $n$ to those greater than $-1$.

Equation (9) represents the intensity distribution to be expected if the particle size distribution has the form of Eq. (7). Conversely if Eq. (9) can be made to fit the experimental data by adjustment of its parameters, then the particle size distribution is obtainable directly from Eq. (7). The adjustment of the parameters can be conveniently done by either of two graphical methods, (a) a curve matching and resolution process, and (b) a curve shifting procedure.

The former procedure makes use of the *standard scattering curves* shown in Fig. 1. These have been calculated[15] according to Eq. (9). If the experimental scattering curve (plotted as $\log I$ *versus* $\log\xi^2$) can be matched to one of these standard scattering curves by suitable displacement of the two graphs along horizontal and vertical axes, the particle size distribution is represented by Eq. (7) with the parameter $n$ determined by the selected standard curve and $r_0$ determined by comparing the location of the $\xi^2$ axis on the experimental graph in relation to the $r_0^2\xi^2$ axis of the standard curve graph. If, however, the experimental data do not match any of the standard curves it is necessary to resolve the experimental curve into the sum (or difference) of two or more component curves each of which is a good match for one of the standard curves. The parameters of the component curves will be determined in the same fashion as in the earlier one-component match and the relative amplitudes of the distributions will be determined by the relative intensities of the component scattering curves. It has been found generally that one standard curve will represent the experimental data, but even when additional component curves have been found necessary the whole resolution process can be carried out in less than one-half hour.

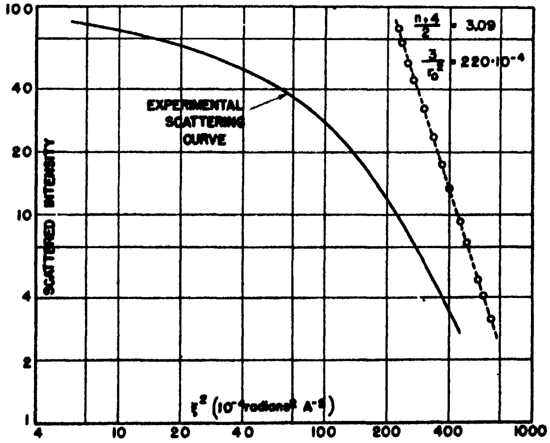

FIG. 2. Typical experimental scattering curve for alumina gel illustrating the shifting procedure for determining the particle size distribution parameters.

---

[15] The calculated values for the scattered intensity produced by various particle size distributions have been tabulated and are available from the authors upon request.

The second method for determining the particle size distribution does not involve the use of the standard curves but is nevertheless quite similar to the former method. Equation (9) can be put into a logarithmic form

$$\log I(\xi)=\log K_1-\left(\frac{n+4}{2}\right)\log[\xi^2+3/r_0^2], \quad (10)$$

with $K_1$ a constant. From this equation it can be seen that a graph of the experimental intensity *versus* $(\xi^2+3/r_0^2)$ on a double logarithmic scale should show a linear relationship between these variables. Moreover the slope of the line through the experimental data would be $-[(n+4)/2]$ and hence $n$ would be determined. It is not possible to plot the above variables directly, since $r_0$ is also an undetermined parameter, but the data can be plotted simply as $I$ *versus* $\xi^2$ (again on double logarithmic paper) and then various values of $3/r_0^2$ added to $\xi^2$ until a straight line is obtained. Figure 2 illustrates the use of this shifting procedure. The experimental data are represented by the solid line and upon adding a fixed quantity ($220\cdot 10^{-4}$ radians$^2$ $A^{-2}$) to the abscissa of the experimental values, the circled points are seen to agree closely with a straight line. The parameters $n$ and $r_0$ are immediately available and the particle size distribution can be represented by Eq. (7). In cases where the shifting process does not lead to a single straight line, the experimental curve can be broken into component curves each of which can be shifted into a straight line. Additional terms are therefore necessary in describing the true particle size distribution. Again this process can be performed in a short time.

## Gaussian Distribution of Particle Size

Let the particle size distribution be represented by

$$M(r)=\frac{2}{\sqrt{\pi}}\frac{\beta}{r_0}\frac{1}{1+H(\beta)}\exp\left[-\frac{\beta^2}{r_0^2}(r-r_0)^2\right], \quad (11)$$

where the coefficient has been selected to make the total mass unity. Substitution of Eqs. (11) and (6) into Eq. (5) gives upon integration

$$I(\xi)=\frac{KI_e\rho_e^2}{\sqrt{\pi}}\frac{r_0^3}{\beta^{\frac{1}{2}}[1+H(\beta)]}D(\beta, r_0\xi) \quad (12)$$

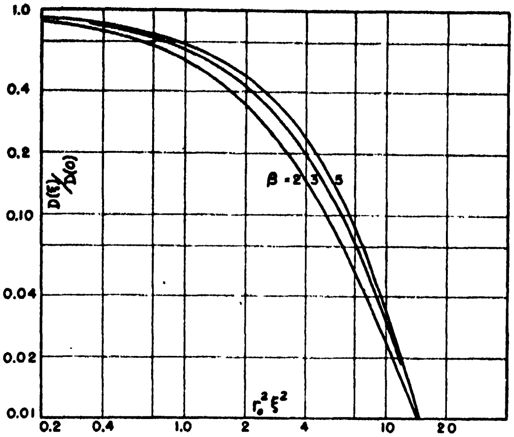

FIG. 3. Calculated scattering curves for Gaussian type of particle size distribution.

with

$$D(\beta, r_0\xi)=\beta^{-13/2}\tau^4\bigg\{(1+\tau^2)\exp(-\beta^2)$$

$$+\frac{\sqrt{\pi}}{2}\tau\exp(\tau^2-\beta^2)[2\tau^2+3][1+H(\tau)]\bigg\}, \quad (13)$$

where

$$\tau^2=\frac{3\beta^4}{3\beta^2+r_0^2\xi^2}$$

and

$$H(x)=\frac{2}{\sqrt{\pi}}\int_0^x \exp(-u^2)du.$$

From Eq. (12) it is seen that the angular dependence of the scattered intensity is wholly within the function $D$. This function has been evaluated for various values of $\beta$, and a typical family of curves is shown in Fig. 3. It should be mentioned that the parameter $\beta$ in the distribution given by Eq. (11) determines the sharpness of the distribution, whereas $r_0$ is the average particle size.

The curves given in Fig. 3 can be used in the same fashion as those of Fig. 1 in interpreting experimental data. If the data can be matched to one of the curves, one expression of the type given by Eq. (11) suffices to describe the particle size distribution. If a simple matching cannot be performed it is necessary to perform the resolution process as outlined for the Maxwellian type of distribution.

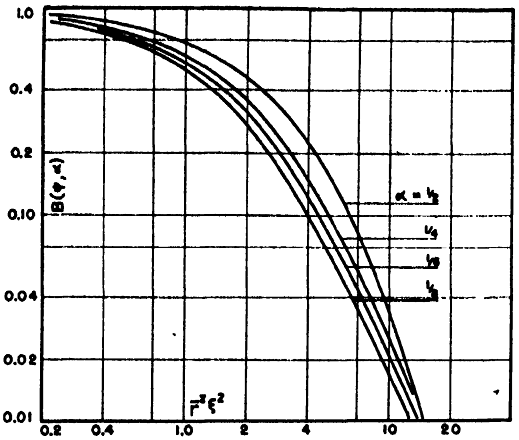

FIG. 4. Calculated scattering curves for rectangular type of particle size distribution.

## Rectangular Distribution of Particle Size

Let the particle size distribution be represented by

$$M(r)=\frac{1}{r_2-r_1}\quad\text{for}\quad r_1\leqslant r\leqslant r_2$$
$$=0\ \text{otherwise.}\qquad(14)$$

Equation (5) now integrates into

$$I(\xi)=\frac{2KI_e\rho_e^2(1-\alpha^4)}{(1-\alpha)(1+\alpha)^3}\bar{r}^3B(\psi,\alpha),\qquad(15)$$

where

$$B(\psi,\alpha)=\frac{2}{(1-\alpha^4)\psi^4}\{(1+\alpha^2\psi^2)\exp(-\alpha^2\psi^2)-(1+\psi^2)\exp(-\psi^2)\}\qquad(16)$$

with

$$\alpha=\frac{r_1}{r_2},\quad \bar{r}=\frac{r_1+r_2}{2}\quad\text{and}\quad \psi^2=\frac{4}{3}\frac{\bar{r}^2}{(1+\alpha)^2}\xi^2.\qquad(17)$$

In Eq. (17), $\bar{r}$ is the average particle size of the rectangular distribution. The angular variation of the scattered intensity is given by the function $B$, and this is graphed in Fig. 4. Curves of this type may be used to evaluate the particle size distribution in a fashion similar to that outlined above.

## Comparison of the Scattering Curves Calculated for Different Distributions

The standard scattering curves which have been given in the preceding sections are all seen to possess three distinct features: (a) a flat section at the very small angles, (b) a curved region (the knee of the curve) at intermediate angles and (c) a steep, linear section at the larger angles. Because of the difficulty of making absolute intensity measurements, the interpretation of the experimental data is based on the shape of the experimental scattering curve, rather than on its absolute level. Since a fit between the observed curve and one of a family of calculated curves is made by effectively multiplying the ordinates and abscissae of the former by arbitrary factors (displacement in the vertical and horizontal directions until a match is found), it is seen that no significant match can be found if the experimental curve has been obtained in an angular region which does not include the curve knee.

In comparing the families of curves in Figs. 1, 3, and 4, it is found that some members in one family are very similar in shape to others in another family. Specifically, the curve for $\beta=2$ in Fig. 3 is very similar (over the angular range illustrated) to the curve for $\alpha=1/4$ in Fig. 4. This means that very accurate and extensive experimental data would be required in order to select the correct distribution form. However, the average particle sizes, obtained by matching an experimental curve with both of these calculated curves, agree very closely in value. Hence it appears that the curve matching method may introduce some ambiguity as to the distribution form but does lead to quite definite values of the average particle size for those cases in which the particle geometry is such that the Guinier scattering function can be used.

Figures 5 and 6 illustrate several particle size distribution curves and their appropriate calculated scattering curves. Distributions $A$, $B$, and

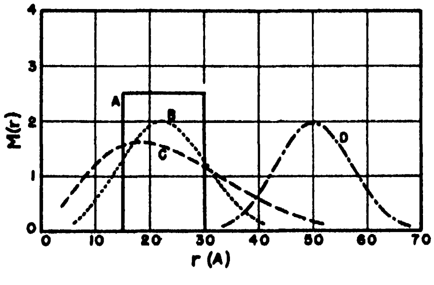

FIG. 5. Various types of particle size distributions.

*C* all have closely the same average particle size. The scattering curves for *A*, *B*, and *C* differ somewhat in the knee curvature with the sharpest distribution (A) showing the most curvature in the scattering curve. Distribution *D* corresponds to a considerably different average particle size and the resultant scattering curve differs markedly from the other curves.

### Experimental Technique

A schematic diagram of the camera used in determining x-ray scattering at small angles is shown in Fig. 7. Basically the camera consists of two parts: (a) a crystal monochromator for insuring that x-rays of only one wave-length pass into the camera, and (b) the scattering chamber which is an evacuated cylinder about 15 cm in diameter and 60 cm in length. Both calcite and rocksalt crystals are used as monochromating crystals: the former when a high degree of collimation is desired and the latter when higher intensity and less collimation is found necessary in the primary x-ray beam. The x-radiation coming from the monochromator passes into the evacuated scattering chamber through a thin beryllium window and then through slits *A* and *B* of respective opening 0.13 by 1.6 and 0.13 by 2.5 mm. These slits serve both to limit the width of the primary beam and to eliminate the weaker component of the $K\alpha$ doublet when a calcite crystal is used. If only one slit is used, the well resolved $K\alpha$ doublet will pass through the camera, and because of the angular separation of its components an unsymmetrical scattering pattern will be obtained. By proper alignment of the calcite crystal and the two slits, a homogeneous primary beam $K\alpha_1$, can be obtained. The half width of this beam after passage through slit *B* has been determined to be 0.10 mm, and at a distance of 50 cm beyond this slit this value has increased to only 0.14 mm. Thus it is seen that very little divergence is present in the beam reflected from the calcite crystal. This collimation is very desirable when the x-ray scattering is to be studied at the very small angles.

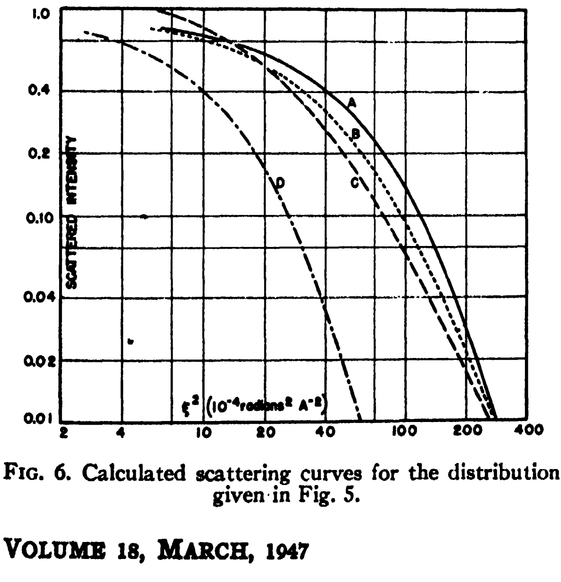

FIG. 6. Calculated scattering curves for the distributions given in Fig. 5.

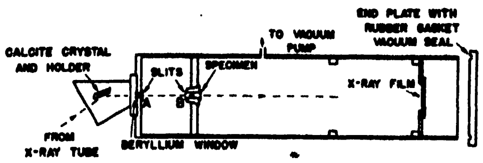

FIG. 7. Schematic diagram of small angle x-ray scattering camera.

The scattering specimen is placed immediately behind the second slit and the scattered radiation recorded on a piece of photographic film located at one of several positions in the scattering chamber. It has been found convenient to pulverize the sample by grinding to a particle size of the order of one micron (much larger than the particles whose size is to be studied by the scattering) and to pack this powder into a rectangular opening about (4 by 2 mm) in a flat metal plate. The thickness of the plate determines the specimen thickness and this can be selected so as to be of optimum value. No binder has been found necessary in this technique. A beam stop of width 0.5 mm is placed 1 cm in front of the film to absorb the primary beam. Specimen to film distances from 60 to over 400 mm have been used, depending upon the range of scattering angles to be investigated. At the conclusion of the main scattering exposure of duration 10 minutes up to 30 hours depending upon the scattering power of the specimen, the beam stop is removed and a short exposure of the primary beam is made. A typical exposure is reproduced in Fig. 8. The image of the primary beam and the scattered radiation on either side of the beam can be seen.

The intensity distribution across the equator (perpendicular bisector of the primary beam

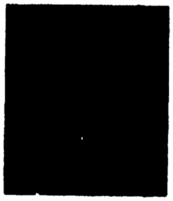

FIG. 8. Typical small angle x-ray scattering photogram.

image) of the film is determined with a microphotometer of scanning area 0.04 by 0.5 mm. Since the scattered x-ray intensity varies over a considerable range (several hundred or a thousand to one) a series of exposures are made with increasing exposure times in order that a large range of photographic density may be covered without exceeding the range in which the x-ray intensity is proportional to the density on any one film. After the individual films are microphotometered, the component intensity curves are combined by graphical matching into a complete scattering curve.

Some tests have been performed in which the use of crystal monochromated radiation is compared with that of filtered and unfiltered x-radiation. Figure 9 shows a series of scattering curves obtained for a sample of alumina with three types of primary radiation. The geometrical conditions of exposure (beam divergence, etc.) were kept unchanged from one exposure to another. It will be seen that intensity errors as large as 50 percent are obtained with unfiltered radiation. Upon filtering out the $K\beta$ radiation component, intensity errors as large as 20 percent are still present, caused by the white radiation band which is transmitted through the filter. The average particle size values as calculated from the filtered and crystal monochromated radiation curves differ by about 25 percent.

It has been mentioned earlier that slit openings, rather than pinholes, were used to define the primary beam. This has been done in order to utilize the increased intensity of scattering available with a slit system. Such technique, however, requires that a correction be applied to the data since the scattered intensity distribution will be altered. Hosemann[1] has considered the case in which the slit openings are infinitely long, but this situation will not be satisfied under the usual experimental conditions. The general theory of slit correction has been worked out and will be outlined in Appendices A and B of this report. As will be shown there, two methods of applying the correction are available and either one may be used.

## Experimental Results

The above procedure of analysis has been applied to several dozen finely divided samples in this laboratory. In general, scattering data were taken over the scattering angle range from about 0.2 to 2.5 degrees. As mentioned above, for the best interpretation of the data it should cover the region of interesting curvature. This region will depend in an approximately inverse fashion on the average particle size: with small particle systems the larger scattering angles are most interesting, while the smaller scattering angles are most profitably studied for systems of large average particle size.

In view of the interpretative assumptions discussed earlier, it is highly desirable to compare the results of x-ray scattering analysis with those obtained by other independent techniques. With crystalline materials the crystal size (as contrasted with the particle size) can be evaluated from studies of the width of x-ray diffraction lines, and for both crystalline and amorphous materials, low temperature gas adsorption can be used for obtaining information on the state of subdivision. Both methods have been used in our studies wherever possible.

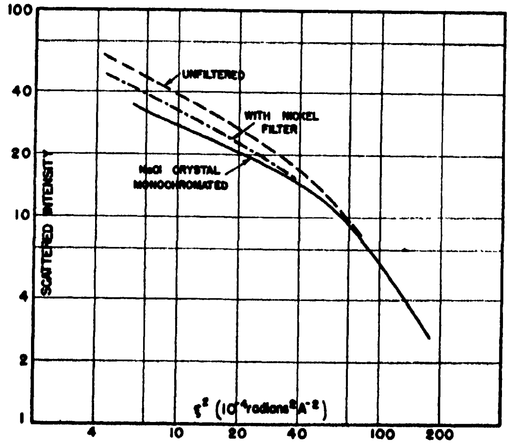

FIG. 9. Comparison of experimental scattering curves obtained with unfiltered, filtered and crystal monochromated primary radiation.

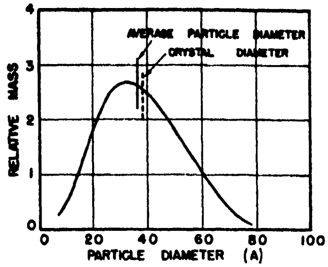

FIG. 10. Particle size distribution obtained for a sample of alumina gel.

In determining the crystal size, the Jones[16] technique of correcting the line broadening for geometrical effects was used. Values of the Scherrer constant used in the crystal size evaluation were those given by Stokes and Wilson[17] and Murdock.[18]

A typical particle size distribution[19] obtained for a sample of alumina gel is shown in Fig. 10. The experimental data and their analysis for this alumina gel have been given in Fig. 2. From the distribution curve, an average particle size can be readily evaluated. For the distribution given in Fig. 10 the average particle size has been determined as 36 angstroms and this has been marked on the distribution curve by the full vertical line. Also shown on the distribution curve by the broken vertical line is the crystal size (38 angstroms) as determined from the diffraction line broadening. The agreement between the crystal and particle sizes is well within the experimental error.

Figure 11 illustrates the correlation which has been obtained between average crystal and average particle sizes. The line drawn represents equivalence of the two values. It is to be emphasized that the particle size may be either equal to or larger than the crystal size, since agglomeration of crystals into larger particles may be present. Crystals larger than particles would not be expected however. The four shaded points to the lower right of the line are believed to signify this agglomeration effect. These four materials were $Al_2O_3$-$MoO_3$ catalysts which had been prepared in a special manner. Independent evidence supporting this hypothesis is obtained from the gas adsorption studies in which the particle size correlated better than the crystal size with the specific surface.

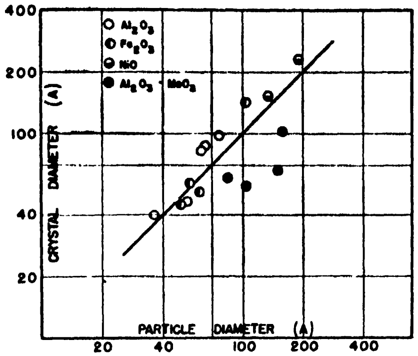

FIG. 11. Correlation between average crystal and particle sizes for a variety of materials. The solid points are believed to represent crystal agglomeration into larger particles.

The unshaded points in Fig. 11 indicate fair agreement between the crystal and particle size. It would appear from the general sequence of the data that the crystal size is a little larger than the particle size, and this may reflect the difference in degree of weighting which the two determinations afford. Jones[16] has shown that the crystal size values will be weighted to the larger sizes and this may account for the observed displacement of values from the line.

Low temperature gas adsorption analysis has been widely used[20] in the study of finely divided solids and this technique provides interesting data for comparison with the x-ray scattering data. One can easily determine the specific surface (surface area per unit mass) and over-all porosity of such solids by this method. It can be shown that the specific surface $S$ of a collection of spherical particles of diameter $D$ is given by

$$S=\frac{6\int_0^\infty \frac{M(D)}{D}dD}{\rho\int_0^\infty M(D)dD} \tag{18}$$

$$=\frac{6}{\rho\bar{D}} \tag{19}$$

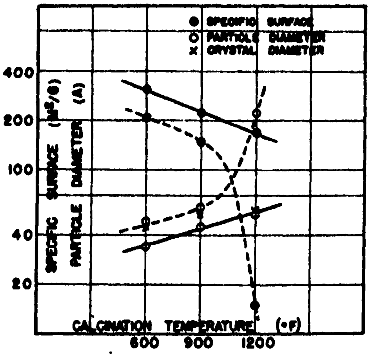

FIG. 12. Average particle size and specific surface variation with calcination temperature for two iron oxide preparations. Solid line—preparation *A*, broken line—preparation *B*.

where $\rho$ is the particle density (not over-all apparent density) and $\bar{D}$ is an average particle size. Thus a linear relationship should exist between $S\rho$ and $1/\bar{D}$.

The specific surface and average particle sizes for a large number of materials have been determined.[21] Typical of the results of such investigations have been those published[7] for various silica-alumina preparations. It was found there that modifications in preparation technique brought about changes in the specific surface of the gel which were followed in all cases by appropriate qualitative changes in the average particle size as determined by small angle x-ray scattering technique.

Figure 12 illustrates additional comparative data obtained by gas adsorption and x-ray scattering analyses. Two preparations of iron oxide were heat treated at the temperatures shown on this graph and the specific surface and average particle size values were obtained. It is seen that for preparation *B* the specific surface falls rapidly and the particle size increases rapidly upon heat treatment about 1000°F. Preparation *A* on the other hand is seen to be quite stable in regard to either measurement at temperatures through 1200°F. Also shown on the graph are several crystal size values and these are seen to agree closely with the particle size determinations.

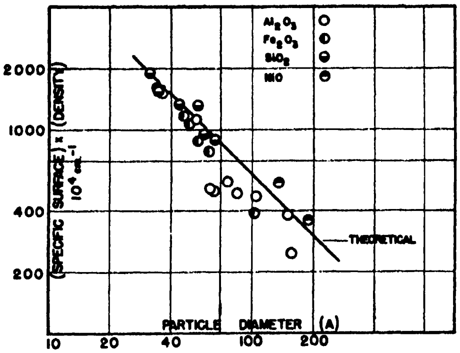

FIG. 13. Correlation between specific surface and particle size for a variety of materials.

Equation (19) predicted a linear relationship between $S\rho$ and $1/\bar{D}$ and Fig. 13 summarizes our data with regard to this. The line shown on this graph is that given by Eq. (19). Considerable deviations are to be noted for individual points but the general trend of the data follows fairly well that to be expected. Data for both amorphous and crystalline materials are represented on this graph.

## ACKNOWLEDGMENT

It is a pleasure to acknowledge the stimulation and encouragement received from Professor B. E. Warren of M.I.T., and several illuminating discussions of interpretational details with Professor A. L. Patterson of Bryn Mawr.

## APPENDIX A. METHOD OF CORRECTING THE SCATTERED INTENSITY DISTRIBUTION OBTAINED WITH A SLIT-SHAPED BEAM TO THAT FOR A PINHOLE BEAM

The experimental data given in the body of this paper were all taken with a slit-shaped primary beam, whereas the theory given is applicable only to data taken for a pinhole beam of very small cross section. Fortunately it is possible to change the experimental intensity distribution into a form equivalent to that which would have been obtained if a pinhole primary beam had been used. The theory of data interpretation given in the body of this paper and the companion paper can then be applied to this modified scattering curve.

A ray diagram of the x-ray optics in the scattering camera is shown in Fig. 14. The x-rays coming from the crystal or target focal line (not shown), in front of the first slit (of length $2l_1$), fan

---

[21] We are indebted to Dr. P. B. Elkin for supplying us with the gas adsorption results.

out from this slit in a vertical plane. Those which pass through the second slit (length $2l_2$), and strike the specimen, are scattered through the scattering angle and may be either (1) recorded on a piece of photographic film placed in a plane perpendicular to the camera axis, or (2) detected by a Geiger counter behind a scanning slit opening. In either case the intensity distribution is determined by means of a scanning slit of finite length ($2y_0$) at different positions along the equator axis. It is obvious that the intensity at any point in the scanning area is a result of the superposition of various intensity elements as scattered through different scattering angles by different scattering elements in the sample.

Consider a specimen element $ds$ which is struck by a ray making an angle $\eta$ with the camera axis. From the camera geometry it is seen that

$$\begin{aligned} d &= \epsilon L, \\ u &= \alpha L, \\ g &= \eta L + s, \end{aligned} \tag{20}$$

since all of the angles under consideration are small (less than 3°). The angle $\alpha$ is characteristic of the position of the scanning slit in the plane of intensity measurement. Since

$$d^2 = u^2 + (g-y)^2,$$

it follows that

$$\begin{aligned} \epsilon^2 &= \alpha^2 + \left(\eta + \frac{s-y}{L}\right)^2, \\ &= \alpha^2 + \sigma^2 \end{aligned} \tag{21}$$

with

$$\sigma = \eta + \frac{s-y}{L}. \tag{22}$$

$g(\alpha)$ will be considered to represent the intensity striking the scanning area with center at angular position $\alpha$, and $I(\epsilon)ds$ the intensity of scattering at an angle $\epsilon$ by a specimen element $ds$. Since $g(\alpha)$ is the summation of the intensity produced by all specimen elements and all primary rays, it follows upon averaging over the scanning area, that

$$g(\alpha) = \frac{1}{2y_0} \int_{-y_0}^{y_0} dy \int_{-l_2}^{l_2} ds \int_{(s-l_1)/L_3}^{(s+l_1)/L_3} I(\epsilon) d\eta. \tag{23}$$

The problem remaining is the determination of $I(\epsilon)$ when $g(\alpha)$ is known. Suppose $I(\epsilon)$ to be represented by

$$I(\epsilon) = \sum_i T_i \exp(-t_i^2 \epsilon^2), \tag{24}$$

with as many terms included in the summation as are necessary to describe the function. It follows from Eqs. (21) and (23) that

$$g(\alpha) = \frac{1}{2y_0} \sum_i T_i \exp(-t_i^2\alpha^2) \int_{-y_0}^{y_0} dy \int_{-l_2}^{l_2} ds \times \int_{(s-l_1)/L_3}^{(s+l_1)/L_3} \exp(-t_i^2\sigma^2) d\eta, \tag{25}$$

$$= \sum_i T_i f(t_i) \exp(-t_i^2\alpha^2), \tag{26}$$

$$= \sum_i T_i' \exp(-t_i^2\alpha^2), \tag{27}$$

with

$$f(t_i) = \frac{1}{2y_0} \int_{-y_0}^{y_0} dy \int_{-l_2}^{l_2} ds \int_{(s-l_1)/L_3}^{(s+l_1)/L_3} \times \exp(-t_i^2\sigma^2) d\eta, \tag{28}$$

and

$$T_i' = T_i f(t_i). \tag{29}$$

The function $f(t_i)$ is independent of $\alpha$ and depends only upon values of $t_i$ and the camera geometry, and the latter remains fixed during the various exposures of one specimen (assuming the specimen-to-detector distance remains unchanged). Equations (24) and (27) permit the desired transformation of $g(\alpha)$ into $I(\epsilon)$ in the following fashion. If $g(\alpha)$ can be represented by a series of exponential terms, each with known values of $t_i$ and $T_i'$, then $I(\epsilon)$ can be represented by the same exponential series but with different term amplitudes, $T_i$.

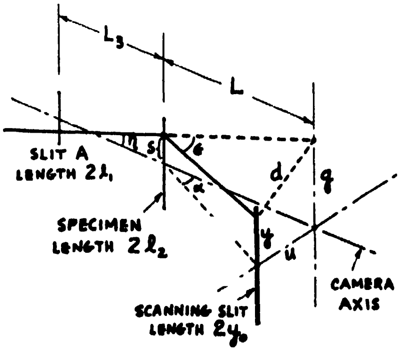

FIG. 14. Ray diagram of the x-ray optics in the scattering camera.

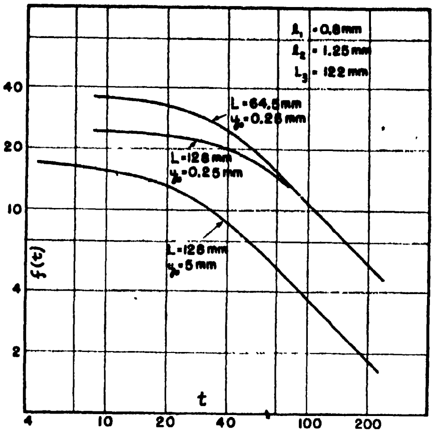

FIG. 15. Slit correction function calculated for various experimental conditions.

The triple integral in Eq. (28) has been integrated with the result that

$$
\begin{aligned}
\frac{4hct_i^3}{L_3}f(t_i)=\frac{\sqrt{\pi}}{2}\{&[1+2t_i^2(a+c)^2]H[t_i(a+c)]\\
&+[1+2t_i^2(c-a)^2]H[t_i(c-a)]\\
&-[1+2t_i^2(b+c)^2]H[t_i(b+c)]\\
&-[1+2t_i^2(c-b)^2]H[t_i(c-b)]\}\\
&+t_i\{(a+c)\exp[-t_i^2(a+c)^2]\\
&+(c-a)\exp[-t_i^2(c-a)^2]\\
&-(b+c)\exp[-t_i^2(b+c)^2]\\
&\quad-(c-b)\exp[-t_i^2(c-b)^2]\},\qquad(30)
\end{aligned}
$$

where

$$
\begin{aligned}
h&=1+\frac{L_3}{L},\\
a&=\frac{hl_2+l_1}{L_3},\qquad(31)\\
b&=\frac{hl_2-l_1}{L_3},\\
&y_0/L_1
\end{aligned}
$$

and

$$H(x)=\frac{2}{\sqrt{\pi}}\int_0^x\exp(-v^2)dv.$$

Equation (30) has been evaluated numerically for various $t_i$ and the function $f(t_i)$ is graphed in Fig. 15 for the experimental conditions generally used in our particular scattering camera. In the present study a microphotometer slit opening of length 0.5 mm was used for scanning across the photographic film and typical curves for this scanning area are given in Fig. 15. If a scanning slit of longer length had been used (as would have been done with a Geiger counter) the values of $f(t_i)$ would have been changed and this is also illustrated in Fig. 15. It is to be emphasized that $f(t_i)$ depends only upon the camera geometry and need be evaluated just once.

The representation of $g(\alpha)$ by a series of exponential terms can be conveniently performed graphically. When the experimental intensity distribution is graphed on log intensity *versus* $\alpha^2$ axes, the curve can be resolved into the sum of a series of straight lines (as is done in analyzing complex radioactive decay curves, for instance). Each straight line corresponds to one of the terms in Eq. (27) and $t_i$ and $T_i'$ can be determined from the slope and intensity axis intercept, respectively, of the straight line. Knowing the values of $f(t_i)$ from Fig. 15, the true scattering curve (for pinhole conditions) can then be reconstructed by use of Eq. (24).

## APPENDIX B. SIMPLIFIED METHOD OF APPLYING THE SLIT CORRECTION WHEN THE EXPONENTIAL SCATTERING FUNCTION IS USED

In Appendix A a general method of correcting the scattered intensity for the slit geometry is given. When the Guinier scattering function is used in interpreting the data, a second and more easily performed procedure is available for taking into account the slit effect. In this procedure the correction is applied to the final particle size distribution rather than to the original intensity data.

The basic integral expression for the intensity of x-ray scattering at an angle $\epsilon$ by a small scattering specimen $ds$ has been given (Eq. (5)) as

$$I(\xi)ds=KI_e\rho_e^2\int_0^\infty M(r)r^3\exp(-\tfrac{1}{3}r^2\xi^2)drds,\quad(32)$$

with $\xi=(2\pi/\lambda)\epsilon$. When many specimen elements and many primary and scattered rays are contributing to the observed intensity, additional integrations must be performed as has been discussed in Appendix A. Applying Eqs. (21) and (23) to (32), the observed intensity distribution is given by

$$g(\alpha)=KI_e\rho_e{}^2\int_0^\infty M(r)r^3$$

$$\times\exp\left(-\frac{4\pi^2}{3\lambda^2}r^2\alpha^2\right)dr\frac{1}{2y_0}\int_{-y_0}^{y_0}dy\int_{-l_2}^{l_2}ds$$

$$\times\int_{(s-l_1)/L_3}^{(s+l_1)/L_3}\exp\left(-\frac{4\pi^2}{3\lambda^2}r^2\sigma^2\right)d\eta, \quad (33)$$

$$=KI_e\rho_e{}^2\int_0^\infty M(r)r^3$$

$$\times\exp\left[-\frac{4\pi^2}{3\lambda^2}r^2\alpha^2\right]drf\left(\frac{2\pi}{\sqrt{3}\lambda}r\right), \quad (34)$$

with $f[(2\pi/\sqrt{3}\lambda)r]$ given by Eq. (28). Let

$$M(r)f\left(\frac{2\pi}{\sqrt{3}\lambda}r\right)=M'(r). \quad (35)$$

It follows that

$$g(\alpha)=KI_e\rho_e{}^2\int_0^\infty M'(r)r^3\exp\left[-\frac{4\pi^2}{3\lambda^2}r^2\alpha^2\right]dr, \quad (36)$$

and this expression has the same form as the original integral expression for pinhole conditions. Thus the function $M'(r)$ can be obtained by procedures given in the body of this paper. Following this, the true particle size distribution can be derived with the use of Eq. (35).

---

## Back Number Prices

ATTENTION is called to the new price scale for single copies and back volumes of this journal as listed on the second cover page. The new price scale was effective March 1, 1947.

The increase is the result of increased handling costs and the fast-diminishing supply of older issues. The increase will make it possible for exhausted issues to be reprinted with no great burden placed on current subscribers for this reprinting.

# X-Ray Scattering at Small Angles by Finely-Divided Solids. II. Exact Theory for Random Distributions of Spheroidal Particles

L. C. ROESS AND C. G. SHULL*
*Beacon Research Laboratory of The Texas Company, Beacon, New York*

(Received August 29, 1946)

The theory of the scattering of x-rays at small angles is given for a continuous distribution in size of randomly spaced and oriented spheroidal particles having arbitrary, but fixed, shape. Families of scattering curves are presented for spheres, and for spheroids ranging in shape from flat disks to long rods. Both Maxwellian and rectangular types of particle mass distribution are used. A fit between the experimental and a calculated scattering curve enables one, under favorable circumstances, to determine the mass distribution in the test sample. However, an unambiguous interpretation of the experimental scattering curve on the basis of the small angle scattering theory is not possible without additional evidence from independent investigations of such quantities as particle shape and sample specific surface.

## INTRODUCTION

IT has been pointed out in the preceding paper[1] that a reasonable, though by no means entirely unambiguous, approach to the interpretation of x-ray scattering at small angles can result from the calculation of the scattering to be expected from assumed mass distributions of particles having a definite shape, followed by an estimation of the actual mass distribution and particle shape by obtaining a fit between the observed scattered intensity curve and one of a series of calculated intensity curves. It is the object of this paper to present the exact theory for the x-ray scattering at small angles by a continuous distribution of randomly spaced spheroidal particles having an arbitrary, but fixed, shape. Scattering by spheres is, of course, a special case of the theory, while the scattering by disks of finite radius but vanishing thickness, and by rods of finite length but vanishing radius form two limiting cases.

## ASSUMPTIONS

It is desirable to state clearly and exactly the assumptions on which the calculations are based:

1. The particles have whatever form of random spacing necessary to produce incoherency in the radiation scattered by individual particles, so that the total intensity is the sum of the individual intensities.
2. The particles have random orientation.
3. The incident x-ray beam is composed of monochromatic and parallel rays, and is of negligibly small cross-sectional extent.
4. The interaction of the scattered radiation with the incident radiation inside the sample to produce an index of refraction is ignored. This effect should be noticeable only at extremely small angles.[2] A closely related assumption is that multiple scattering can be neglected.
5. The effects of finite sample size are ignored. They also should be noticeable only at extremely small angles.
6. The effects of variations on an atomic scale of the electron density distribution inside a particle are ignored.
7. The particles all have the same shape.[3]
8. Absorption of x-radiation inside a particle can be neglected.

## GENERAL THEORY

The general equation for the scattered intensity $I(\xi)$ is[4]

$$I(\xi)=AI_e\rho_e^2\int_0^\infty V^2(R)N(R)\langle S(R,\xi)\rangle_{Av}dR, \quad (1)$$

$$=AI_e\frac{\rho_e^2}{\rho}\int_0^\infty V(R)M(R)\langle S(R,\xi)\rangle_{Av}dR, \quad (2)$$

with

$$\xi=\frac{4\pi}{\lambda}\sin\theta, \quad (3)$$

$\lambda$ = wave-length,
$2\theta=\epsilon$ = scattering angle,

[3] The mathematical methods used in this paper have also been applied to calculate the scattered intensity for particle distributions varying in both shape and size.

[4] R. Hosemann, Zeits. f. Physik 113, 751–768 (1939). See also Eq. (4) of reference 1.

$I_e$ = Thomson scattering factor for a single electron,[5]
$A$ = absorption factor,[6]
$\rho_e$ = average electron density of particle, electrons per cm$^3$,
$\rho$ = mass density of individual particles, gram cm$^{-3}$.

$V(R)$ is the volume of a particle characterized by the size parameter $R$, $\langle S(R, \xi)\rangle_{\mathrm{Av}}$ is the scattering function (the shape function[7] or form factor for the particle averaged over-all orientations), and $N(R)dR$ and $M(R)dR$ are, respectively, the number and the mass of the particles having size parameters in the range $R$, $dR$.

## SHAPE FUNCTIONS FOR SPHEROIDS

Patterson[7] and Guinier[8] have shown that the shape function for a spheroid having principal axes $R$, $R$, $vR$ in a system of Cartesian coordinates $(x, y, z)$ is

$$S(R\xi, v) = S(u) = 9\left(\frac{\sin u - u\cos u}{u^3}\right)^2, \tag{4}$$

with

$$u = R\xi(\sin^2\vartheta + v^2\cos^2\vartheta)^{\frac{1}{2}}. \tag{5}$$

In Eq. (5), $\vartheta$ is the angle between the $z$ axis and the difference $\mathbf{s}-\mathbf{s}_0$ between the unit vectors $\mathbf{s}_0$ and $\mathbf{s}$ which specify the direction of the incident and scattered beams, respectively.

The effect of random orientation of the spheroids can be obtained most simply by considering the spheroid fixed, and averaging over-all directions of the vector $\mathbf{s}-\mathbf{s}_0$. This is equivalent to integrating $S$ over the surface of a sphere, and gives

$$\langle S(R\xi, v)\rangle_{\mathrm{Av}} = \frac{1}{4\pi}\int_0^{\pi}\int_0^{2\pi} S[R\xi(\sin^2\vartheta + v^2\cos^2\vartheta)^{\frac{1}{2}}]\sin\vartheta d\vartheta d\varphi,$$

or, putting $x = \cos\vartheta$,

$$\langle S(R\xi, v)\rangle_{\mathrm{Av}} = \int_0^1 S[R\xi(1+(v^2-1)x^2)^{\frac{1}{2}}]dx. \tag{6}$$

It follows directly from formulas given by Watson[9] that Eq. (4) may be written

$$S(u) = \frac{9\pi}{2}\frac{J_{3/2}{}^2(u)}{u^3}, \tag{7}$$

$$= {}_1F_2(2; 4, (5/2); -u^2). \tag{8}$$

The generalized hypergeometric function is defined[10] by

$$\begin{aligned}{}_pF_q(\alpha_1, \alpha_2, \cdots\alpha_p; \beta_1, \beta_2, \cdots\beta_q; z) \\ = \sum_{m=0}^{\infty}\frac{(\alpha_1)_m(\alpha_2)_m\cdots(\alpha_p)_m z^m}{m!(\beta_1)_m(\beta_2)_m\cdots(\beta_q)_m},\end{aligned} \tag{9}$$

with

$$(\alpha)_0 = 1; \quad (\alpha)_m = \alpha(\alpha+1)\cdots(\alpha+m-1). \tag{10}$$

Obviously ${}_pF_q$ is an integral function when $q \geqslant p$.

Substituting Eq. (8) in Eq. (6), and integrating term by term, using[11]

$$\int_0^1 [1+(v^2-1)x^2]^m dx = {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2), \tag{11}$$

one obtains

$$\langle S(R\xi, v)\rangle_{\mathrm{Av}} = \sum_{m=0}^{\infty}\frac{(2)_m(-R^2\xi^2)^m}{m!(4)_m(5/2)_m} \times {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2), \tag{12}$$

$$= {}_1G_2(2; 4, (5/2); -R^2\xi^2, v), \tag{13}$$

where we define

$$\begin{aligned}{}_pG_q(\alpha_1, \alpha_2, \cdots\alpha_p; \beta_1, \beta_2, \cdots\beta_q; z, v) \\ = \sum_{m=0}^{\infty}\frac{(\alpha_1)_m(\alpha_2)_m\cdots(\alpha_p)_m z^m}{m!(\beta_1)_m(\beta_2)_m\cdots(\beta_q)_m} \\ \times {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2).\end{aligned} \tag{14}$$

For spherical particles, $v=1$, ${}_2F_1(-m, \frac{1}{2}; \frac{3}{2}; 0) = 1$, and $\langle S(R\xi, 1)\rangle_{\mathrm{Av}} = S(R\xi)$.

In the limit $v \to 0$

$${}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2) \to {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1) = \frac{(1)_m}{(\frac{3}{2})_n}, \tag{15}$$

so that

$$\langle S(R\xi, 0)\rangle_{\mathrm{Av}} = {}_2F_3(1, 2; 4, (5/2), \tfrac{3}{2}; -R^2\xi^2). \tag{16}$$

---

[5] Because of the small angular range involved, the state of polarization of the incident beam has negligible effect on the angular variation of intensity.

[6] The absorption may be assumed independent of angle for the small angles under discussion.

[7] A. L. Patterson, Phys. Rev. 56, 972–977 (1939).

[8] A. Guinier, Thèses (Masson et Cie, Paris, 1939), or Ann. de Physique 12, 161–237 (1939).

[9] G. N. Watson, *Theory of Bessel Functions* (Cambridge University Press, Cambridge, 1922), pp. 54 and 147.

[10] For example, reference 9, p. 100.

[11] Note that Eq. (11) is valid for any value of $m$ if $v \neq 0$.

This is the scattering function for a disk of radius $R$ and vanishingly small thickness.

If we let $v \to \infty$, but simultaneously $R \to 0$ in such a way that $Rv \to L$, the spheroid approaches a rod of length $2L$ and vanishingly small radius. The scattering function for such a rod may be obtained most simply from Eq. (6).

$$\lim_{\substack{R\to 0\\ v\to\infty\\ Rv\to L}} \langle S(R\xi, v)\rangle_{\mathrm{Av}} = \langle S_\infty(L\xi)\rangle_{\mathrm{Av}} = \int_0^1 S(L\xi x)dx \tag{17}$$

$$= {}_2F_3(\tfrac{1}{2}, 2; 4, (5/2); \tfrac{3}{2}; -L^2\xi^2), \tag{18}$$

since

$$\frac{1}{2m+1} = \frac{(\frac{1}{2})_m}{(\frac{3}{2})_m}. \tag{19}$$

By direct integration, using Eq. (4), it can readily be shown that

$$\langle S_\infty(x)\rangle_{\mathrm{Av}} = \frac{6}{5}\frac{Si(2x)}{x} - \frac{3}{2x^4} - \frac{9}{10x^6} + \frac{3\cos 2x}{5x^2}\left(1 - \frac{1}{2x^2} + \frac{3}{2x^6}\right) + \frac{3}{10}\frac{\sin 2x}{x^3}\left(1 + \frac{6}{x^2}\right), \tag{20}$$

in which

$$Si(x) = \int_0^x \frac{\sin t}{t} dt. \tag{21}$$

A similar closed expression for $\langle S(R\xi, 0)\rangle_{\mathrm{Av}}$ has not been found.

### MASS DISTRIBUTION FUNCTIONS

Hosemann[4] introduced the Maxwellian type of mass distribution function[12]

$$M(R) = B\left(\frac{R}{R_0}\right)^n e^{-(R/R_0)^2};$$

$$B = \frac{2}{R_0\Gamma\left(\frac{n+1}{2}\right)}, \tag{22}$$

which has a maximum at

$$R_{\max} = (n/2)^{\frac{1}{2}} R_0, \tag{23}$$

and showed that a wide variety of distribution forms could be obtained by varying the parameters $n$ and $R_0$. Consideration of the more general function

$$M(R) = B\left(\frac{R}{R_0}\right)^n e^{-(R/R_0)^m} \tag{24}$$

has shown that no advantage with respect to variety of the mass distribution form is gained by choosing $m \neq 2$, while considerable simplicity is lost in evaluating the integral in Eq. (2).

It must be pointed out here that, since the incident beam has a finite cross section, the effective scattering specimen has a finite volume, so that

$$M(R) = 0, \quad R > R',$$

where $R'$ is of the order of the beam radius. A mass distribution function expressed by

$$\left.\begin{aligned} M(R) &= BR^n(R'-R)^\mu, & 0 \leq R \leq R' \\ &= 0, & R > R' \end{aligned}\right\} \tag{25}$$

in which $\mu$ is very large, has been tried and found to give results essentially the same as the Maxwellian type. The increased simplicity of the analysis using the latter type is thus sufficient to justify its use, despite the infinite range of $R$.

### INTENSITY SCATTERED BY MAXWELLIAN MASS DISTRIBUTIONS

Since for a spheroid

$$V(R) = \frac{4\pi}{3} vR^3, \tag{26}$$

substitution of Eqs. (26), (22), and (13) in Eq. (2), and term by term integration gives, using Eq. (14),

$$I(\xi, v) = K \sum_{m=0}^{\infty} \frac{(2)_m \left(\frac{n+4}{2}\right)_m (-R_0{}^2\xi^2)^m}{m!(4)_m(5/2)_m} \times {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2), \tag{27}$$

$$= K\,{}_2G_2\left(2, \frac{n+4}{2}; 4, (5/2); -R_0{}^2\xi^2, v\right), \tag{28}$$

with

$$K = AI_e \frac{4\pi v R_0{}^3 \rho_e{}^2}{3\rho} \frac{\Gamma\left(\frac{n+4}{2}\right)}{\Gamma\left(\frac{n+1}{2}\right)}. \tag{29}$$

---

[12] With the value of $B$ given in Eq. (22), the total mass is unity.

Equation (27) is the formal solution of the scattering problem. It is worth noting that the parameter $R_0$ enters directly as a scale factor, while the parameter $n$ affects the shape of the intensity function.

The series in Eq. (27) converges for all values of $\xi$, $R_0$, $n$, and $v$. However, numerical calculation by direct summation of the series becomes impractical for large values of $R_0\xi$ or $R_0\xi v$. In these ranges asymptotic series must be used for the calculation; the form of these series depends upon the value of $v$. Three ranges of $v$ are important:

$$v \ll 1; \quad v \cong 1; \quad \text{and} \quad v \gg 1.$$

In each range, a suitable form of ${}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2)$ must be used.[13]

It can be shown that Eq. (27) can be written

$$I(\xi, v) = \frac{K}{(1-v^2)^{\frac{1}{2}}} \times \left\{ {}_3F_3\left(1, 2, \frac{n+4}{2}; 4, \frac{5}{2}, \frac{3}{2}; -R_0{}^2\xi^2\right) - \frac{v^2}{2} \sum_{m=0}^{\infty} \frac{\left(\frac{n+4}{2}\right)_m (-R_0{}^2\xi^2 v^2)^m}{(4)_m (5/2)_m} \times {}_2F_1(\tfrac{1}{2}, m+1; m+2; v^2) \right\}. \tag{30}$$

Equation (30), while valid for all values of $v$, is useful for numerical calculation when $v \ll 1$. For large $R_0\xi$ an asymptotic expansion[13] of the first term is required.

Equation (27) can also be written

$$I(\xi, v) = K \sum_{m=0}^{\infty} \frac{(2)_m \left(\frac{n+4}{2}\right)_m (-R_0{}^2\xi^2)^m}{m!(4)_m(5/2)_m} \times {}_3F_3\left(2+m, \frac{n+4}{2}+m, \frac{1}{2}; 4+m, \frac{5}{2}+m, \frac{3}{2}; -R_0{}^2\xi^2(v^2-1)\right). \tag{31}$$

Equation (31) is also valid for all values of $v$ and, when used with the asymptotic expansion[13] for the ${}_3F_3$ terms, is suitable for numerical calculation when $v \gg 1$.

When $v \cong 1$, the series in Eq. (27) suffices for numerical calculation when used with its asymptotic expansion[13] for large $R_0\xi$.

## INTENSITY SCATTERED BY RECTANGULAR MASS DISTRIBUTIONS

If the mass distribution is defined as follows

$$\left.\begin{aligned} M(R) &= \frac{1}{R_2 - R_1}, \quad R_1 \leqslant R \leqslant R_2 \\ &= 0, \qquad \text{otherwise} \end{aligned}\right\} \tag{32}$$

so that it is normalized to unit mass, the scattered intensity given by Eq. (2) becomes, using Eq. (26),

$$I(\xi, v) = \frac{K'}{R_2 - R_1} \times \{R_2{}^4 {}_2G_3(2, 2; 4, 3, (5/2); -R_2{}^2\xi^2, v) - R_1{}^4 {}_2G_3(2, 2; 4, 3, (5/2); -R_1{}^2\xi^2, v)\}, \tag{33}$$

with

$$K' = AI_e \frac{4\pi v \rho_e{}^2}{3\rho}. \tag{34}$$

If we put $\alpha = R_1/R_2$, Eq. (33) can be written

$$I(\xi, v) = \frac{K'R_2{}^3}{1-\alpha} \times \sum_{m=0}^{\infty} \frac{(2)_m(2)_m\, {}_2F_1(-m, \tfrac{1}{2}; \tfrac{3}{2}; 1-v^2) \times (-R_2{}^2\xi^2)^m(1-\alpha^{4+2m})}{m!(4)_m(3)_m(5/2)_m}. \tag{35}$$

The series (divided by $1-\alpha^4$) has been calculated for $v=1$ and $\alpha = 0$, 0.5, 0.9, and 1.0. (When $\alpha = 1$, the intensity is that produced by a group of spheres all having the same radius $R_2$, and is given by Eq. (8) with $u = R_2\xi$.)

## NUMERICAL RESULTS

Calculated scattered intensity curves[14] are plotted on a double logarithmic scale on Figs. 1 to

---

[13] A summary of the formulas giving the relevant asymptotic series, as well as a discussion of the procedure used in obtaining them, has been prepared and is available from the authors on request.

[14] Numerical values have been tabulated, and are available from the authors upon request.

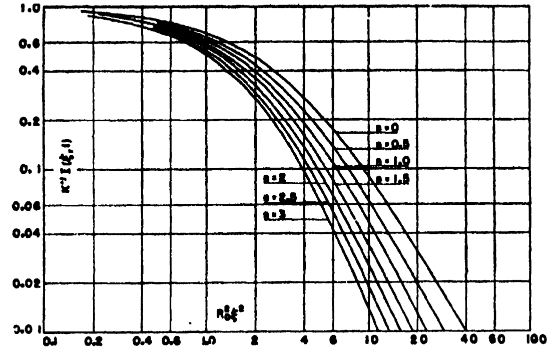

FIG. 1. Calculated intensity scattered by Maxwellian distributions of spheres, $v=1$ (Eq. (27)).

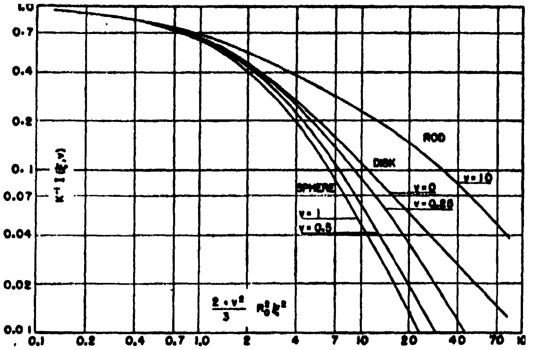

FIG. 2. Calculated intensity scattered by the same Maxwellian distribution of spheroids having various shapes.

5. Figure 1 shows the effect of varying the parameter $n$ (which controls the form of the mass distribution) on the shape of the angular distribution of the intensity scattered by a Maxwellian distribution of spheres. The increased curvature observed as $n$ increases is associated with an increased sharpness in the mass distribution. As is shown by the asymptotic expansions, all curves for $n>0$[15] approach the same slope $(-2)$ as $R_0^2\xi^2$ becomes large.

Figure 2 shows the effect of particle shape ($v=0$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 10) on the angular distribution of the intensity scattered by a mass distribution having a fixed form ($n=1$). The abscissa are chosen proportional to the radius of gyration[16] of the particle in order to make the curves merge at small values of $R_0\xi$. Distinct differences are apparent between the disk-shaped ($v=0$) and rod-shaped ($v=10$) particles. The smaller slopes at large $R_0\xi$ values are predicted by the asymptotic expansions: for $v=0$ the limiting slope is $-1$ and for $v$ very large the limiting slope is $-\frac{1}{2}$.

Figures 3 and 4 show the effect of varying $n$ on the shape of the angular distribution of the intensity scattered by oblate spheroids having the fixed shape parameters $v=0$ and $v=\frac{1}{4}$, respectively.

Figure 5 shows the calculated angular distribution of scattered intensity produced by rectangular mass distributions (cf. Eq. (32)) having various values of $\alpha=R_1/R_2$. The curvature is considerably greater than that associated with the Maxwellian distributions. Also, although it is not shown on the plot, the scattered intensity shows a series of maxima and minima, for $\alpha=1$, 0.9, and 0.5 at $R_2\xi$ values greater than those for which the curves are drawn.

It may be shown by superposition that the curve for $v=\frac{1}{2}$, $n=1$ on Fig. 2 has very nearly the same shape as that for $v=1$, $n=\frac{1}{2}$ on Fig. 1, while the curves $v=1$, $n=0$ and $v=\frac{1}{4}$, $n=5$ form a similar isomorphic pair. These examples show that when both particle shape and mass distribution form are varied, near coincidences can occur, rendering the interpretation in the scattered intensity curves very uncertain. Obviously, if a distribution in particle shape were also considered, the possible ambiguity would become even greater. Other independent evidence must be taken into account in deciding between the various possibilities. In general, a mass distribution

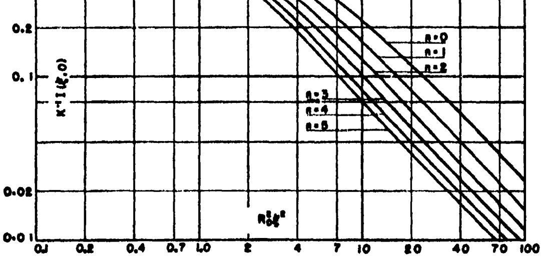

FIG. 3. Calculated intensity scattered by Maxwellian distributions of thin disks, $v=0$.

---

[15] When $n=0$ the leading term in the asymptotic expansion is proportional to $\frac{\ln R_0\xi}{(R_0\xi)^4}$.

[16] $R_g=\left(\frac{2+v^2}{5}\right)^{\frac{1}{2}}R$, cf. A. Guinier, Ann. de Physique 12, 161-237 (1939).

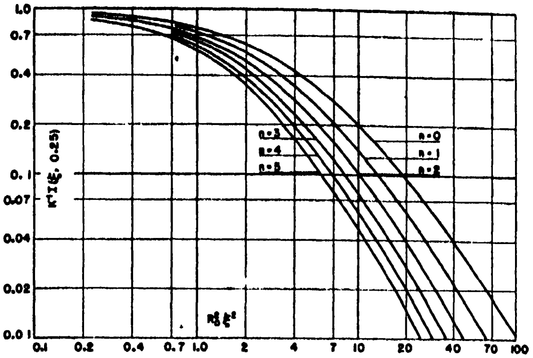

FIG. 4. Calculated intensity scattered by Maxwellian distributions of oblate spheroids, $v=0.25$.

having a small value of $n$ is improbable, so that the ambiguity of the above examples could be at least partially resolved by this argument. If a crystalline material is under investigation, independent information on particle shape can be obtained from x-ray line width measurements.[17]

In each of the examples cited above only one scattering curve is involved. When the radius of gyration of the average particle in each of the two mass distributions calculable from each scattering curve is computed, it is found that those of the spheroidal particles are appreciably greater than those of the spherical particles. This shows that when a given intensity curve is interpretable in terms of two or more distributions of differently shaped particles, the resulting average radii of gyration are by no means identical, as would be required, for example, by the approximate theory using the Guinier scattering function.[1]

The matching of the scattered intensity curves with the experimental data has been discussed in the previous paper.[1]

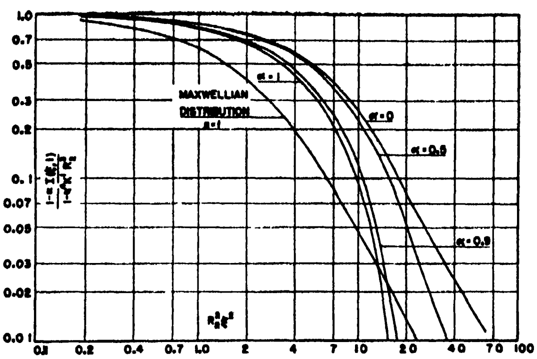

FIG. 5. Calculated intensity scattered by rectangular distributions of spheres (Eq. (35)). $\alpha=R_1/R_2$. The intensity fluctuations at large values of $R_2^2\xi^2$ are not shown. The intensity scattered by a Maxwellian distribution of spheres is also plotted for comparison.

## ERRORS DUE TO USE OF THE GUINIER SCATTERING FUNCTION

The exact scattering function for randomly oriented particles of fixed size and shape has a primary peak centered at zero scattering angle and a series of secondary peaks at larger angles whose amplitudes decrease as some negative power of the angle. In contrast, the Guinier function used in the approximate theory given in the preceding paper[1] has a primary peak only, and decreases exponentially at larger angles. This neglect of the secondary peaks leads to appreciable errors in the calculated scattered intensity at relatively large angles.[18] However, these errors are small for $R_0\xi$ values up to 1.5 or 2, and since the region enclosing the knee of curve[1] rarely extends to $R_0\xi$ values greater than 2.5 to 3, no really serious errors of interpretation result from the use of the Guinier function in place of the corresponding exact scattering function, when the particles are reasonably symmetrical in shape.

---

[17] For the crystalline materials discussed in reference 1, no evidence for shape asymmetry has been found from line width measurements.

[18] This may be illustrated by the asymptotic proportionality of the Guinier function scattered intensity to $(r_0\xi)^{-(n+4)}$, while the exact function for spheres gives $(R_0\xi)^{-4}$ for all $n>0$.

# Excess Noise in Cavity Magnetrons

ROBERT L. SPROULL*
*RCA Laboratories, Princeton, N. J.*†

(Received October 17, 1946)

The magnetron oscillator of some frequency-modulation radars also furnishes the "local oscillator" excitation for the crystal mixer of the receiver. Excess noise generation by the magnetron was observed to reduce greatly the receiver sensitivity. This noise exhibited a strong dependence upon anode voltage and current, and changed with time in a perplexing manner. After many experiments, a hypothesis of the cause of excess noise was developed, and further experiments confirmed this hypothesis. The noise is thought to be caused by ionization of atoms of the cathode oxide coating, which atoms are removed from the cathode by electron bombardment. In order to reduce the generation of excess noise, and still preserve the advantages of an oxide-coated cathode, a special shape of cathode has been developed. The coated regions of this cathode are sheltered from electron bombardment, and the noise is much reduced. Use of cathodes of this general type should also produce magnetrons with longer operating lives than present tubes.

THE magnetron oscillator in some[1] frequency-modulation, continuous-wave radars also furnishes the "local oscillator" excitation of the crystal mixer of the receiver. It was observed that the magnetron oscillations were frequently modulated with large amounts of noise, thereby impairing the sensitivity of the receiver. The cause of this excessive noise modulation (many times ordinary shot noise) was made the subject of a special investigation, the results of which are reported here. Excess noise is not noticed in the usual use of a magnetron as a transmitter tube, since the signal-to-noise ratio is at least 60 db. However, the noise phenomena may

increase our understanding of magnetron operation, are important in special applications of magnetrons, and are of interest in any development of receiving tubes utilizing magnetic fields.

## I. DESCRIPTION OF THE NOISE PHENOMENA

Figure 1 shows the experimental arrangement used to detect noise modulation and to estimate its magnitude. Since the magnitude of the oscillating field in the crystal cavity was kept constant by varying the attenuation between the magnetron and this cavity, the receiver detector current "$I_n$" was roughly inversely proportional to the signal-to-noise ratio of the magnetron oscillations.

Figure 2 shows the "noise current" $I_n$ as a function of magnetron d.c. anode voltage ($V_a$) for several anode currents ($I_a$) in a 4000 megacycle, continuous-wave magnetron[2] developed in this laboratory. To obtain such a plot, the magnetic field was varied to produce different values of $V_a$ at constant $I_a$. It is apparent that at low voltages the total noise current is substantially constant, and in this region the contribution of the magnetron noise to the total receiver noise is small. At some voltage, which we shall call $V_{ao}$, a relatively sharp break in the curve appears, and above this voltage the magnetron noise dominates noise from other sources and becomes hundreds or thousands of times as large as at low voltages. This region ($V_a > V_{ao}$) of excess noise contained the ordinary operating point of the oscillator. Phenomena very similar to those portrayed in Fig. 2 were also observed in a magnetron[3] of quite different design.

Curves such as those of Fig. 2 are not reproducible in detail. The "peaks" and "valleys" of the curves cannot be repeated even a few minutes after they are observed. The most useful feature for comparing noise phenomena in different tubes is the voltage $V_{ao}$. Even this parameter changes with time, however, and may have quite different values in two tubes constructed (as nearly as possible) identically. Several tubes must, therefore, be constructed in order to be certain of the dependence or lack of dependence of noise upon some one feature of the design. Figure 2 is representative of the early 4000 megacycle tubes and exhibits the increase in noise with decrease in anode current which was observed with all tubes.

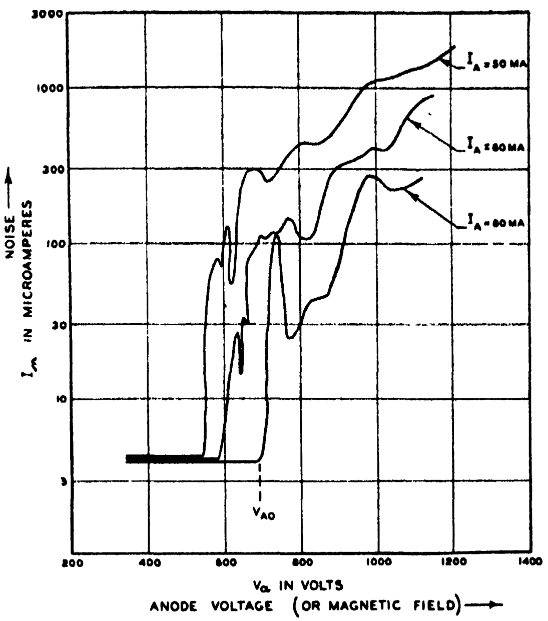

FIG. 2. Noise in early 4000 megacycle magnetrons. At constant anode current, anode voltage and magnetic field are approximately proportional. Therefore the abscissa may be considered (except for units) as either voltage or magnetic field strength.

After vigorous oscillation in these magnetrons has begun at a sufficiently high anode voltage, the cathode heater power may be removed. Back-bombardment of the cathode by electrons which have received energy from the oscillating field produces secondary electrons and warms the cathode sufficiently to produce some thermionic electrons. The excess noise was invariably less when the ordinary heater power was removed. All of the measurements and correlations reported here refer to operation with no applied heater power.

The receiver (Fig. 1) was ordinarily tuned to pass modulation components in the frequency range 1496 to 1504 kilocycles, but other frequency regions were also explored. In general the noise was less the higher the receiver frequency,

and the excess noise was quite small at a receiver frequency of 30 megacycles.

## II. CORRELATIONS OF NOISE WITH MAGNETRON PROPERTIES

Many tubes were constructed with slightly different features from the ordinary magnetron in order to test the dependence of noise upon different aspects of the design. In each case correlation of noise properties with the changes made was attempted. Correlations were also attempted between noise properties and operating conditions of the tube.

The high-frequency load presented to the magnetron by the antenna and transmission system changed the details of the excess noise, but any standing wave ratios and phases which produced reasonably stable operation with moderate efficiency produced about the same values of $V_{ao}$. The presence or absence of discontinuities in the straps of the magnetron resonator, the presence or absence of "hats" on the ends of the cathode produced no consistent changes in noise. The geometry and potentials of electrodes near the ends of the cathode affected the noise only very slightly. Small changes in anode diameter produced no effect. A variation of almost a factor of two in cathode size produced marked changes in efficiency and stability; but the noise was little changed except with very small or very large diameters, and in these cases the noise was greater than with intermediate diameters.

These and other experiments were used to show that several more or less obvious hypotheses of the causes of excess noise were not tenable. For example, any axial oscillations (such as observed in magnetron structures many years ago by Megaw[4]) should be strongly affected by end plate potentials, and if the noise were related to such oscillations it should be a function of these potentials. Other hypotheses were concerned with the resonant modes of the resonator and with the space-charge and electric field distributions in the cathode-anode space. The results of the studies with various cathode and anode diameters, the fact that the excess noise was observed in a magnetron of quite different construction, and the occurrence of noise over a wide range of anode voltages and currents, made such hypotheses of the cause of noise very unlikely.

Three successful correlations emerged from this work, but none gave immediately a clear indication of the cause of the noise. These correlations will be briefly described here. The first was a correlation of noise with low efficiency accompanied by high back-bombardment of the magnetron cathode. Tubes which exhibited considerably lower efficiency than others of similar construction were usually very noisy. Experimental tubes were constructed with windows which allowed observation of the cathode during operation, and this correlation was verified in such tubes. This correlation is probably related to the reduction in noise as the normal cathode heater power is removed; in both cases high noise accompanies high cathode temperature.

The second correlation was between excess noise and the length of the cathode sleeve which was coated with oxides. It was found that if the emitting length were confined to less than two-thirds of the length of the anode, the voltage ($V_{ao}$) at which noise began could be materially increased. It was not certain that the ends of the cathode did not emit electrons, but the carbonate spray was carefully cleaned from all except the central region of the cathode sleeve in the hope that no emission would occur in the end regions. The suggestion was that the r-f and d.c. fields were distorted there, and it might be desirable to prevent the interaction of electrons with such fields.

The third correlation was between noise and the thermionic emission properties of the cathodes. The critical voltage ($V_{ao}$) was used as a measure of the former, and the heater current required to permit a thermionic current of 50 milliamperes at 100 volts (no magnetic field) was used as a measure of the latter. The correlation coefficient[5] of $V_{ao}$ with this current was 0.79 for thirteen experiments with ten tubes. This shows a definite relation, with low noise accompanying low thermionic activity. This correlation was strengthened by observations on a single tube during the early part of its life, when both the

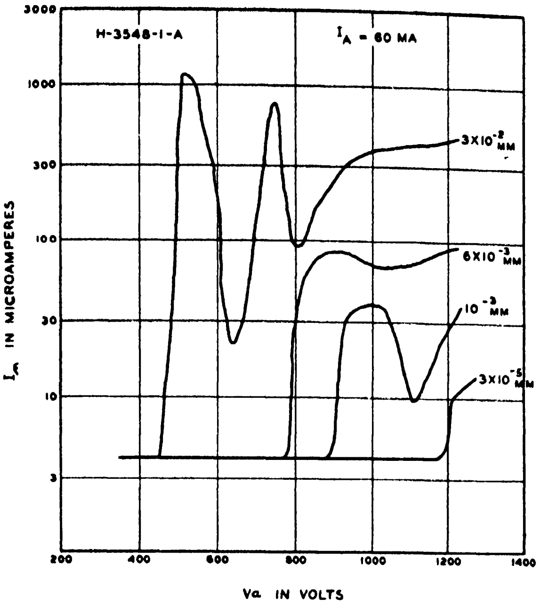

FIG. 3. Noise as a function of pressure. This tube had a helical tungsten filament in place of the usual oxide-coated cathode.

cathode activity and the noise were changing. Magnetrons were constructed with strontium oxide coatings on the cathodes, since the emission from SrO is known[6] to be considerably less than that from the SrO-BaO mixtures ordinarily used. These tubes showed high values of heater current for 50 milliamperes thermionic current, but the noise properties did not differ appreciably from other tubes. This experiment indicated that noise was not directly related to the cathode's thermionic activity, but that for cathodes of the same composition, high noise accompanied high activity.

## III. IONIZATION NOISE

One of the first hypotheses of the cause of the excess noise was that it originated in the ionization of gas atoms in the interaction space of the magnetron. To test this, several tubes were continuously pumped while noise data was taken, and neon gas was admitted to vary the pressure. No variation of noise with pressure was observed for pressures less than about $5\times10^{-3}$ mm of mercury. At pressures greater than this, the noise increased and the efficiency decreased rapidly; this behavior was not surprising since at $10^{-2}$ mm a glow discharge was beginning. The pressures could not be measured inside the magnetron itself, but they were measured in an ionization gauge connected to the magnetron.

Several magnetrons were constructed with tungsten helices in place of the usual oxide-coated cathodes. Two of these were continuously pumped, and noise was observed as a function of pressure. Figure 3 represents the behavior of these tubes. Unlike the results with oxide-cathodes, the data here show a continuous increase in $V_{ao}$ (that is, decrease in noise) as the pressure decreases. For pressures less than $10^{-6}$ mm, $V_{ao}$ was greater than 1200 volts for tungsten filament tubes. But lowering the pressure below $10^{-3}$ mm did not change the noise in oxide-coated cathode tubes, and even at $10^{-6}$ mm $V_{ao}$ was no larger than 800 or 900 volts. If the cause of the noise is the same in the tubes with these two types of cathodes, it must be that there is a condensable gas in the oxide-coated cathode magnetrons which is present in the anode-cathode space but which is not measured by external pressure gauges.

Evidence to support this interpretation came from quite different experiments. Observations upon tubes with windows revealed a luminescence in the anode-cathode space or upon the cathode surface. Spectrographic investigation showed that the line spectra of barium and strontium (the metallic constituents of the cathode coating) were represented by their most persistent lines. Since the lines were quite sharp, it was apparent that the luminescence was not fluorescence of the solid (such fluorescence is also observed on activated cathodes, but its spectrum is broad and diffuse). It appeared therefore that there were substantial quantities of Ba and Sr atoms in the interaction space. At least some of these were ionized, since some of the spectral lines observed were those of the positive, singly-charged ion.

In order to obtain further information about the atoms and ions in the anode-cathode space, "double-triode" tubes were built. In these tubes electrons from the central cathode bombarded both a nickel anode and an oxide-coated anode, which had been activated as if it were a cathode and which could be heated by a tungsten heater. A negative grid was placed in each half of the

---

[6] M. Benjamin and H. P. Rooksby, "Emission from Oxide-coated Cathodes," Phil. Mag. 15, 810 (1933).

tube, and the positive ion currents to these grids were measured. Both anodes were maintained at approximately the same potential, and the electron currents in the two parts of the tube were the same. The grid current in the nickel anode space was about 0.01 microampere when 10 milliamperes electron current was flowing; this corresponds to roughly $10^{-6}$ mm pressure of residual gas in the tube. The grid current in the other side of the tube was always many times this value, and when the oxide-coated anode was heated to 700–800°C, grid currents of 10–40 microamperes were observed. It was apparent, therefore, that atoms or ions were released from the bombarded surface, and that these formed a condensable gas phase which could not be observed outside the immediate neighborhood of the bombarded surface. Noise measurements were also made on these tubes; excess noise was observed, and it was substantially proportional to the ion current collected by the grid.

From these experiments it was possible to derive the following interpretation of the phenomena of magnetron noise: (1) Some of the electrons (of the order of 20 percent) emitted from the cathode return to it after gaining considerable energy from the r-f field. If the cathode is oxide-coated, these back-bombarding electrons remove atoms or ions of the cathode material. Any ions emitted quickly return to the cathode, but they alter the space charge in the region of the potential minimum and permit a momentary excess of electrons to be emitted. Atoms emitted have between a 1 percent and a 10 percent chance of being ionized before they strike the anode or other parts of the tube. Ions thus produced alter the space charge and may release other atoms or ions when they bombard the cathode. (2) Noise in excess of ordinary shot noise is produced by these processes. The noise occurring in space-charge limited electron currents when appreciable numbers of positive ions are present has been investigated by Thompson and North.[7] Most of the noise effects observed in the present tests of special triodes are consistent with their work. In general, however, the excess noise in magnetrons is greater than that obtained in any other vacuum tubes, and it would be necessary to assume pressures of the order of 0.1 to 0.01 mm of mercury in a magnetron in order to explain the observed excess noise by simple extrapolation of the work of Thompson and North. (3) The very great noise in magnetrons and the irregular dependence of noise upon time, current, and voltage, may be the result of cumulative or chain effects. The equivalent pressure of barium and strontium atoms near a hot magnetron cathode is of the order of $10^{-2}$ mm; this figure is derived from measurements on the "double-triode" tubes and is checked by the fact that at neon pressures less than $5\times10^{-3}$ mm the noise in an oxide-coated cathode magnetron was independent of pressure. At such a large pressure the contribution of positive ions to the space-charge distribution is considerable, and increasing the pressure by a factor of ten would cause oscillation to cease and a gas discharge at low voltage to occur. Under operating conditions the magnetron may therefore be on the verge of a Townsend breakdown. The ionization of a single atom may result in a burst of charge reaching the anode that is many times the electronic charge, and a correspondingly large increase in noise may occur. Among the processes which could participate in such a breakdown are ionization by electron impact, removal of atoms from the cathode by electrons, removal of atoms from the anode surface (which is soon contaminated with cathode material) by electrons, secondary electron emission at the cathode, and removal of atoms and electrons from the cathode surface by positive ion bombardment. It is not clear why such a breakdown does not occur, however, instead of merely threatening to occur.

Our interpretation is therefore that the dominating cause of the excess noise is associated with the presence of gas atoms in the interaction space. In a tungsten filament tube, these atoms are of residual gases and by sufficiently extensive pumping and gettering the excess noise may be substantially removed. In an oxide-coated cathode tube which is well out-gassed and gettered, the atoms are at least predominantly atoms removed from the cathode by electron back-bombardment.

The correlations reported in the preceding section give some support to these conclusions. The first correlation (noise *vs.* degree of back-bombardment) is evidently related to the de-

---

[7] B. J. Thompson and D. O. North, "Fluctuations Caused by Collision Ionization," RCA Review 5, 88 (1941).

pendence of the rate of removal of cathode material upon the number of bombarding electrons and the cathode temperature, both of which are higher in magnetrons with excessive back-bombardment. Experiments showed that the equivalent pressure of cathode material was an exponentially increasing function of the cathode temperature. Therefore, under conditions of severe back-bombardment, it would be expected that noise would be greater than with moderate bombardment. This is just what was observed.

The reduction in excess noise by reducing the sprayed length of the cathode is presumed to be related to the first correlation. In several tubes with short-spray-length cathodes, the cathodes operated at temperatures less than 700°C. Most full-length-sprayed cathodes operated at considerably higher temperatures. This is evidence of smaller back-bombardment when the electrons do not interact with electric fields near the ends of the anode.

The third correlation is still obscure. It may be that a very active thermionic cathode, which may have a surface layer of barium or strontium atoms, yields more atoms or ions when bombarded with electrons than a less active cathode.

A number of apparently unconnected relations are consistent with the gas-ionization hypothesis of the cause of excess noise: The decrease of noise with increasing I.F. frequency, the decrease of noise when the cathode heater power is removed, the negative results of various experiments with end-plate potentials and geometries, observations of the appearance of anode and cathode surfaces after many hours of operation, the occurrence of excess noise in magnetrons of quite different construction, the lack of dependence of noise phenomena upon cathode and anode diameters, and the irregular changes of noise with time, are all susceptible to explanation by this hypothesis.

There are three outstanding difficulties: (1) The physical process whereby atoms or ions are released from the cathode coating by bombarding electrons is not known, though several processes seem to be capable of producing this result. (2) The exact way in which ions and ionization of emitted atoms combine with the electron flow and the electric and magnetic fields to produce such large amounts of noise is not known. (3) The decrease of noise with increasing anode current does not seem to be explained.

Despite these difficulties, the hypothesis of the cause of the noise is felt to be reasonably well established. More detailed information is required about the mechanism of release of cathode material in order to advance our understanding of noise. Experiments with a mass spectrometer are planned to determine what molecules, atoms, or ions are released. The results of these experiments may make possible a quantitative theory of noise generation. Preliminary results with "double-triode" tubes indicate that at least some of the cathode material is removed as atoms and that the exponential increase of removed atoms (per unit electron current) has an exponent which corresponds to an "activation energy" of 40–50 kilocalories per mole. The heats of sublimation of barium and strontium are 44 and 38 kilocalories. This may be a coincidence, or it may be that electron bombardment produces small patches of barium and strontium, from which atoms readily volatilize at the cathode operating temperature.

## IV. PROGRESS IN THE REDUCTION OF EXCESS NOISE

The increase in $V_{a0}$ by reducing the sprayed length of the cathode has already been reported. This change and the improvement of the efficiency and reduction of back-bombardment resulting from further development of the frequency-modulated magnetrons[2] resulted in a large percentage of magnetrons which were not "noisy" in the ordinary operating region, near $V_a = 850$ volts.

The hypothesis of the cause of noise which was advanced in the preceding section suggested that the cathode be modified in order to reduce the excess noise and to raise $V_{a0}$ still further. No hope was entertained of eliminating the back-bombarding electrons, so a means was sought for preventing the removal of cathode material by such electrons. There is considerable evidence that electrons returning to the cathode do not strike at normal incidence, but at angles varying between 45° and tangential incidence. Furthermore, for a fixed magnetic field, the sense of rotation of all electrons about the cathode is the same. These facts permit the construction of a cathode such that returning electrons strike a nickel surface instead of striking the cathode

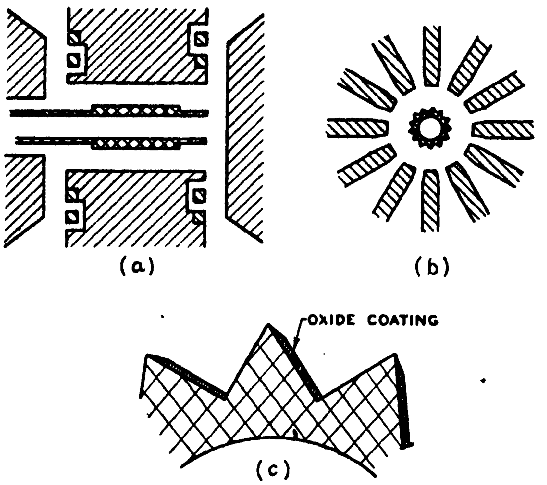

FIG. 4. Grooved cathode.

coating. One such cathode is shown in Fig. 4. The active length of the cathode is in the form of a 13-pointed star; only one side of each star point is coated with oxides. To accomplish this, the entire cathode was coated, and the spray was carefully scraped from areas where it was not wanted. This process was tedious, since the diameter of the cathode was only 0.070 inches, but was quite practical for experimental tubes.

Figure 5 shows the noise behavior of one of the four tubes constructed with the cathode of Fig. 4. By "correct" direction of the magnetic field we mean that direction which allows back-bombarding electrons to strike only the nickel surface (this is the clockwise sense of rotation in Fig. 4). It is evident that the noise is much less if the oxide-coating is sheltered from bombardment. This provides increased confidence in the hypothesis of the cause of noise which was advanced in the preceding section.

Three other tubes with cathodes as shown in Fig. 4 were built. One of these showed somewhat less noise for the "incorrect" direction of magnetic field than for the "correct" direction. This tube exhibited very high back-bombardment, more noise than other tubes of this type, and low efficiency. When it was dissected this tube was found to have a cathode which was not parallel to the axis of the anode. These facts make the information from this test of questionable value, but it is still not understood why this tube exhibited more noise when the electrons were rotating in the proper sense.

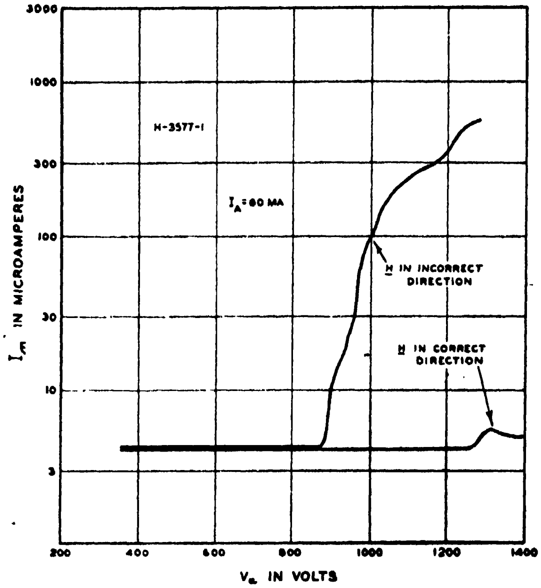

FIG. 5. Noise in magnetron with grooved cathode. When the magnetic field is in the "correct" direction, the oxide-coated surfaces are sheltered from back-bombarding electrons.

The remaining two tubes showed substantially the same behavior as the first (Fig. 5) and therefore confirmed the conclusions from that tube. The net result of all such experiments was that $V_{ao}$ is 200–300 volts larger when the magnetic field is applied in the "correct" sense.

An interesting possibility of cathodes of the general type of Fig. 4 is that they may permit substantially longer life than has previously been experienced with magnetrons. There is much evidence (some of it contained in the present work) that cathode life in a magnetron is limited more by the destruction of the cathode by back-bombardment than by the processes of cathode decay observed in ordinary diodes and negative grid tubes. If long life, not low excess noise, were the chief requirement, the oxide-coating could initially cover the entire cathode. Removal of part of the surface by back-bombardment would not cause failure, because at least part of the surface would be sheltered from back-bombarding electrons.

It is a privilege to acknowledge the cooperation of Messrs. G. R. Kilgore, C. I. Shulman, and Dr. J. Kurshan in this study, and the suggestions and encouragement of Dr. L. P. Smith and Dr. I. Wolff.

# A Semi-Polar Form of Fourier Series and Its Use in Crystal Structure Analysis

JOSEPH S. LUKESH
*Crystallographic Laboratory, Department of Geology, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received September 27, 1946)

A new form of Fourier series for crystal structure analysis is developed and a graphical method of summation described. The procedure is designed to permit simple and fairly rapid computation and recording of the density contributions of all planes at all points in the unit cell. Its particular advantage is in the case of centrosymmetrical projections where phases must be assigned experimentally. Adjustment of phases involves only re-addition of numbers rather than a complete new summation. The method also requires a minimum of equipment which is easily constructed at negligible expense.

THE distribution of electron density throughout the unit cell of a crystal can be determined by the summation of a Fourier series of the following general type

$$\rho(xyz)=\frac{1}{V}\sum_h\sum_k\sum_l F_{(hkl)}e^{-(2\pi i/N)(hx+ky+lz)} \qquad (1)$$

at each point, $xyz$, for all values of $F_{(hkl)}$. The coordinates, $xyz$, are given in integral numbers of $N$, the number of subdivisions of the axes. On expansion, Eq. (1) becomes

$$\rho(xyz)=\frac{1}{V}\left[\sum_h\sum_k\sum_l A_{(hkl)}\frac{\cos 2\pi}{N}(hx+ky+lz)\right.$$
$$\left.+\sum_h\sum_k\sum_l B_{(hkl)}\frac{\sin 2\pi}{N}(hx+ky+lz)\right]. \qquad (2)$$

In most crystal pattern syntheses, the series is restricted to a two-dimensional one whose summation gives a projection of the electron density. Considering only the reflections, $(hk0)$, for instance, the series is

$$\rho(xy)=\frac{1}{A}\left[\sum_h\sum_k A_{(hk0)}\frac{\cos 2\pi}{N}(hx+ky)\right.$$
$$\left.+\sum_h\sum_k B_{(hk0)}\frac{\sin 2\pi}{N}(hx+ky)\right]. \qquad (3)$$

Summation of Eq. (3) at all points, $xy$, gives a representation of the electron density projected on 001. Projections on 100 and 010 are obtained by considering only the $0kl$ and $h0l$ reflections, respectively.

Because of the tedious nature of the computations involved in even the two-dimensional series, a number of computational aids have been devised. All of these aids are characterized by the trigonometric separation of Eq. (3) into a group of one-dimensional series which can be summed easily by means of strips on which are printed the products of all possible magnitudes of $A$ and $B$ times all possible values of the cosine and sine. Summation is reduced to the addition of previously computed numbers.

Use of the computational aids reduces the labor of any one summation, but it may actually increase the total labor of a crystal structure determination. If one is dealing with a centrosymmetrical projection, the phases are all either 0 or $\pi$ and the equation to be summed is

$$\rho(xy)=\frac{1}{A}\sum_h\sum_k F_{(hk0)}\cos 2\pi(hx+ky). \qquad (4)$$

If the phase of a given reflection is 0, the sign of $F$ is positive; if it is $\pi$, the sign is negative. In most structure determinations, the phases are unknown and must be determined by trial and error. Given a trial structure, one may compute phases and these may then be used in the summation. In general, many of the signs will be found to have been incorrectly determined and the electron density will not be a faithful representation of the structure. It will then be necessary to change phases either experimentally or by making adjustments in the trial structure and re-computing. Each time phases are changed, a complete new summation must be made. When accurate parameters are being sought, a number

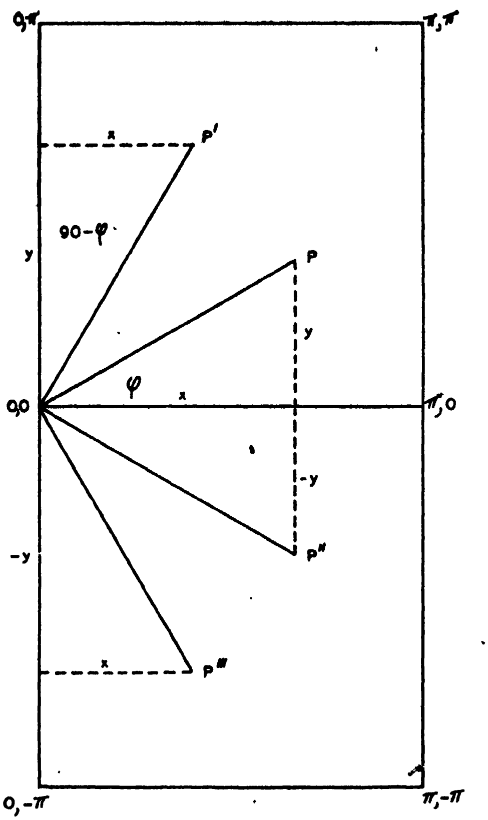

FIG. 1. The relation between rectilinear and semi-polar coördinates for points in a half-unit cell.

of approximations must usually be made before the final electron density map is obtained.

If, instead of summing Eq. (4) by use of strips, one employs a method in which the contributions of each plane at each point are determined individually and recorded, adjustment of phases will not require additional summations. To change signs, one need merely re-add columns of numbers. In the form of Eq. (4), the series requires a great deal of computation. However, if it is put into a new form, to be described in the following section, a graphical method of summation can be used which is both simple and reasonably rapid. In addition, the graphical method has an advantage in that the equipment required is a minimum, consisting of a chart, a scale, and a table of numbers.

### THEORY OF THE SEMI-POLAR SERIES

The point, $P$, in Fig. 1 is conventionally specified by the rectilinear coordinates $x$ and $y$. As an alternative, one may choose to locate $P$ by the coordinate $x$ and the angle, $\varphi$, between the $x$ axis and a line from the origin to $P$. Since

$$y = x\tan\varphi, \tag{5}$$

the rectilinear coordinate, $y$, may be replaced by $x\tan\varphi$. Equation (4) becomes

$$\rho(x, x\tan\varphi) = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \times\cos\frac{2\pi}{N}(hx+kx\tan\varphi). \tag{6}$$

In a similar manner, the point, $P'$, in Fig. 1 may be specified by the coordinates $y\tan(90-\varphi)$ and $y$. In this case, the series is given by

$$\rho[y\tan(90-\varphi), y] = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \times\cos\frac{2\pi}{N}[hy\tan(90-\varphi)+ky]. \tag{6'}$$

For all of the points along a line of constant $\varphi$ or $90-\varphi$, the tangent is a constant. Equations (6) and (6′) may, therefore, be written

$$\rho(x, c) = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \cos\frac{2\pi}{N}x(h+ck), \tag{7}$$

$$\rho(c', y) = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \cos\frac{2\pi}{N}y(c'h+k), \tag{7'}$$

where $c$ and $c'$ are the tangents of $\varphi$ and $90-\varphi$. For the points, $P''$ and $P'''$, the corresponding expressions are

$$\rho(x, -c) = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \cos\frac{2\pi}{N}x(h-ck), \tag{7''}$$

$$\rho(-c', -y) = \frac{1}{A}\sum_h\sum_k F_{(hk0)} \times\cos\frac{2\pi}{N}(-y)(-c'h+k). \tag{7'''}$$

The expressions are the same, except that $c$, $c'$, and $y$ are negative. Since the cell is centrosymmetrical, only half need be considered.

The important feature of Eq. (7) and its related expressions is that for any given reflection, *hk*0, and any given slope, *c*, the entire expression in parentheses is a constant. Equation (7) may, then, be written

$$\rho(xc)=\frac{1}{A}\sum_h\sum_k F_{(hk0)}\cos\frac{2\pi}{N}xC. \qquad (8)$$

The density contribution of any plane at each point, *x*, along the line whose slope is *c* is found by multiplying $F$ by the cosine of $(2\pi C/N)\cdot 0$ (for $x=0$), $(2\pi C/N)\cdot 1$ (for $x=1$), $(2\pi C/N)\cdot 2$ (for $x=2$), etc. If one is interested in the density at any one point, *x*, *c*, Eq. (8) reduces to

$$\rho(xc)=\frac{1}{A}\Big[F_{(hk0)}\cos\frac{2\pi}{N}xC_{(hk0)} + F_{(h'k'0)}\cos\frac{2\pi}{N}xC_{(h'k'0)} + F_{(h''k''0)}\cos\frac{2\pi}{N}xC_{(h''k''0)}+\cdots\Big]. \qquad (9)$$

## A POLAR GRID

If the points on the rectilinear grid that is usually used in structure analysis are specified in the semi-polar form just described, there will be

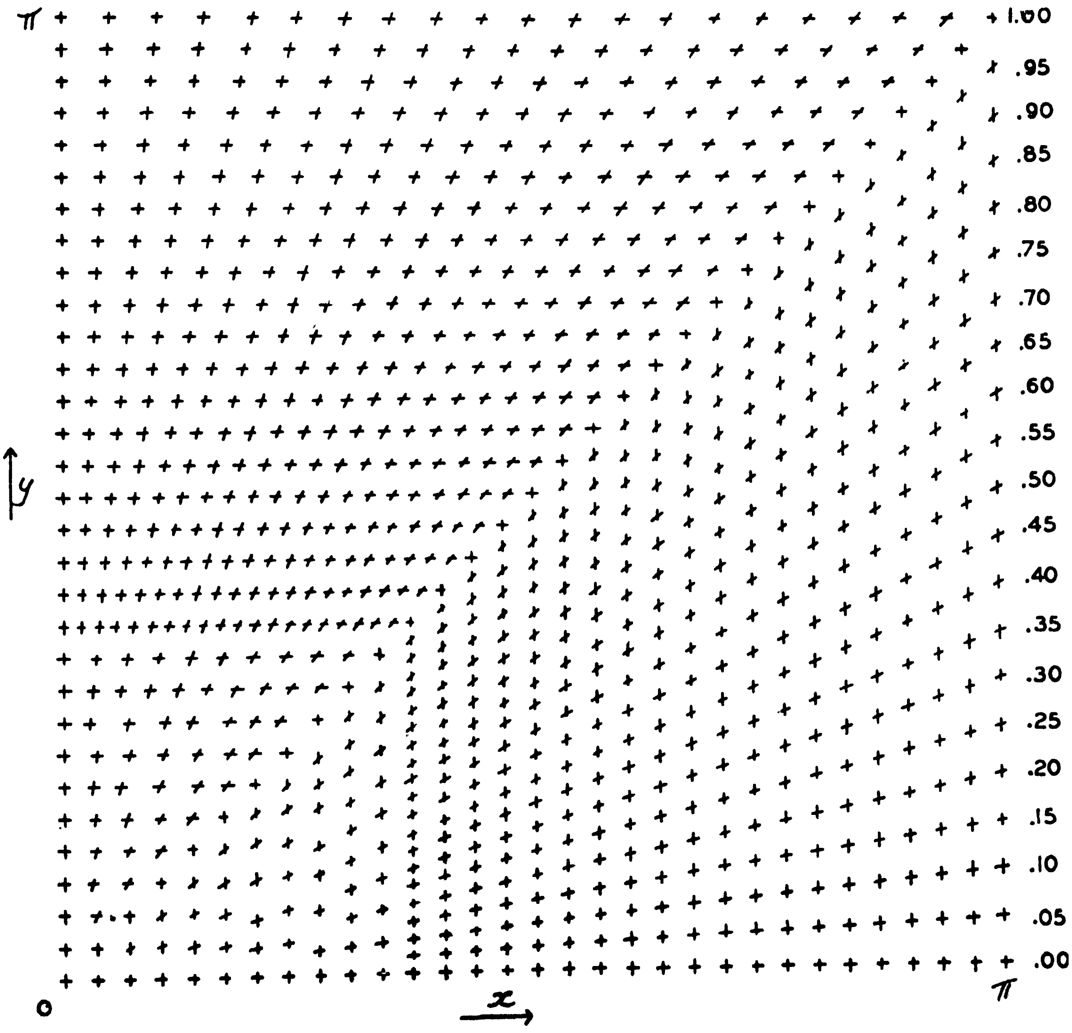

FIG. 2. The polar grid for one-quarter of the unit cell.

TABLE I. Values of $(2\pi/N)\cdot Cx$ for $C=4.80$.

| $x$ | $(2\pi/N)\cdot Cx$ |
|---|---|
| 0 | $(2\pi/N)\cdot 0.00$ |
| 1 | $(2\pi/N)\cdot 4.80$ |
| 2 | $(2\pi/N)\cdot 9.60$ |
| 3 | $(2\pi/N)\cdot 14.40$ |
| 4 | $(2\pi/N)\cdot 19.20$ |
| 5 | $(2\pi/N)\cdot 24.00$ |
| 6 | $(2\pi/N)\cdot 28.80$ |
| 7 | $(2\pi/N)\cdot 33.60=(2\pi/N)\cdot 26.40$ |
| 8 | $(2\pi/N)\cdot 38.40=(2\pi/N)\cdot 21.60$ |

TABLE II. Product of $F$ times $\cos(2\pi/N)\cdot Cx$.

| $x$ | $Cx$ | $F\cos(2\pi/N)\cdot Cx$ |
|---|---|---|
| 0 | 0.00 | 100 |
| 1 | 4.80 | 89 |
| 2 | 9.60 | 53 |
| 3 | 14.40 | 6 |
| 4 | 19.20 | −43 |
| 5 | 24.00 | −80 |
| 6 | 28.80 | −99 |
| 7 | 26.40 | −95 |
| 8 | 21.60 | −64 |

a large number of constants, $c$, corresponding to the tangents of the various angles, and, in general, their numerical values will not be simple numbers. Because of this, computation of the constant, $C$, will not be easy. Furthermore, there will be only a few points along each line, except in special cases. The value of having a "constant" will be reduced. Both of these difficulties can be eliminated if one abandons the conventional grid in favor of one defined by the intersections of the $x$ and $y$ coordinates with radial lines of simple slopes. For each radial line, there will be $N/2$ points, assuming the summation is made from the origin to $\pi$.

A grid suitable for most purposes is formed by allowing $N$ to equal 60. There are, then, thirty divisions along each axis from 0 to $\pi$. To approximate the distribution of points formed by such a rectilinear grid, a series of radial lines whose slopes are .05, .10, .15, .20, etc. has been chosen. Intersections of these with the $x$ coordinates locate the points of the grid for the first segment, in Fig. 1, of the cell. For the second segment, a symmetrical array is obtained by using the intersections of the $y$ coordinates and radial lines whose slopes, $c'$, have the same values. The grid thus defined for the first two segments of the cell is shown in Fig. 2. The principal disadvantage, outside of the unconventional array, lies in the fact that there are only twenty points along each of the axes, $x=\pi$ and $y=\pi$. To offset this, points half-way between those shown may be handled by interpolation. The point density near the origin has been reduced by eliminating some of the points, those from the origin to $x$ and $y$ equal four being, actually, coincident with points of the conventional grid.

It might be well at this time to discuss, briefly, the mathematics of the semi-polar coordinate system just developed. Heretofore, the tacit assumption has been made that the unit cell is square so that a point at $x=10$ and $y=5$, for instance, actually lies along a radius which makes an angle with the $x$ axis whose tangent is .50. It may not be immediately obvious that the same relation holds for a rectangular or oblique cell. Actually, the expression, $\tan\varphi=y/x$, is merely a convenient mathematical shorthand for referring to the ratio of units of distance along the $y$ axis to that along the $x$ axis. No matter what the absolute lengths of the two units may be or the angle between the axes, the statement, $\tan\varphi=.50$, simply means that the point is twice as many $x$ units from the origin as $y$ units. This holds, of course, only when the axes are divided into the same number of parts.

## GRAPHICAL SUMMATION OF THE SEMI-POLAR SERIES

As was mentioned in an earlier section, for a given plane, $hk0$, and a radial line of slope, $c$, the term, $(h+ck)$, in Eq. (7) is a constant for all points along the line, and the series may be expressed in the form of Eq. (8). The density contribution of $hk0$ at each point of the grid along the radial line is computed by multiplying the amplitude, $F$, by the cosines of a series of angles which are multiples of $2\pi C/N$. The discrete values of the cosine so obtained may be computed, once for all, and tabulated. Since they depend only on the geometry of the plane and are independent of the structure, such a table could be used for any structure determination. However, use of a table of cosines would require that multiplication be performed for each plane at each point, which is an extremely tedious task. Inasmuch as Eq. (8) is a periodic cosine function, the product can be determined readily by graphical means. Given a cosine curve and a vertical scale appropriate to the magnitude of $F$, it is only necessary to know what points along the axis of the curve correspond to multiples of $2\pi C/N$. These, of course, can be determined in advance and tabulated.

As an example, the density contributions of the plane, 420, along the radial line whose slope is .40 will be determined. The amplitude will be assumed to be +100. The constant, $C$, in Eq. (8) is given by

$$\begin{aligned} C &= h + ck, \\ &= 4 + .40 \cdot 2, \\ &= 4.80. \end{aligned}$$

The values of the product, $2\pi C/N$ times $x$ for the first eight points along the radial line are listed in Table I. Because the cosine function is sym-

TABLE III.* Part of the tabulation of $C$ times $x$ as a function of $C$ and $x$.

* *Explanation of Table III.* This table contains that portion of the tabulation of the product of the constant, $C$, times the coordinate, $x$, for $C$ between 4.00 and 5.00, inclusive. The values listed are obtained by multiplying $C$ by $x$, any product larger than 30 being reduced to an equivalent value less than 30. The remainder of the tabulation, covering the rest of the [illegible] The values listed in the table are the coordinates along the axis of a cosine curve, graduated in terms of $2\pi/60$, at which a scale should be set in order to determine graphically the product of the amplitude times the appropriate cosine.

metrical about 0 and $\pi$, one-half a cycle of the curve is sufficient if all values of the product greater than $\pi$ are recomputed to a symmetrical value less than $\pi$. In the present case, the product is equal to $\pi$ when $C$ times $x$ is equal to 30.

The products listed in Table I are the angles by whose cosines the amplitude must be multiplied to determine the density contribution of the plane, 420, at each of the first eight points of the grid along the radial line whose slope is .40. If the cosine curve is calibrated in terms of $2\pi/N$, it is only necessary to set the scale at the points 4.80, 9.60, 14.40, etc. and to read off the product. The values so obtained are listed in Table II.

In order to perform the computations for all planes at all points in the cell, it is necessary to tabulate all possible solutions of $x$ times $(h+ck)$ and the related functions. This might at first seem to require an extensive table since the values of $h$ and $k$ may become quite large in large cells. However, the symmetry of the cosine function reduces the number of independent solutions to a finite number. The highest independent value of the product of $C$ times $x$, and hence of $C$ itself, is that which makes the product $(2\pi C/N)\cdot x$ equal to $\pi$. In the present case, the value is 30. Any value of $C$ greater than thirty is symmetrical with one less than thirty. This is evident from $x=7$ and $x=8$ in Table I. Furthermore, since the cosine function is symmetrical about 0, negative value of $C$ are the same as positive, and the sign of $C$ may be disregarded. With $N$ equal to 60, there are only 600 possible values of $C$, and the products of $C$ times $x$ can be tabulated conveniently. Such a table can be used for all structure determinations. A portion of the table is shown in Table III.

In many cases, it is sufficient to base a grid on $N$ equal to 30. Radial lines of slopes .1, .2, .3, etc. may be used. The tabulation of $C$ times $x$ requires only 150 values of $C$ against 15 values of $x$.

## SUMMATION PROCEDURE

In determining the electron density by the method just developed, it is convenient to compute the density contributions of each plane at each point along a given radial line at the same time, as was done in the example. Worksheets can be prepared for each radial line on which are columns for the indices, the constants for each reflection, the $F$ values, and for the density contributions at each $x$ coordinate. The contributions of each plane, in turn, can then be easily determined by setting the proper scale at the points along the cosine curve indicated in the tabulation of $C$ times $x$. When all planes have been handled, the columns of density contributions are totaled, and the totals plotted on the polar grid. If the resulting electron density map indicates that adjustments must be made in phases, it is only necessary to re-add the columns.

## SUMMARY

A semi-polar form of Fourier series has been developed and a graphical method of summation described. Although the procedure is somewhat more tedious than the conventional strip methods of Fourier series summation, it may be found useful, particularly when phases must be assigned experimentally in centrosymmetrical projections. An added advantage is the simplicity of the equipment, which can be constructed at a negligible cost.

# The Insulation of High Voltages in Vacuum

JOHN G. TRUMP
*Department of Electrical Engineering*

AND

R. J. VAN DE GRAAFF
*Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received December 23, 1946)

Breakdown studies have been made between electrodes in high vacuum at constant voltages from 50 to 700 kv. These further demonstrate the inadequacy of the field emission theory to account generally for high voltage breakdown in vacuum. Experiments are described which investigate some of the "total voltage" breakdown mechanisms, including positive-ion emission by electron impact, electron emission by positive-ion impact and by photons. In the d.c. case these processes contribute to a steady interchange of charged particles between cathode and anode which increases with voltage until breakdown ensues. At higher breakdown voltages the cathode gradient has diminished far below the value for field emission. Measurements of electron emission by electrons with energies up to 300 kv for tungsten, steel, aluminum, and graphite are reported. The possibilities of predicting and of improving the insulating strength of electrode gaps in high vacuum by the study of the coefficients of the electrode materials are discussed.

## INTRODUCTION

THE use of vacuum for the insulation of high voltages has become of increasing importance in modern science. In physics, vacuum insulation is essential for the acceleration of charged particles to high energies for nuclear studies, and generally for the production of high energy radiations. In engineering, the primary application of vacuum insulation has been in electronic tubes, including high vacuum rectifiers and high voltage x-ray tubes. The present applications of vacuum to low power switches and low loss high frequency condensers merely suggest the possible future importance which vacuum insulation may have in electrical power engineering.

During the last decade, the technique of producing and maintaining vacuum in large volumes has developed to the extent that vacuum may now be regarded as an available voltage-insulating medium. Nevertheless, although solid, liquid, and gaseous dielectrics have been intensively studied for many years, relatively little effort has been directed toward understanding and developing the unique electrical insulating properties of vacuum. After interruption by the war, the study of vacuum insulation, particularly at high voltages, is being resumed in the Department of Electrical Engineering at M.I.T. Some of the information obtained in these prior studies, as well as comments on our present picture of the mechanism of voltage breakdown in vacuum, is reported herein.

Vacuum insulation may be said to exist when the breakdown strength between metallic electrodes is independent of the pressure of the intervening gas. In an insulating vacuum the mean free path of electrons and positive ions moving in the residual gas must, therefore, be large compared with the inter-electrode gap in order that the contribution of gaseous ionization to the breakdown mechanism be negligible. While this condition may be achieved at atmospheric pressure for gaps of a small fraction of the wave-length of light, for the more ordinary gaps of physics and engineering a residual gas pressure of $10^{-4}$ mm of Hg or less is generally adequate. Further reduction in pressure does not increase the insulating strength of the gap except insofar as residual gas pressure may affect the absorbed gas and molecular layers of contaminating material which are in equilibrium on the electrode surfaces.

Vacuum insulation is more susceptible to quantitative analysis than any other insulating medium. Being free from the obscurities and limitations of intervening materials, the situation between metallic electrodes immersed in high

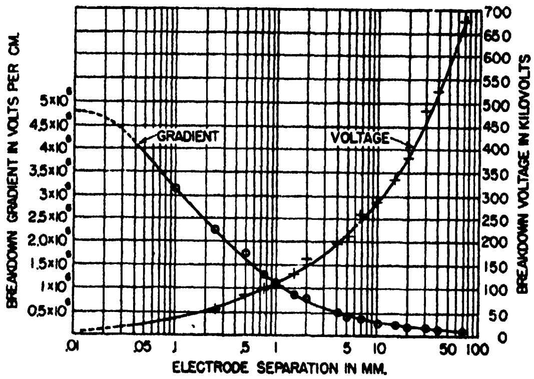

FIG. 1. Breakdown voltages and gradients between 1″ stainless steel ball and 2″ steel disk in vacuum.

vacuum may be more precisely described in terms of the electric field configuration, the number and energy of the charged particles, and other factors which influence the current flow and breakdown strength. Compared to a gas gap at high pressure, the phenomena in a vacuum gap are fewer and more direct. All of the ionization and recombination processes which occur in the gas are eliminated along with the field-distorting influence of space charge; only the electrodes remain effective in contributing or removing charged particles from the inter-electrode gap.

## FIELD EMISSION BREAKDOWN AT LOW VOLTAGES

Much work has been done on vacuum insulation at low d.c. voltages and high field strengths with the object of studying the phenomena of high field emission. These experiments in general were made using well-outgassed electrodes in a highly evacuated chamber, the electrode arrangement consisting variously of concentric cylinders with the inner cylinder a filament easily outgassed by heating, of a point directed at a plane, of two fine crossed wires, or of sphere gaps. These experiments indicated that gradients at the cathode surface of several times $10^6$ volts per centimeter could be insulated before breakdown ensued, and that gradients at least ten times higher than this value could be insulated on the anode surface. Hayden[1] reports a maximum cathode gradient of $1.3\times10^6$ volts per centimeter between outgassed molybdenum spheres. Piersol[2] observed a cathode gradient of $5.4\times10^6$ volts per centimeter between molybdenum plates outgassed at 1400°C. In the work described in the present paper it was found that at voltages less than 50 kilovolts it is quite easy to support gradients above $10^6$ volts per centimeter on steel cathode surfaces after conditioning the surface by permitting low energy flashover.

In the voltage range below 20 kilovolts detectable high field emission from cathode surfaces in vacuum begins at a fairly definite gradient which depends on the electrode material and its surface condition and increases exponentially with increasing gradient until flashover. This effect was first quantitatively analyzed by Schottky,[3] who modified the Richardson thermionic emission equation by reducing the true work function of the metal to account for the attractive influence of the electric field on the escaping electrons. The later experiments of Millikan[4] and others indicated that, unlike the prediction of the Schottky equation, high field emission is substantially independent of the cathode temperature, at least up to about 1200°C, beyond which it is overshadowed by the thermionic emission. This non-dependence has been more adequately explained by the newer Fowler-Nordheim relation.[5]

Both the Schottky and Fowler-Nordheim relations assume the existence of a smooth cathode surface. Actually, high field emission, like thermionic emission,[6] takes place preferentially from the microscopic projections, crystal edges, and spots of impurities which usually exist on surfaces. This consideration of surface roughness and contamination explains to a considerable extent the discrepancy between the experimentally observed cathode gradients and the higher values predicted by theory. Since field emission varies exponentially with gradient, it is evident that an intensification as small as 10

percent because of surface projections would cause most of the field-emission current to flow from such points. The adverse influence on the breakdown gradient of such factors as contaminating surface films, rough electrode surfaces, and low work-function electrodes has become generally appreciated.

It is now well established that voltage breakdown between metal electrodes in high vacuum at high gradients, but relatively low voltages is initiated by high field emission. This emission increases exponentially with gradient and results in local temperature increases and enhanced secondary effects which lead to instability. For many years it has been generally believed that this same high field mechanism accounted for breakdown at high voltages. That this cannot be the case is demonstrated by the data of Fig. 1, in which breakdown voltage and gradient are shown as a function of electrode separation for constant voltages from 20 to 650 kilovolts. It is seen that, while fairly constant gradients of several million volts per centimeter are required to produce breakdown at voltages less than 50 kilovolts, the cathode gradient required at voltages higher than this decreases rapidly. Thus, whereas a gradient of 3000 kilovolts per centimeter is required when the total voltage between the electrodes is 20 kilovolts, a gradient of less than 100 kilovolts per centimeter is the maximum that can be supported at 650 kilovolts. This gradient is evidently inadequate of itself to insure breakdown through the mechanism of high field emission.

## HIGH VOLTAGE BREAKDOWN

The explanation of high voltage breakdown suggested some years ago by one of us[7] pictures an interchange of charged particles and photons between cathode and anode. Thus, an electron starting from the cathode and accelerated by the voltage between the electrodes, impinges on the anode with the resultant possible emission of both a positive ion and photons. Such positive ions and some of the photons would return to the cathode and cause further electron emission. When the conditions are such that this interchange becomes cumulative, breakdown results. To represent this mechanism quantitatively, let coefficient $A$ represent the average number of positive ions produced by one electron, and coefficient $B$ the average number of secondary electrons produced by one of these positive ions; similarly, let $C$ represent the photons produced by one electron, and $D$ the secondary electrons produced by an average photon. Then, when the condition

$$AB+CD>1$$

is realized, the interchange becomes cumulative and breakdown ensues. It is evident that these coefficients will be functions of the accelerating voltage between the electrodes and the gradient at the electrode surfaces, as well as of the electrode material and the surface condition. Some preliminary experiments to measure these coefficients were undertaken before the war with the collaboration of J. R. Maull, and work in this direction is now being resumed.

The experimental arrangement for determining coefficient $A$ is shown in Fig. 2. Electrons starting from the filament are accelerated by the voltage between electrodes, and impinge on the upper target, where they are measured. Because of the uniform field, any positive ions produced by these primary electrons return along the same path and are measured by collection in the

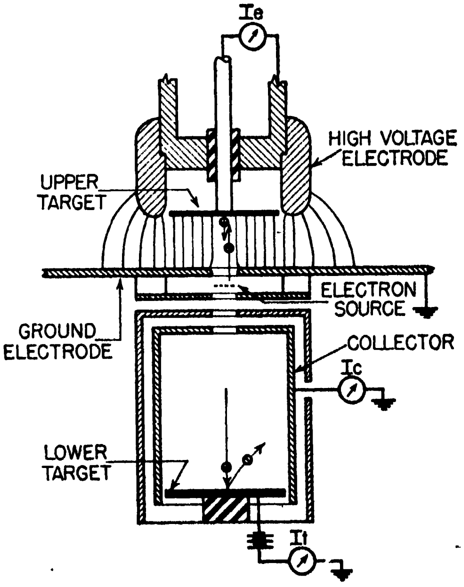

FIG. 2. Electrode arrangement for measuring "breakdown coefficients."

---

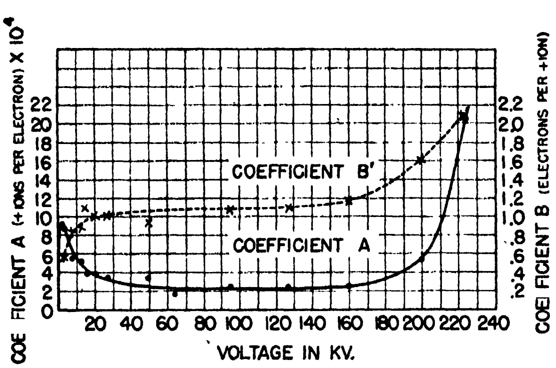

FIG. 3. Breakdown coefficients for steel electrodes with 2-cm gap.

Faraday cage. The ratio of the positive-ion current to the electron current is the coefficient $A$, and can thus be determined over a range of voltages and gradients and different electrode materials. It is noteworthy that the emission of positive ions due to electron impact is assisted in this experiment by the electric field at the anode surface. This is exactly the condition which exists in an actual gap in high vacuum.

Figure 3 shows the coefficient $A$, the ratio of secondary positive ions to electrons, for a parallel-plane steel gap as a function of the gap voltage. This curve was quite reproducible after the steel target had been outgassed by electron bombardment. The low voltage peak was found to be caused by the ionization of the residual gas and varied closely with its pressure. As would be expected, this residual gas ionization reduces with increasing gap voltage so that at the higher voltages the returning positive ions are owing primarily to secondary ion emission from the anode. The small proportion of residual gas ions to ions from the anode itself accounts for the small dependence on pressure of breakdown voltages in high vacuum.

That a definite positive-ion current could be measured from the electron bombarded target is evidence that this mechanism contributes to breakdown in vacuum. The small value of coefficient $A$, in this case 2 to $20\times10^{-4}$ in the energy range below breakdown, indicates the cathode coefficient $B$ must be large if this particle mechanism is to be important. The sharp increase in coefficient $A$ near the breakdown voltage is to be noted. The existence of secondary positive-ion emission is also supported by two observations of Anderson in the course of a doctorate research in this program.[8] With constant applied potential and a substantially uniform field, Anderson found deposition of anode (copper) material on the cathode after some minutes of operation near the breakdown value. He also showed a definite, though small, cathode temperature rise under such conditions—this temperature rise being a fraction of one percent of the rise of this same electrode when the polarities were reversed.

It should be expected that the coefficient $A$ will in general differ from one metal to another and show considerable dependence on surface condition.

The same arrangement shown in Fig. 2 may be used to give an idea of the coefficient $B$, the average number of electrons produced at the cathode by the impact of one high energy positive ion. The returning positive ions, having been accelerated by the full gap voltage, are permitted to impinge on a second target within the collector cage. The resultant secondary electrons are collected as current $I_c$ in this experiment. Figure 3 shows that under these conditions the secondary electrons increase slowly with the energy of the impacting positive ions, the ratio being a small number at energies below 220 kv. This result checks generally with the measurements of Allen,[9] Linford,[10] Hill *et al*,[11] in which secondary electron emission under high energy positive-ion bombardment and low cathode field were found to be small (2 to 20) and usually increased with voltage.

Since, in an actual gap, the cathode is subjected to a high electric gradient which would have the effect of assisting in the escape of electrons, the cathode coefficient shown in Fig. 3 is labeled $B'$ and must be regarded as low, perhaps low by the large factor required to make the particle mechanism of importance in vacuum breakdown. It is evident that a heavy positive ion having an energy of the order of a hundred kilovolts will produce brief, but extremely intense, local heating at its point of impact on the cathode. The effect of a high cathode gradient

---

would be to reduce the space charge limitation to electron emission during this short period of intense local heat. Thus under the conditions of high cathode gradient a relatively large number of electrons might escape because of the impact of a single positive ion. Experiments are now planned to determine coefficient $B$ under the complete conditions of voltage and gradient.

Unless retarded by the external circuit, the collapse of the insulating strength of a vacuum gap is characterized by unusually rapid development greatly exceeding that of gaseous or solid insulator gaps. Evidently the conditions for instability are sharply defined and the subsequent discharge is relatively unimpeded. This is to be expected because of the short transit times involved in the energy interchange between electrodes and the absence of space-charge phenomena in the early phases. At an intermediate stage, after the condition for instability has been reached, self-focusing processes probably concentrate the discharge into a thin-cored channel and further enhance the emission of charged particles from the surfaces through thermionic emission. It has been observed that higher voltages can be insulated in the case of somewhat ununiform fields than when the interchange of particles can proceed undeviating along a straight line path between electrodes. The problem of vacuum insulation must be met primarily by reducing the emission characteristics of the electrode surfaces so as to prevent the onset of instability until well beyond the required conditions of voltage and gradient.

### EMISSION OF ELECTRONS BY HIGH ENERGY ELECTRON IMPACT

Primarily by replacing the upper target of Fig. 2 with a tungsten filament, the experimental set-up was adapted for measuring the number of secondary electrons emitted due to impact of high energy primary electrons, as a function of voltage and electrode material. Figure 4 shows the ratio of secondary electrons to primary electrons from 30 kv to 340 kv for tungsten, steel, aluminum, and graphite. It is seen that this ratio diminishes with increasing primary energy and that the ratio is a function of the atomic number of the electrode. A study of the energy of these secondary electrons showed a low energy group with energies less than 20 volts. Most of the remainder of the secondaries had energies in excess of 800 volts, some extending in the limit up to the energy of the primaries. As can be seen from the ascending curves of Fig. 4, the proportion of these high energy secondaries increased with voltage, becoming fairly constant above 200 kv. These more energetic electrons result from elastic nuclear scattering and from electron-electron collisions.

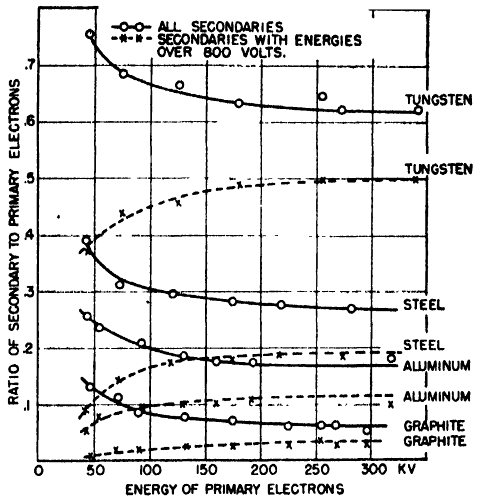

FIG. 4. Secondary emission of electrons by electrons with energies up to 340 kv.

To the picture of vacuum breakdown this information adds the concept that electrons from the cathode striking the anode cause repeated opportunities—though each time with diminished energy—to bring about the emission of positive ions and photons. The reduction of this secondary emission coefficient at the higher voltages illustrates how some breakdown factors may actually become diminished at extreme voltage values.

Experiments have been devised, but not yet carried out, for measuring the contribution of the photoelectric mechanism to high voltage breakdown in vacuum. It is well known that the efficiency of x-ray production increases markedly with voltage, though with an increasing tendency for the radiation to continue in the forward direction. Only backward-scattered radiation would be effective in releasing more electrons from the cathode. Although a high electric field at the cathode would assist the photoelectric emission, the probability of this mechanism being important appears to be small.

The several processes which contribute to the interchange of charged particles are seen to depend in an important way on the total available voltage between the vacuum-immersed electrodes. The breakdown voltage curve of Fig. 1 clearly shows that, at the higher voltage values across a given gap, it is the voltage and not primarily the gradient that affects the insulation performance. For these reasons the term "total voltage mechanism" has been applied to vacuum breakdown in the high constant voltage range.

### PULSED MICROWAVE VOLTAGES

Some studies have recently been made by the linear accelerator group at M.I.T. of the insulation of microwave voltages in high vacuum.[12] In a copper cylindrical cavity, 3000 mc voltages in pulses 2 $\mu$sec. in duration and calculated at $2\times10^6$ volts peak were insulated across the 5-cm gap. The pulse nature and high frequency of these insulation tests is in favor of both high voltages and gradients since the time and energy available to accomplish breakdown is limited. It would seem that positive ions can have relatively less influence with this type of voltage and that the breakdown mechanism would depend on high field and photoelectric emission of electrons from both electrode surfaces viewed as alternate cathodes.

### POSSIBILITIES FOR REDUCING SURFACE BREAKDOWN COEFFICIENTS

The striking dependence of secondary electron emission on the electrode material illustrates the way in which the breakdown coefficients $A$ and $B$ may also depend on materials, and hence the need of quantitative information on these factors. When these breakdown coefficients are sufficiently known, it should be possible to begin to design and predict the insulation strength of electrodes in vacuum. Moreover, it may prove possible to improve substantially the insulating strength between electrodes in vacuum by various measures which reduce the electrode coefficients. Various possible procedures are suggested, including the use of composite electrode surfaces in which the surface layer is of low atomic number and, therefore, inefficient as a source of heavy secondary particles and x-rays, the use of highly porous surfaces and of grids or insulating films to repress secondaries, the local distortion of the surface field so as to delay the focusing effects of a particle interchange, the magnetic deflection of the interelectrode electrons, and the more complete conditioning of the electrode surfaces. The experimental determination of surface coefficients under these various conditions can in principle be performed in a more quantitative way than is generally possible in experiments on material insulating media. Such studies should not only widen our understanding of the essential factors in vacuum breakdown, but they may extend insulation strength of high vacuum into the region of usefulness for electrical power engineering and various scientific purposes.[13]

### ACKNOWLEDGMENT

It is a pleasure to acknowledge the effective assistance of J. R. Maull in making some of the measurements reported herein.

# Preparation and Uses of Silica Replicas in Electron Microscopy

CHARLES H. GEROULD
*The Dow Chemical Company, Midland, Michigan*

(Received November 21, 1946)

A detailed description of the preparation of silica replicas and substrates and their many and varied uses is presented with photographs and electron micrographs. A method of preparing silica replicas of specimens which cannot be subjected to the temperatures and pressures of the ordinary technique is described. It consists of applying a polystyrene lacquer to the specimen surface in place of the conventional molding. The question of "up and down" in stereo pictures of silica replicas is definitely settled by adding a metal oxide smoke (MgO) to the polystyrene replica before the silica evaporation. A successful powder dispersing technique consists of dispersing the powder in an ethyl cellulose lacquer and depositing upon a silica substrate. Several other techniques are also included.

## INTRODUCTION

WITHIN the last two years the field of electron microscopy has expanded many fold resulting in a great need for the development of new and improved electron microscopic techniques as well as the optimum use of those available. The great diversity of the recent entrants into the microscopic field has made an even greater need for literature on techniques which are of general application.

The polystyrene-silica replica technique of Heidenreich and Peck[1] is one which has succeeded in solidly establishing itself and is now being widely used on many and varied research problems involving the electron microscope. Among these we might mention the application of silica replicas to such metallurgical specimens as steels, copper alloys, and magnesium alloys.[2–5] We might mention also their application to nonmetallic materials such as teeth,[6] bones, minerals, glasses, ceramics, resins, woods, and textile fibers.[7] In addition, we must include the use of structureless silica substrates[8] as supports for many different types of electron microscope specimens such as bacteria, viruses, powders, emulsions, metallic oxide smokes, thin evaporated films, microtome sections, etc.

These many and varied uses of silica replicas have resulted in a demand for more explicit information on their preparation and uses. It is the purpose of this paper to fill this need and at the same time make available to the field some of the more recently developed, and as yet unpublished, microscope techniques in which silica replicas are an essential part.

These new techniques include a new method

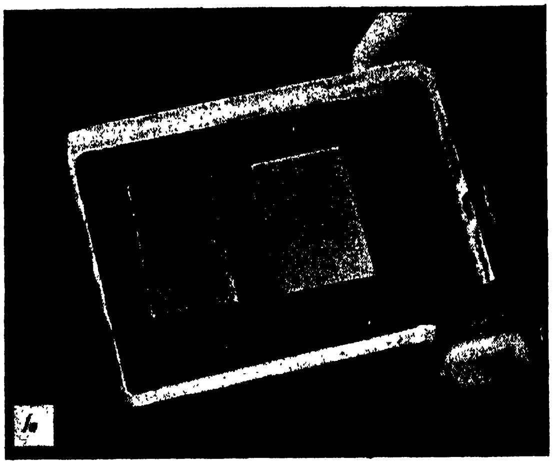

FIG. 1a. Block of clear polystyrene containing two specimens of a magnesium alloy sheet whose surfaces have been covered with a corrosion resistant coating. Silica replicas are to be prepared of this coating. The molding was formed from molding granules at a temperature of 160°C and a pressure of about 1500 lb./sq. in.

FIG. 1b. Polystyrene impression on left and coated metal specimen on right. Mechanical separation has been accomplished by sawing away the excess polystyrene from the edges of the specimen and then pulling the two surfaces apart. Specimens may be dissolved with acids or alkalies if necessary.

of preparing replicas for stereoscopy which makes it possible to settle definitely the question of "up and down" in stereo pictures, a procedure for preparing silica substrates, an ethyl cellulose lacquer particle dispersing technique for use with such substrates, a method of preparing silica replicas utilizing a room temperature produced polystyrene impression and several other miscellaneous techniques.

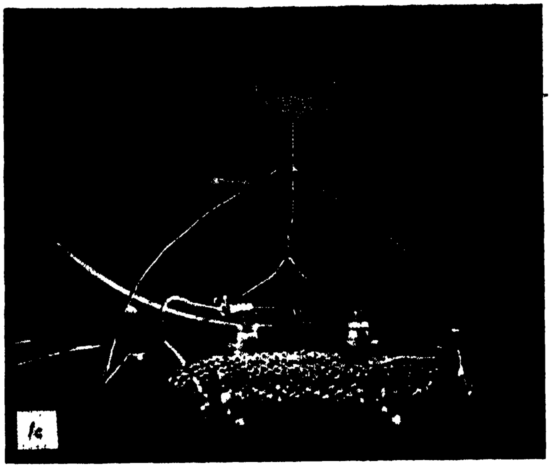

FIG. 1c. Polystyrene impression of specimen mounted 7 to 10 cm above conical tungsten filament containing approximately 1 mg of silica in the form of quartz.

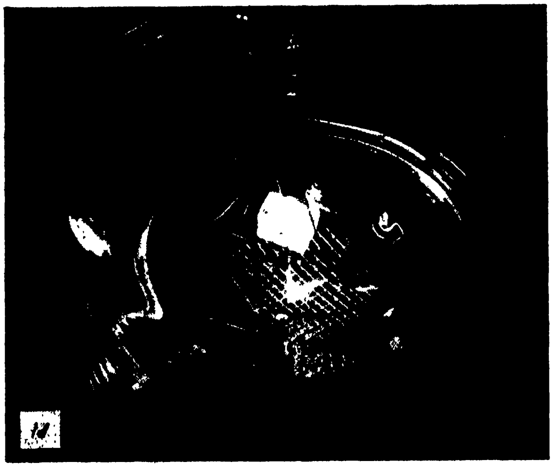

FIG. 1d. Actual evaporation of silica with filament incandescent under a vacuum of about $10^{-4}$ mm of Hg. Silica is completely evaporated in 5 to 15 seconds, part of which condenses on surface of polystyrene to give a continuous film of approximately 200A thickness.

All micrographs were obtained with either the RCA type B or U electron microscope.

## PREPARATION OF SILICA REPLICAS

The cleanliness of the specimen surface is one of the most important points to be considered in preparing silica replicas. In the case of an etched metal the prepared surface must be free of reaction products, grease, stains, oxide, or hydroxide films or any material which may either adhere to the replica or prevent it from reproducing the true metal surface. When working with non-metallic specimens, the surface must likewise be free of any foreign material which would contaminate the replica. It is our belief that many of the difficulties met in preparing silica replicas by the polystyrene-silica technique arises from improperly prepared surfaces, mainly dirty surfaces.

The polystyrene-silica technique can best be illustrated by a series of photographs of the various steps involved in preparing the polystyrene impression, evaporating the silica upon the plastic, and removing the silica replica film. These various steps are described in detail in order that one may experimentally follow the technique and obtain good replicas with a minimum of difficulty.

The first step, after the specimen has been given a suitable surface preparation, is to mold polystyrene against the surface. This is accomplished quite simply by imbedding the specimen in polystyrene as illustrated in Fig. 1a. Polystyrene molding granules of medium viscosity or molecular weight* are best for this.

The molding may be accomplished in an ordinary electrically heated metallographic specimen mounting press or a steam-heated compression molding die. The specimen is placed in the molding die with the prepared surface upward and sufficient molding granules added to give a final clear molding at least ¼ inch thicker than the specimen. The actual molding is accomplished by heating the molding granules to a temperature of 160°C, care being taken that no pressure is applied until they are thoroughly softened. Otherwise they may be pressed against the specimen surface causing deformation. After the granules have had a chance to soften thoroughly (5 to 10 minutes usually is required), pressure is applied up to about 1500 lb./sq. in. and the cooling of the die commenced at once. The pressure is maintained until the molding has cooled below 80°C since release of the pressure at higher temperatures may result in the formation of bubbles in the molding.

The specimen is now separated from the plastic impression by first sawing away the excess material from the edges of the specimen and then separating the two, mechanically if possible. Figure 1b shows a magnesium alloy specimen which has just been mechanically separated or stripped from the polystyrene.

If mechanical separation is impossible without fracturing or otherwise distorting the polystyrene, chemical reagents may be used to dissolve the specimen. Mineral acids or strong caustic solutions may be used on most specimens without damage to the plastic impression.

Figures 1c and 1d show the next step in which silica is evaporated in vacuum upon the surface of the plastic impression. The molding is mounted 7 to 10 cm above a spiral tungsten filament (cone shaped of about 5-mm length with a 35° angle) containing about 1 mg of clear quartz in the form of small slivers weighing roughly 0.2 mg each. The filament of the type shown in the photographs is heated to incandescence for a period of 5 to 15 seconds, using 25 to 30 amp. at 10 to 15 volts. The silica is completely evaporated in a few seconds, providing the individual splinters of silica are not too large and the vacuum is $10^{-4}$ mm of Hg or better.

The tungsten filament used in this evaporation is prepared by winding 20-mil tungsten at a dull red heat on a tapered mandrel having about a 35° included angle. The quartz used may be prepared quite easily by breaking up a natural clear quartz crystal by means of mortar and pestle and then screening to obtain particles of the proper size. Other laboratories have successfully used cloudy quartz, fused silica, or Santocel.

The block of polystyrene supporting the silica film is now prepared for the removal of the film. The sides and bottom are first scraped thoroughly to remove all undesirable silica film and any dirt which may contaminate the solvents. The silica film is scored into slightly over ⅛" squares and the polystyrene block lowered to the bottom of a dish of high purity ethyl bromide and benzene with the replica side up as shown in Fig. 2a. The block will stick to the bottom of the dish as the plastic softens. About 10 percent of benzene is added to the ethyl bromide to decrease its volatility and thus prevent moisture condensation upon the silica films as they are removed from the solvent. Such moisture condensation is invariably accompanied by precipitation of the polystyrene. Ethyl bromide is used for this step

---

* Such a material is available commercially as Styron No. 379-clear.

FIG. 2a. Silica film has been scored into squares and the whole polystyrene block is about to be immersed in ethyl bromide plus 10 percent benzene.

FIG. 2c. Silica films are being transferred on a piece of 200-mesh stainless steel screen to a rinse consisting of ethyl bromide plus a few percent of iso-amyl alcohol.

FIG. 2b. Silica films are seen as they start floating off from the polystyrene block stuck to the bottom of the dish of ethyl bromide and benzene. Silica films generally come free from the polystyrene 1 to 5 min. after immersion in the solvents.

FIG. 2d. Catching the silica films on a standard electron microscope specimen screen after they have washed in the solvent rinse for at least 5 min. After catching, the screens are blotted on a filter paper and viewed directly in the electron microscope.

in the replica technique for the following reasons: 1. It is an excellent solvent for polystyrene; 2. its density is sufficiently high to cause the films to float about in the solvent; 3. its great volatility tends to produce convection currents which aid in washing the films free from polystyrene; 4. its refractive index is such that the silica films are generally readily visible in the solvent.

The silica films will generally free themselves from the polystyrene 1 to 5 minutes after immersion. Side illumination with a dark red background is of great help in seeing them. Figure 2b shows the films as they come free from the polystyrene. They are transferred almost at once to a rinse containing ethyl bromide plus a few percent of iso-amyl alcohol added to reduce the solvent's volatility. Benzene is not used because an effective concentration is probably upwards of 10 percent. Transfer of the silica films to the rinse is easily accomplished by using a piece of 200-mesh stainless steel screen as shown in Fig.

2c. The films readily loose themselves from the screen when it is lowered into the rinse provided they are not allowed to dry during transfer.

The silica films are allowed to wash at least five minutes and then caught on the standard microscope specimen screens as shown in Fig. 2d. The screen with the films are dried by blotting on a filter paper. Such films are believed to have a thickness of about 200A.

Figures 3–8 show examples of silica replicas as applied to a magnesium alloy, quartz crystal, etched glass, tooth, bone, and wood.

One often finds in replica work a need for obtaining silica films from specific areas of a specimen. This is not difficult since the polystyrene molding with the silica film may be examined quite readily with the light microscope at magnifications up to 1000× using illumination through the specimen. Regions which are of particular interest may be outlined readily by scribing the surface with a needle point and then scraping off all the silica film except that of particular interest. This film may then be removed in the usual manner. Such a technique is often found very useful in studying interfaces between dissimilar materials.

As has been mentioned before, many of the difficulties experienced when preparing silica replicas arise from improperly prepared surfaces. Dirty surfaces often give silica replica films which tend to roll or fold up and which may refuse to straighten out by the customary method of "teasing" the films with a specimen screen as they float in the rinse. Another difficulty often experienced in preparing silica replicas is fragility of the films caused by lack of appreciable fine structure in the original specimen. It appears that fine detail in a specimen adds considerably to the mechanical strength of silica replicas.

On the other hand, silica replicas of single phase or electrolytically polished metals, glass, or other microscopically smooth surfaces are very often extremely fragile. Care must be taken to handle these films delicately and even then part of the film may break up on the specimen screen.

Occasionally one wishes to prepare replicas of surfaces which for some reason cannot be subjected to the temperatures and pressures necessary to obtain a polystyrene impression. In such cases an alternate method is used in which a polystyrene lacquer is applied to the specimen to give a heavy coating, stripped off and then used to prepare silica films in the ordinary manner. This technique has given quite reliable results in practice using a 1 percent solution of polystyrene in benzene for the initial application and then backing this film up with several applications of a more viscous lacquer of 2 to 3 percent polystyrene in benzene. By means of the more concentrated solution one can build the original film up to the point where it may be mechanically stripped from the specimen or the specimen dissolved if it is felt to be advisable. Figures 9a and b show a comparison between the conventional method and this polystyrene lacquer technique.

The resolution possible with this technique appears to be very good though very likely not equal to that of the pressure molding technique whose resolution is apparently better than 100A. The resolution of this "cold" replica technique can probably be improved, as suggested by Matheson,* by vacuum boiling of the specimen in the lacquer as a means of outgassing the surface. The initial lacquer coating can then be built up as previously described.

## STEREOSCOPY

The use of stereoscopy as an electron microscope technique has become of quite general application and is held to be invaluable in interpreting electron micrographs by many microscopists. The stereoscopic technique is especially well suited for use with silica replicas.[9] However, one of the difficulties experienced in such application has been the impossibility of definitely establishing the "up and down" of the stereo pictures unless something was known about the topography of the original specimen surface.

A very simple procedure is now being used to remove this uncertainty. This consists of adding a metal oxide smoke to a known side of the silica replica film and using this oxide smoke to determine the correct viewing arrangement. This is best accomplished by depositing the oxide smoke on the polystyrene impression of the specimen surface. Magnesium oxide smoke works very successfully, an even distribution being obtained by wafting the molding through the smoke of burning magnesium. Zinc oxide smoke can also be used but is much more difficult to distribute evenly.

Silica is evaporated upon the polystyrene impression and the films removed in the usual manner carrying the oxide smoke with them,

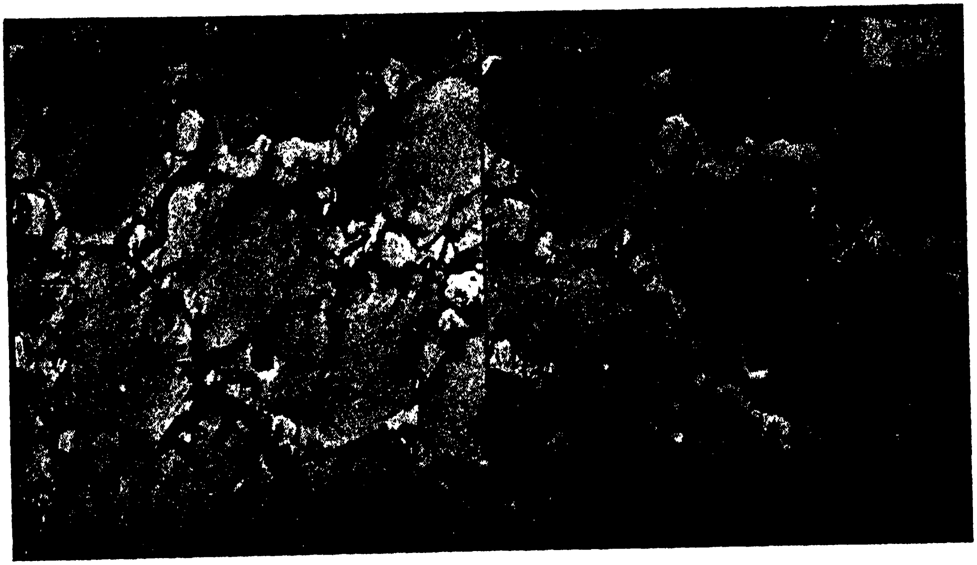

FIG. 10. Stereo pair from a fine grain magnesium alloy showing the addition of magnesium oxide smoke (indicated by arrows) to the replica film. The question of "up and down" is answered by viewing the stereo pair arranged so the oxide cubes appear below the surface. Compound precipitation can be observed projecting upward in relief from the grain boundaries. Magnification 6000X.

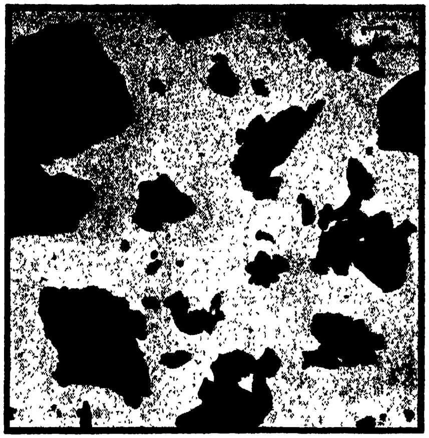

FIG. 12. $CaCO_3$ dispersed in ethyl cellulose on a silica substrate, 4500×.

attached to the side reproducing the specimen's surface structure. Electron micrograph stereo pairs of these films are then obtained and viewed through the stereoscope with the pictures arranged so the oxide smoke appears below the surface, the proper arrangement. By this method the question of "up and down" is definitely settled. Figure 10 shows a stereo pair of a magnesium surface with MgO smoke on the replica.

## SILICA SUBSTRATES AND A POWDER DISPERSING TECHNIQUE

Structureless silica substrates have been found very useful as supports for a variety of electron microscope specimens. They can be prepared having a thickness of from <100 to 200A and are completely structureless and without holes or fibers. The films are structurally strong as compared to organic films, and may be subjected to very intense electron beams with a minimum of electron scattering, "charging up," and breakage. Microscope specimens may be heat treated at elevated temperatures for short periods of time while supported on silica substrates. They also can be successfully used as the support for specimens for electron diffraction transmission study.

These substrates are prepared by dipping a clean and dry microscope slide in a 2–5 percent solution of polystyrene in benzene and allowing to dry. The silica film is formed upon the lacquer film by the same technique as used for replicas except that 10 or 20 percent less silica is generally used. The films are removed in the same manner as other silica replica films and caught on standard electron microscope specimen screens. However, the silica films separate from the thin polystyrene film quite slowly, ½ hour to several hours usually being required.

Difficulties are occasionally met in preparing these films and they seem to be largely caused by improper thickness of the polystyrene film. For some inexplicable reason, if this film is too thick, the silica films are fragile, and if too thin, the silica films come loose from the lacquered slide with great difficulty or may not come loose at all.

FIG. 13. Polystyrene emulsion dispersed on a silica substrate, 7500×.

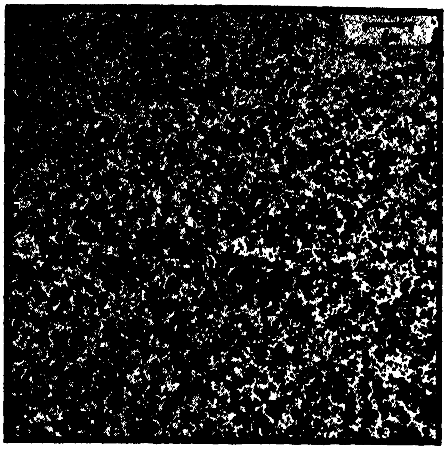

FIG. 14. Magnesium-aluminum alloy evaporated in vacuum and condensed on a silica substrate, 6500×.

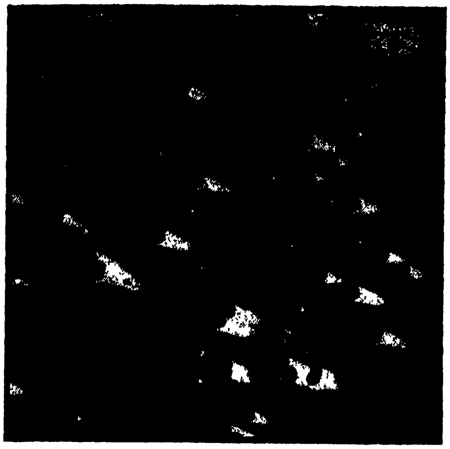

FIG. 16. Lampblack dispersed in ethyl cellulose on a silica substrate and shadowed with chromium, 3500×.

It appears that a 2–5 percent lacquer solution gives a film of optimum quality.

Precautions must also be taken to see that the lacquer is relatively moisture-free and the glass slide dry. Failure to observe these precautions may result in a cloudy lacquer film and substrates which show bubbles.

Many different particle dispersing techniques have been published[10, 11] which make it possible to determine accurately particle size and shape. Most of these techniques can be successfully used with silica substrates with improved results. A powder dispersing technique has been in use here for several years which has given excellent results on a wide variety of powdered materials ranging in size from <0.01 micron to several microns. This technique consists of dispersing the powder in an ethyl cellulose lacquer as a thick slurry, diluting and adding to the silica substrate. This is accomplished in practice by placing a few milligrams of the powder in a mortar and adding a drop or two or an ethyl cellulose lacquer consisting of 2 percent ethyl cellulose in 70 percent amyl acetate and 30 percent ethyl alcohol. The mixture is lightly ground with mortar and pestle to a thick slurry or paste during which time the dispersion of the particles actually takes place. Amyl acetate is then added slowly at first and the concentrated dispersion diluted to the proper concentration for adding to the silica substrate on a specimen screen. Tests have indicated that the effect of the grinding action upon the particle size and shape is negligible in specimens having a particle size of less than 5 microns.

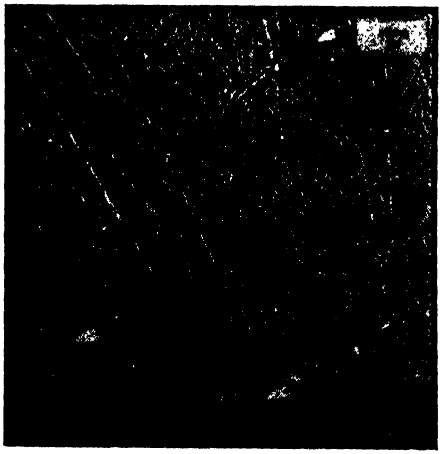

FIG. 15. Silica replica of a polished steel surface shadowed with chromium, 3500×.

Ability to judge the proper quantities and dilutions is readily obtained with a little experience. Generally the slurry dilution is about 1:50. Quantities should be varied so that the minimum thickness of dried ethyl cellulose is used, i.e., just sufficient to keep the particles firmly attached to the silica film. Figures 11 and 12 show typical particle dispersions obtained by this technique.

FIG. 17. Silica replica of a magnesium-nickel alloy showing not only a replica of the globular $Mg_2Ni$ particles but also some of the actual particles themselves on the silica replica film. The faithfulness of the technique in reproducing the size and shape of the particles is evident. Figure 3 also shows this same phenomenon on a smaller scale. Magnification 4000×

Silica substrates may also be used for supporting a variety of other types of specimens as illustrated by Figs. 13 and 14 showing an emulsion and an evaporated magnesium alloy. Emulsions are readily dispersed by diluting to the proper concentration and then adding a drop of the liquid to the substrate on a specimen screen.

## MISCELLANEOUS USES AND TECHNIQUES

Silica replicas and substrates have also been found to be useful in the field of heavy metal "shadow-casting."[12] This technique is probably not of great value on silica replicas for the purpose of improving contrast since silica replicas normally show considerable contrast. However, the technique has definite possibilities as a means of making elevation determinations without the use of stereoscopy.

Shadowing of silica replica films is probably best accomplished by evaporating the heavy metal upon the silica film while it is on the surface of the polystyrene molding. The films are then removed in the usual manner. Figure 15 shows an example of the "shadow-casting" of a polished steel specimen.

Shadowing of various electron microscope specimens supported on silica substrates is of definite value both from the point of view of improving contrast and of making elevation determinations. This technique is probably best accomplished by applying the polystyrene lacquer film to a glass slide, evaporating the silica, adding the specimen, "shadow-casting," and then removing the silica film in the usual manner. It seems advisable to use such a procedure rather than attempt the shadowing of the substrate and specimen while supported by the specimen screen. In this case the silica film may be uneven, making it a very poor target for accurate "shadow-casting." Figure 16 shows a specimen of lampblack "shadow-cast" in this above recommended manner.

A very interesting and often valuable use of silica replicas lies in the isolating of impurities and certain second phase elements or compounds from some metals. This occurs occasionally in metals which contain one or more elements or compounds which are present as a second phase and which are relatively insoluble in the etchant used during the surface preparation. Such constituents of the metal are often either left lying on the metal surface after etching or are protruding from the surface and only loosely attached to the metal. When polystyrene is molded against the metal surface and separated, these particular constituents are imbedded in the polystyrene and removed with it. When the silica evaporation is completed and the polystyrene dissolved, as the silica films are removed, the particles are often transferred to the silica replica and attached to it. As a result we find that in the electron microscope we see not only a replica of certain second phase constituents in the metal but also some of these particular constituents actually attached to the replica film. Figures 3 and 17 show examples of this phenomenon. Such materials can often be identified by transmission electron diffraction.

Occasionally one finds an electron microscope specimen in particle form which tends to sublime when subjected to the high vacuum and heat of electron bombardment in the microscope. This sublimation may be appreciably decreased by supporting the specimen on a silica substrate

---

[12] R. C. Williams and R. W. G. Wyckoff, J. App. Phys. 15, 712 (1944).

and then evaporating more silica over the surface of the specimen. Sulfur is a material which may be treated in this manner.

### CONCLUSIONS

1. Silica replicas of a variety of bulk materials such as metals, minerals, glasses, ceramics, resins, woods, etc., can be successfully prepared using a heat and pressure molded polystyrene impression plus evaporated silica.

2. Silica replicas can be successfully prepared from bulk materials which cannot tolerate either the temperatures or pressures of (1), by applying a heavy polystyrene lacquer, removing and evaporating silica upon the lacquer impression.

3. The question of "up and down" in stereo pictures of silica replicas can definitely be established by depositing a metal oxide smoke on the polystyrene impression before evaporation of the silica.

4. Structureless silica substrates are well suited as the supporting membranes for specimens such as powders, emulsions, metallic oxide smokes, thin evaporated films, bacteria, viruses, microtome sections, etc.

5. Excellent dispersions of powders from <0.01 to several microns in diameter may be obtained on silica substrates using an ethyl cellulose lacquer dispersing technique.

6. Heavy metal "shadow-casting" can be effectively applied to both silica replicas and silica substrates.

7. Isolation of metallic phases directly on silica replicas of metal surfaces is often useful in minutely examining and identifying these constituents.

# The X-Ray Storage Properties of the Infra-Red Storage Phosphor and Application to Radiography

O. E. Berg and H. F. Kaiser
*Naval Research Laboratory, Washington, D. C.*

(Received November 4, 1946)

An application of the characteristics of infra-red storage phosphors to radiography is described, whereby the expense and trouble of x-ray film processing may be partially or completely eliminated. The properties of these materials to store x-ray energy for periods of time and release that energy upon exposure to infra-red radiation have proved practical for either temporary and permanent recording of the latent x-ray image. One distinct feature of this method is the complete removal of harmful x-radiation to the technician. The possibility of a new field of radiography in "flash fluoroscopy" is also suggested by the authors. Graphs and charts exhibiting the characteristic behavior of infra-red phosphors to x-ray energy are included as well as actual photographs and radiographs comparing radiography with phosphorography.

The image storage phosphor was a research development required in war work as a practical and sensitive means for the detection of infra-red radiation. In the course of research[1] carried on to produce such phosphors it was found possible to produce phosphors which exhibited storage properties not only for visible light, but also for cathode rays, and x-rays. The optical characteristics of such materials have been described in papers of Roland Ward[2] and of N. F. Miller and C. E. Barnett.[3]

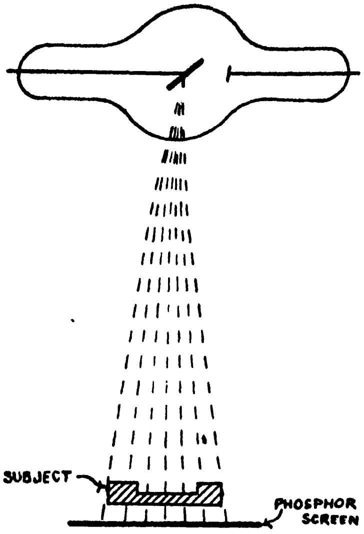

FIG. 1A.

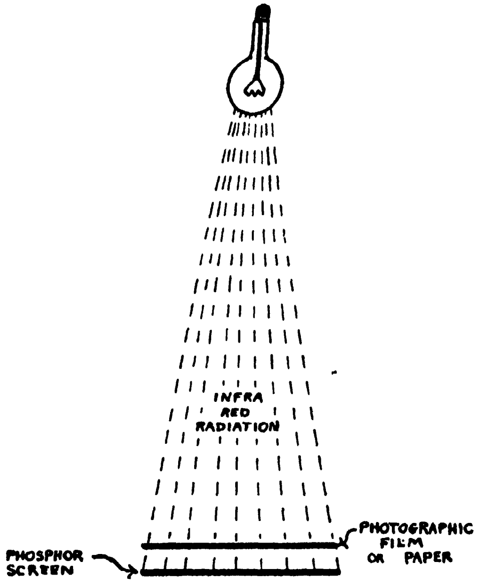

FIG. 1B.

Since no attempt had been made to study these materials for x-ray energy storage characteristics, the authors have carried out a series of experiments on materials kindly furnished by the Brooklyn Polytechnic for this purpose. The ability of these materials to save x-ray energy suggests their application to radiography as a possible substitute for the photographic emulsion for the retention of a latent image.

The ability of these materials to store radiant energy is not surprising in view of the fact that all phosphors exhibit such properties when cooled to liquid air temperature, exposed to an energy source to fill the electron traps and then warmed up, whereupon the freeing of electrons from the traps is indicated by bursts of light.[4]

Phosphors may be produced which store energy from x-rays, beta-rays, gamma-rays, and visible light and which hold this energy for indefinite periods of time. The energy is released, in the form of light varying from red to ultraviolet, by infra-red radiation with speed of release governed by intensity of the infra-red radiation. Figure 1A and B shows how these effects may be employed in radiography. The x-rays pass through the subject into the phosphor plate or screen, and by differential intensity record in detail thereon producing a latent image. This latent image is quite stable for many phosphors.

Then, in an adjoining room, away from harmful x-radiation, and at the convenience of the operator, the image is made visible to the eye by irradiating the plate with infra-red radiation. If a particular area of the image is of special interest to the technician, he may expose it separately with an infra-red spotlight (photographic masking technique is also applicable here). The length of viewing time of a phosphor plate may be determined from its energy decay rate graph shown in Fig. 2A which indicates the intensity of the released light as a function of time and intensity of the infra-red source.

When plotting light units against log time as in Fig. 2B, we get several linear portions indicating that the decay of luminescence is not of simple exponential character, but occurs in a set of several such processes. Light values are given as arbitrary light units measured by a 931A photo-cell multiplier with voltage regulators.

If a permanent record of the x-ray image is desired, it is an inexpensive and a simple task to expose the phosphor image directly to a sensitized paper (sensitive in the color region of the particular phosphor in use). Such a process eliminates the need for double emulsion x-ray film.

A 4"×5" experimental phosphor viewing plate was prepared according to the following procedure:

---

[4] "Characteristics of luminescent materials for cathode-ray tubes," J. Inst. Elec. Eng. 92, Part III, No. 20, 300 (December, 1945).

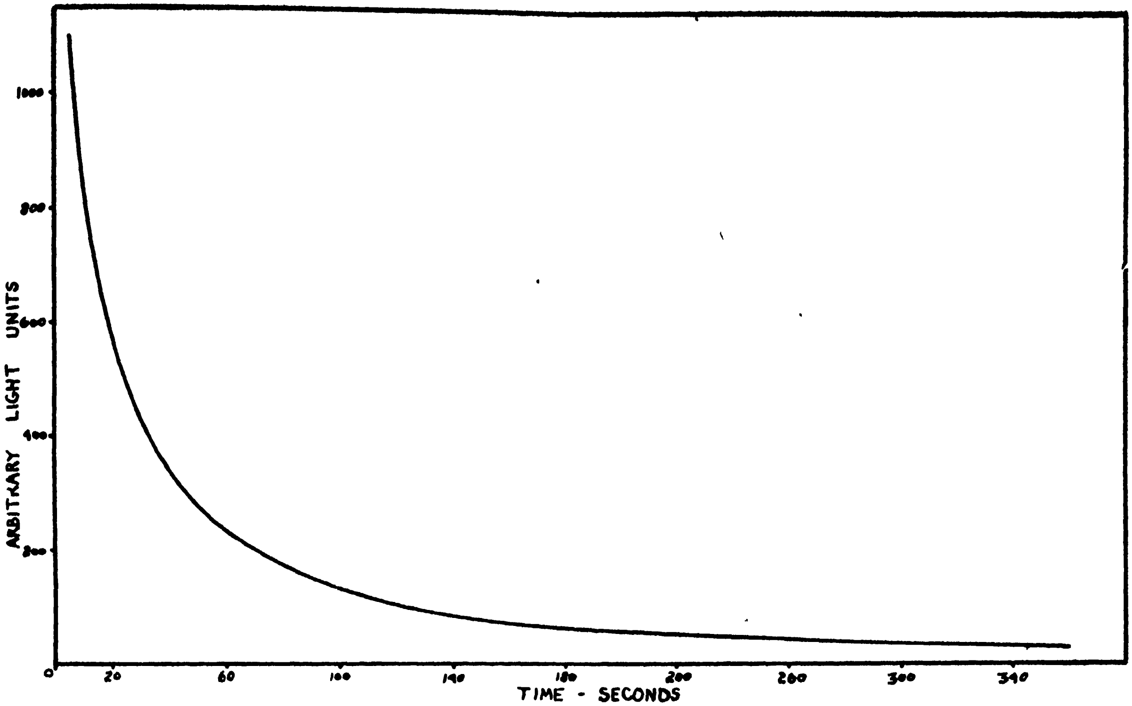

FIG. 2A.

While it might have been desirable to apply the phosphor to a thin cardboard base as for a fluorescent screen, because of the high processing temperatures involved, it was found necessary and advantageous to use a $\frac{1}{32}''$ steel plate with a thick silver plating. This base plate was not affected by high temperatures and its silver coating prevented chipping or peeling of the phosphor during experimentation.

Furthermore, silver plated steel is preferable to a paper base in that it serves as an absorbing medium for transmitted x-radiation after the x-rays have transversed the subject and the phosphor, thereby reducing scatter.

An emulsified mixture of phosphor, ethylene dichloride, and jasonite (plastic binder) was applied with a small artist's spray gun, and dried at 850°C to remove excess binder and render the phosphor active.[5] After a few experiments, it was found that a .020-inch coating of the phosphor was sufficiently thick to produce peak luminescence.

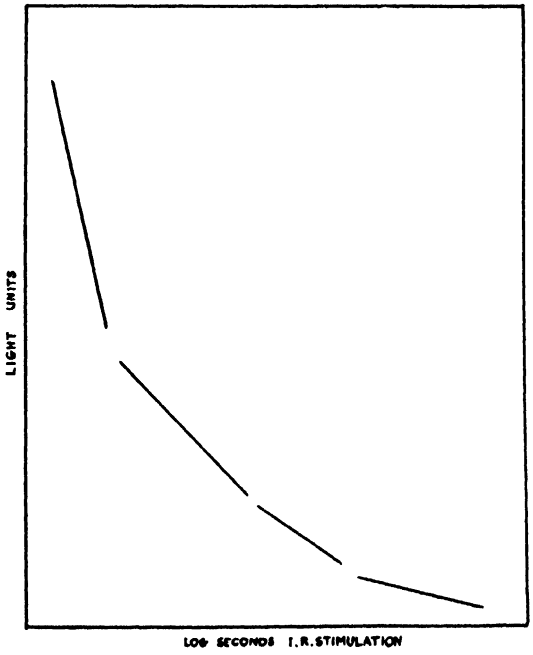

FIG. 2B.

Test exposures were made on the resultant plate at various kilovoltages and exposures. Figures 3 and 4 are comparative results of an x-ray film image and a phosphor image, respectively, of a 3-inch ammeter. It is an indication

---

[5] For further information on phosphor coating application see OSRD Report No. 5643.

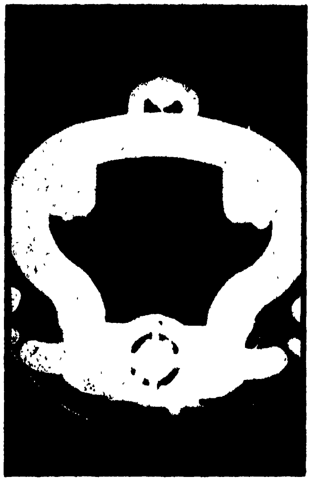

FIG. 3. Radiogram of 3 inch meter. X-ray exposure made on fine grain industrial x-ray film.

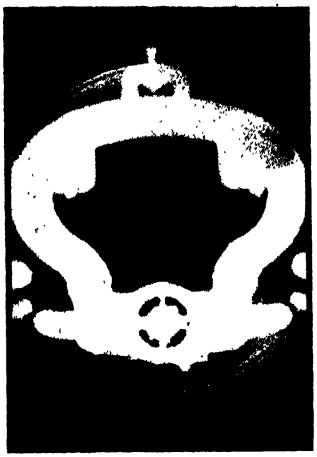

FIG. 4. Phosphorogram of 3-inch meter. Dark areas indicate uneven phosphor coating.

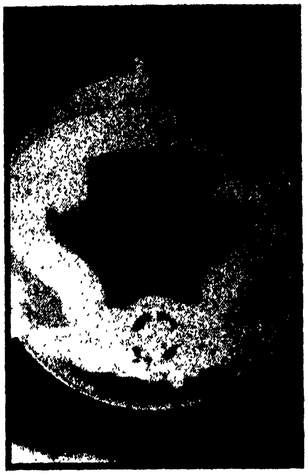

FIG. 5. Secondary film exposure to phosphor image of meter. Notice increased latitude and preservation of detail.

of the definition and latitude obtainable in a "phosphorogram."

An interesting and advantageous feature concerning latitude in this method of exposure is revealed in Fig. 5, another photograph of the same exposure after some diminution by previous

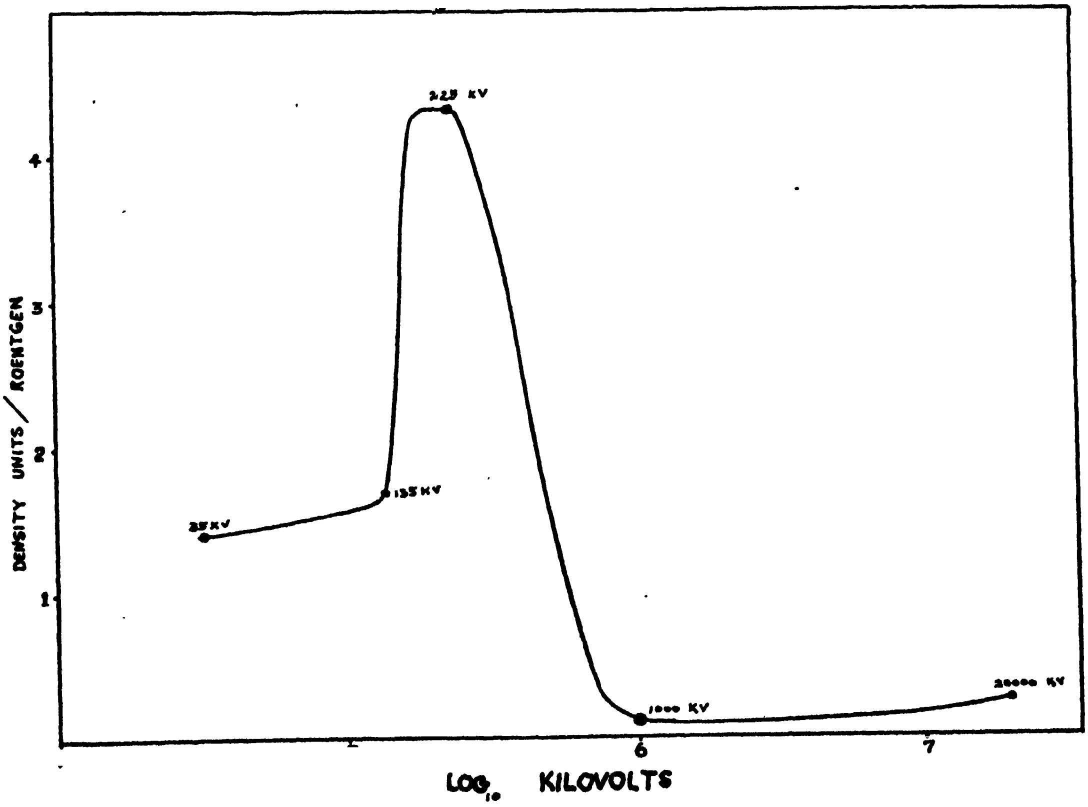

FIG. 6. The storage sensitivity curve in the x-ray region of the spectrum for one particular infra-red phosphor.

infra-red exposure. The definition is as sharp as before and areas that were overexposed (too brilliant) in the previous photographic exposure now appear in readable detail. The latitude of a phosphorogram is thus extensive and flexible. An overexposed plate can be irradiated with infra-red till it reaches a readable intensity. Likewise, an underexposed plate can be increased in intensity to a readable density by increasing the infra-red radiation.

Figure 6 shows the storage sensitivity curve in the x-ray region of the spectrum for a particular phosphor. Each type of storage phosphor has its own sensitivity curve and exhibits its own characteristic properties as well. Although a blue-green phosphor was used extensively in these experiments, it is now possible to obtain a phosphor for any color region in the visible spectrum. Blue-green is a comfortable color to the eye, but it is not the most efficient color for definition.

In general, the results of these experiments have revealed numerous possibilities of infra-red phosphors in radiography. Their properties, however, are not always advantageous.

Referring back to Figs. 3 and 4, we recognize the same undesirable characteristics of graininess and diffusion as in the fluorescent screen. This might be corrected to a large extent by more refined processing methods. Figure 2 shows another disadvantage—a reluctant release of stored energy, because of the exponential decay rate, which may handicap the speed of repeated exposures upon a given phosphor plate. For all practical purposes, however, the energy remaining in the phosphor after reasonable exposure to infra-red radiation is negligible and the contrast of the recorded image appears to diminish with time.

Phosphorography will not immediately replace the x-ray film nor the fluorescent screen. It will supplement these methods and be particularly valuable in special cases. For example: flash fluoroscopy will be possible with the high current condenser-discharge x-ray tubes, whereby an image made with a very short x-ray exposure of high intensity will be made immediately visible, and retained long enough for inspection or recording on paper or film.

Grateful acknowledgment is extended to Drs. R. E. Ward and R. T. Ellickson of the Polytechnic Institute of Brooklyn for their willing cooperation in supplying information and material for this work.

# A Flux Plotting Method for Obtaining Fields Satisfying Maxwell's Equations, with Applications to the Magnetron

PRESCOTT D. CROUT
*Radiation Laboratory,* Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received September 13, 1946)

In this report the flux plotting methods which have previously been applied to fields satisfying Laplace's and Poisson's equations are extended to fields satisfying Maxwell's equations. Application is made to the hole and slot, and vane types of magnetron tubes.

## 1. INTRODUCTION

"FLUX plotting" is a procedure for drawing two mutually orthogonal families of curves in such a way that the rectangles so formed have a specified geometric shape at each point. This shape is so determined that the curves represent a field which satisfies a specified partial differential equation. This equation, which characterizes the field, is not used directly, but it or its equivalent is used only indirectly to determine the geometrical condition that is used in actually constructing the plot. Flux plotting procedures for obtaining fields satisfying Laplace's equation, Poisson's equation, and certain other equations have been devised and applied successfully to wide varieties of problems.[1] The purpose of this paper is to extend these methods to fields characterized by Maxwell's equations. In so doing we do not use these equations directly, but use Ampere's law and Faraday's law instead. These laws together with Stoke's theorem evidently give Maxwell's equations. Some familiarity with flux plotting methods is assumed.

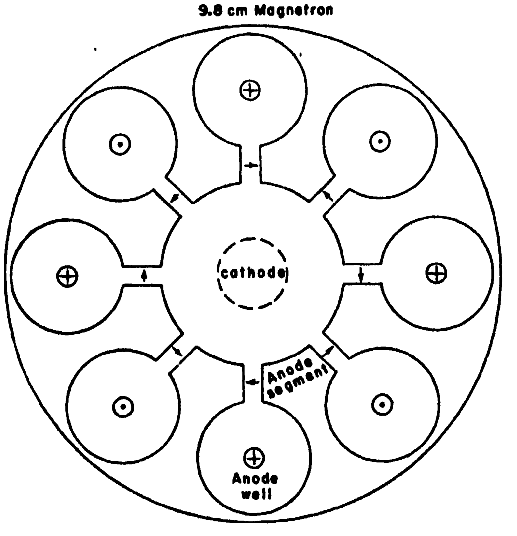

FIG. 1. Cross section of hole and slot type magnetron. Magnetic field is axial (perpendicular to the plane of the paper). Its directions in the anode wells at a certain instant are shown by the circles ⊕ and ⊙. Electric field is across the gaps between the anode segments. Its directions at a certain instant are shown by the arrows.

For the sake of clarity the new method will be described in connection with the specific application which gave rise to it—that of an infinite, hole and slot type magnetron, a cross section of which is shown in Fig. 1, operating in its main mode ($+ - + -$ or $\Pi$ mode).[2] Later in Section 6 application is made to the vane type magnetron. All fields are sinusoidally alternating. The electric current which links each anode well (cavity) and passes across the gap between two adjacent anode segments produces the axial magnetic field in the well (Ampere's law); also the rate of change of this axial magnetic field produces the voltage which maintains the electric current (Faraday's law). Because of symmetry we need consider only the field which lies between two axial planes which bisect, respectively, an anode segment and an anode well, Fig. 2.

## 2. NATURE AND CONSTRUCTION OF THE FLUX PLOT

The peak electric field is shown in Fig. 2 by means of a number of electric lines of force, which divide the region into corresponding tubes of flux; and a number of lines of no work, which are orthogonal to the lines of force, and which divide the region into corresponding strips. The peak magnetic field is perpendicular to the plane of the paper. Let the various tubes and strips be numbered consecutively as indicated, and let

$L_{ij}$ = length of elementary rectangle common to $i$th tube and $j$th strip measured along a line of force through the center;
$W_{ij}$ = width of elementary rectangle common to $i$th tube and $j$th strip measured along a line of no work through the center;
$A_{ij}$ = area of elementary rectangle common to $i$th tube and $j$th strip;
$\sigma_i\phi$ = electric flux in the $i$th tube, $\phi$ being the arbitrarily chosen flux per unit tube; (1)
$E$ = electric intensity = electric flux density since dielectric constant = 1;
$H$ = magnetic intensity = magnetic flux density since permeability = 1;
$\omega$ = angular frequency;
$c$ = velocity of light.

### Gaussian units are used throughout

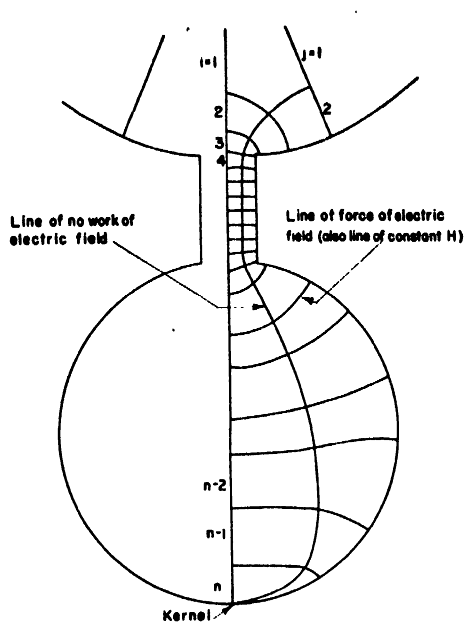
We shall first consider the equilibrium of an elementary rectangle, and shall leave till later the consideration of the elementary triangles which occur at the "kernel" or point of intersection of the lines of no work. The total peak displacement current flowing outside (on the cathode side) of the center of rectangle $ij$ is[3]

$$\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)\frac{\phi\omega}{4\pi};\tag{2}$$

hence, noting Ampere's law, we see that the value of $H$ at this point is independent of $j$, and is given by

$$\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)\frac{\phi\omega}{c}.\tag{3}$$

The total magnetic flux in the $j$th strip between the center of rectangle $ij$ and the kernel is therefore



i=1
j=1

Kernel

FIG. 2. Electric field in hole and slot type magnetron.

$$\frac{\phi\omega}{2c}\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)A_{ij}+\frac{\phi\omega}{c}\sum_{l=i+1}^{n-1}\left(\tfrac{1}{2}\sigma_l+\sum_{k=1}^{l-1}\sigma_k\right)A_{lj}+\frac{\phi\omega}{c}\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)A_{nj},\tag{4}$$

where

$A_{ij}=L_{ij}W_{ij}$ for *rectangle ij*,
$L_{nj}$ = base of triangle in $j$th strip,
$W_{nj}$ = altitude of triangle in $j$th strip,
$A_{nj}$ = area of triangle in $j$th strip = $(L_{nj})_{\text{average}}W_{nj}$, (5)
$\alpha_j$ = fraction of $W_{nj}$ from the last line of force to the center of gravity of the last triangle (equals $\frac{1}{3}$ for triangles with straight sides).

By using the center of gravity as the point at which to evaluate $B$ in an elementary rectangle or triangle, multiplication of this value of $B$ by the elementary area gives the flux exactly if the surface which represents $B$ is a plane, regardless of whether or not that plane is horizontal ($B$ constant). The first term in (4) gives the peak magnetic flux in half of rectangle $ij$, whereas the last gives that in the triangle.

---

[3] From here on the word "peak" will be omitted, it being understood that all quantities are peak values of sinusoidally varying quantities. Complex notation can be used if desired, in which case the magnetic intensity will be purely imaginary.

Noting Faraday's law we see that the electric flux in the $i$th tube can be obtained from the rate of change of the magnetic flux given by (4), thus

$$\sigma_i\phi=\left\{\frac{\phi\omega}{c}\left[\tfrac{1}{2}\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)A_{ij}+\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)A_{nj}+\sum_{l=i+1}^{n-1}\left(\tfrac{1}{2}\sigma_l+\sum_{k=1}^{l-1}\sigma_k\right)A_{lj}\right]\right\}\frac{\omega W_{ij}}{cL_{ij}}. \tag{6}$$

Here the brace is the magnetic flux given by (4), which with $\omega$ gives the rate of change of this flux, or the induced voltage in abvolts.[8] Division by $cL_{ij}$ gives the electric intensity in statvolts/cm, and multiplication by $W_{ij}$ gives the total electric flux in the rectangle, which must equal $\sigma_i\phi$. Cancelling $\phi$ and transposing, (6) becomes

$$\frac{L_{ij}\sigma_i}{W_{ij}}=\left(\frac{\omega}{c}\right)^2\left\{\tfrac{1}{2}\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)A_{ij}+\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)A_{nj}+\sum_{l=i+1}^{n-1}\left(\tfrac{1}{2}\sigma_l+\sum_{k=1}^{l-1}\sigma_k\right)A_{lj}\right\}, \tag{7}$$

which is the desired equilibrium condition for the *rectangle*.

We shall next obtain the equilibrium condition for a triangular area at the kernel. Let the triangular area Fig. 3 be broken up into elementary bands of constant width $dx$ by a suitable family of curves, $x$ being measured along the orthogonal trajectory which passes through the center of gravity. We shall suppose that $H$ is essentially constant over the triangle, its value $H_0$ being taken as that at the center of gravity; also we shall suppose that the length of the elementary band at $x$ is given closely by

$$L=Kx^m, \tag{8}$$

where $K$ and $m$ are constants. The total magnetic flux in the triangle from the vertex to the elementary band is

$$\int_0^x H_0Kx^m dx=\frac{H_0Kx^{m+1}}{m+1};$$

hence the electric intensity at the band is

$$\left(\frac{1}{Kx^m}\right)\left(\frac{H_0Kx^{m+1}}{m+1}\right)\left(\frac{\omega}{c}\right), \tag{9}$$

in which the last two factors give the voltage across the band. Integrating (9) we obtain $\sigma_n\phi$, the total electric flux in the triangle, thus

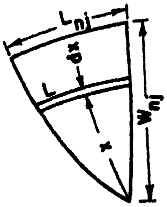

FIG. 3. Triangular area at kernel.

$$\sigma_n\phi=\int_0^{W_{nj}}\frac{H_0\omega x}{c(m+1)}dx=\frac{H_0\omega W_{nj}^2}{2c(m+1)}. \tag{10}$$

Noting the last term of (4) we replace $H_0$ by its value

$$\frac{\phi\omega}{c}\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right), \tag{11}$$

and obtain, after cancelling $\phi$ and transposing,

$$W_{nj}^2=\frac{2(m+1)\sigma_n}{\left(\frac{\omega}{c}\right)^2\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)}. \tag{12}$$

Dividing the left hand side by $L_{nj}W_{nj}$, and the right by its equal $KW_{nj}^{m+1}$, and noting that

$$A_{nj}=KW_{nj}^{m+1}/(m+1),$$

we finally obtain

$$\frac{L_{nj}\sigma_n}{W_{nj}}=\frac{1}{2}\left(\frac{\omega}{c}\right)^2\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)A_{nj}, \tag{13}$$

which is the desired equilibrium condition for the *triangle*. We note that this expression contains neither $K$ nor $m$; also, in comparing (13) with (7) we note the presence of the factor $\frac{1}{2}$ in (13).

As usual with flux plotting methods, the actual process of making the plot is one of systematic trial and error. The choice of the $\sigma_i$'s is a matter of convenience. If $\sigma_i$ is put equal to one, the $i$th tube is a unit tube; however, at the edge of the plot and in the weaker parts of the field it is desirable to use fractional tubes so that more lines show on the plot.

In constructing the plot a step-by-step process can be used whereby the values of $L_{ij}$, $W_{ij}$, and $\sigma_i$ taken from one approximate plot are placed in (7) and (13) to obtain improved values of $L_{ij}/W_{ij}$ and $\sigma_i$, which are then made the basis of the plot which constitutes the next approximation. The first plot would be largely assumed from physical considerations. One step of the step-by-step process will now be described.

First we note that the $\sigma_i$'s associated with a plot may be multiplied by any constant without altering the plot. This is evident from (7) and (13), and also from the fact that the effect is merely to magnify the field strength. Values of $L_{ij}$, $W_{ij}$, and $\sigma_i$ taken from the given approximate plot are now placed in the right hand sides of (7) and (13) to give for each rectangle or triangle the value of $L_{ij}\sigma_i/W_{ij}$ to be used in constructing the next approximate plot.[4] In so doing the unknown factor $(\omega/c)^2$ is replaced by an arbitrary constant multiplier $k$; hence the values obtained are of the form $k\beta_{ij}$ where the $\beta_{ij}$'s are computed numbers. Dividing by the measured values of $L_{ij}/W_{ij}$ we obtain a set of values of $k\beta_{ij}W_{ij}/L_{ij}$, which we denote by $\bar{\sigma}_{ij}$. If $k$ can be chosen so that $\bar{\sigma}_{ij}=\sigma_i$ for all rectangles and triangles, then this value of $k$ can be taken as $(\omega/c)^2$, all conditions are satisfied, and the given plot is final. Actually this cannot be done except with the final plot; hence in general we choose the new set of $\sigma_i$'s so that $\sigma_i$ approximates all the $\bar{\sigma}_{ij}$'s in the $i$th tube. Since $\sigma_i$ is of the form $k\gamma_i$ this is equivalent to choosing $\gamma_i$ so as to approximate all the values of $\beta_{ij}W_{ij}/L_{ij}$ in the $i$th tube. This can be done by choosing an average value or perhaps better, a weighted average with the areas as weighting factors. Dividing the computed values of $L_{ij}\sigma_i/W_{ij}$, namely $k\beta_{ij}$, by these new values of $\sigma_i$ we obtain the values $\beta_{ij}/\gamma_{ij}$, which we use as a new set of $L_{ij}/W_{ij}$ values in constructing the new plot.[4] We note that these are independent of $k$, which may be given any convenient numerical value.

The step-by-step process ends when a value of $k$ can be chosen for which $\bar{\sigma}_{ij}=\sigma_i$ for all rectangles and triangles, this value being $(\omega/c)^2$, as stated above.[5] The most accurate value of $\omega/c$ is probably given by equating the total electric energy to the total magnetic energy obtained from the final plot, as described in Section 4.[3]

### 3. ALTERNATIVE PROCEDURE USING A PLANIMETER

Let

$s_j$ = distance from the kernel measured along a line of no work at the center of the $j$th strip, (14)

$\Phi=\sigma\phi$ = total electric flux outside of the line of force at $s_j$. Here $\phi$ is again the arbitrarily chosen "normal" flux per tube.

$A_j$ = area of $j$th strip from the kernel to $s_j$;

then proceeding as with (3), noting Ampere's law, the magnetic flux density for any $s_j$ is

$$\Phi\omega/c=\sigma\phi\omega/c. \tag{15}$$

The total magnetic flux in $A_j$ is therefore

$$\frac{\omega\phi}{c}\int_0^{A_j}\sigma dA_j,$$

it being permissible to consider $\sigma$ a function of $A_j$ since both $\sigma$ and $A_j$ are functions of $s_j$. Continuing as with (6), noting Faraday's law, we multiply by $\omega/c$ to obtain the voltage

$$\phi\left(\frac{\omega}{c}\right)^2\int_0^{A_j}\sigma dA_j \tag{16}$$

across the strip at $s_j$. Choosing for $s_j$ the value at the center of the $i$th tube, dividing by $L_{ij}$ to obtain the electric intensity, and multiplying by $W_{ij}$ we obtain the flux $\sigma_i\phi$ of the tube, thus

$$\sigma_i\phi=\phi\left(\frac{\omega}{c}\right)^2\frac{W_{ij}}{L_{ij}}\int_0^{\bar{A}_{ij}}\sigma dA_j,$$

where $\bar{A}_{ij}$ is the strip area to the center of the $i$th tube. Cancelling $\phi$ and transposing we ob-

---

[4] Each computed value of $L_{ij}\sigma_i/W_{ij}$ is associated with the center of its rectangle or the center of gravity of its triangle, respectively. If the center of a new rectangle differs appreciably from that of the old, interpolation in this field of values may be necessary. The same is true of triangles.

[5] From the derivation of (7) and (13) or, later, of (17) and (18) it is evident that the above method of successive substitutions is equivalent to using the first approximate electric field to determine the corresponding magnetic field, corresponding to which, in turn, is obtained an electric field, which is taken as the second approximation—and so on. A method of successive substitutions may not be desirable in some cases, in which the new set of $L_{ij}/W_{ij}$ values may be chosen arbitrarily after comparing the new values computed as above with those of the preceding plots.

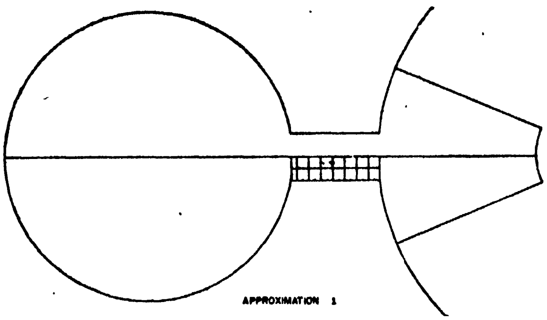

FIG. 4. Electric field in hole and slot type magnetron. Approximation 1.

tain finally

$$\frac{L_{ij}\sigma_i}{W_{ij}}=\left(\frac{\omega}{c}\right)^2\int_0^{A_{ij}}\sigma dA_j, \tag{17}$$

which is the desired equilibrium condition for a *rectangle.*

We shall now derive a condition analogous to (17) which can be applied to the triangles at the kernel. Denoting by $\mathcal{E}_j$ the voltage, given by (16), across the strip at the base of the $j$th triangle, and noting from (9) that for any approximating function $Kx^m$ for triangle width the field intensity varies linearly with $x$, we have for the total electric flux in the triangle

$$\sigma_n\phi=\frac{\mathcal{E}_j}{L_{nj}}\int_0^{W_{nj}}\frac{x}{W_{nj}}dx=\frac{\mathcal{E}_jW_{nj}}{2L_{nj}},$$

or, substituting from (16), cancelling $\phi$, and transposing,

$$\frac{L_{nj}\sigma_n}{W_{nj}}=\frac{1}{2}\left(\frac{\omega}{c}\right)^2\int_0^{A_{nj}}\sigma dA_j, \tag{18}$$

where the upper limit of the integral is the area of the triangle. This is the desired equilibrium condition for the *triangle.* In contrast to (17) we note the factor $\frac{1}{2}$ in (18), also the fact that $L_{nj}$ and $W_{nj}$ are the base and altitude of the triangle, respectively.

In applying (17) and (18) a convenient set of $\sigma_i$'s for the various tubes is chosen, and $A_j$ is obtained with a planimeter for values of $s_j$ corresponding to lines of force on the plot. These values of $A_j$ are then plotted against the corresponding known values of $\sigma$. This curve gives $\sigma$ as a function of $A_j$; hence a planimeter or approximate integration can be used to give the integrals in (17) and (18). Such a curve is drawn for each strip.

The step-by-step process described at the end of Section 2 evidently applies here, (17) and (18) being used instead of (7) and (13). As before $\omega/c$ is not determined until the final plot has been made, after which $\omega/c$ is obtained by equating the total electric and magnetic energies as described in Section 4.

## 4. ELECTRIC AND MAGNETIC FIELD ENERGY. DETERMINATION OF $\omega/c$

In any strip the electric flux passing through an elementary band bounded by two lines of force is $\phi d\sigma$. Dividing by $ds_j$ we obtain the electric intensity. The total electric energy in the strip is therefore[6]

Electric energy in $j$th strip

$$=\frac{\phi^2}{8\pi}\int_0^{A_j}\left(\frac{d\sigma}{ds_j}\right)^2dA_j. \tag{19}$$

Noting (15) we also have

Magnetic energy in $j$th strip

$$=\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\int_0^{A_j}\sigma^2dA_j. \tag{20}$$

Using the method of Section 3 a curve of $\sigma$ as a function of $s_j$ can be plotted, and $d\sigma/ds_j$ obtained by approximate differentiation; also a curve of $\sigma$ as a function of $A_j$ is already available.[7] The integrals in (19) and (20) can hence be obtained

---

[6] The expression for electric energy obtained by means of the magnetic field using (16) merely duplicates (20), as is shown by the following.

Electric energy in $j$th strip

$$=\frac{1}{2}\int_0^{\sigma}\left[\phi\left(\frac{\omega}{c}\right)^2\int_0^{A_j}\sigma dA_j\right]\frac{\phi d\sigma}{4\pi}$$

$$=-\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\int_0^{A_j}\left[\int_0^{A_j}\sigma dA_j\right]\frac{d\sigma}{dA_j}dA_j.$$

Integrating by parts noting that $\sigma=0$ when $A_j$ takes its greatest value, this becomes

Electric energy in $j$th strip

$$=-\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\left\{\left[\sigma\int_0^{A_j}\sigma dA_j\right]_0^{A_j}-\int_0^{A_j}\sigma^2dA_j\right\}$$

$$=\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\int_0^{A_j}\sigma^2dA_j,$$

which is (20).

[7] Tables for approximate differentiation are given in Crout, "An application of polynomial approximation to the solution of integral equations arising in physical problems," J. Math. and Phys. 19, 34 (1940).

using a planimeter or approximate integration. Adding the energies of the various strips the total electric energy and the total magnetic energy can be obtained, both being proportional to $\phi^2$. Equating these, $\phi^2$ cancels out, and we have

$$\frac{\omega}{c}=\left[\frac{\sum^{j}\int_0^{A_j}\left(\frac{d\sigma}{ds_j}\right)^2 dA_j}{\sum^{j}\int_0^{A_j}\sigma^2 dA_j}\right]^{\frac{1}{2}}, \qquad (21)$$

the upper limits on the integrals being the strip areas, and the summations being over the strips. This method of determining $\omega/c$ reminds one of Raleigh's method in elastic vibration problems, and offers probably the most accurate way of using the flux plot to obtain the resonance frequency.

We shall finally obtain expressions for the electric and magnetic energies which are applicable if the individual rectangles and triangles are considered separately, as in Section 2. The electric energy in a rectangle is evidently

Electric energy in rectangle

$$=\frac{1}{2}\left(\frac{\sigma_i\phi}{4\pi}\right)\left(\frac{\sigma_i\phi L_{ij}}{W_{ij}}\right)=\frac{\sigma_i^2\phi^2 L_{ij}}{8\pi W_{ij}}; \qquad (22)$$

also, noting (3), the magnetic energy of a rectangle is seen to be

Magnetic energy in rectangle

$$=\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\left(\tfrac{1}{2}\sigma_i+\sum_{k=1}^{i-1}\sigma_k\right)^2 L_{ij}W_{ij}. \qquad (23)$$

From (9) it follows that in a triangle the electric intensity is of the form $K_1x$ where $K_1$ is a constant. $K_1$ can be determined by the relation

$$\sigma_n\phi=\int_0^{W_{nj}}K_1x\,dx=\frac{K_1W_{nj}^2}{2},$$

whence the electric intensity becomes

$$E_{nj}=\frac{2\sigma_n\phi x}{W_{nj}^2}.$$

The electric energy in the triangle is therefore, noting (8),

Electric energy in triangle

$$=\frac{1}{8\pi}\int_0^{W_{nj}}\left[\frac{2\sigma_n\phi x}{W_{nj}^2}\right]^2 Kx^m dx$$

$$=(\sigma_n\phi)^2 K W_{nj}^{m-1}/2\pi(m+3),$$

Electric energy in triangle $\qquad (24)$

$$=(\sigma_n\phi)^2 L_{nj}/2\pi(m+3)W_{nj},$$

where $L_{nj}$ and $W_{nj}$ are the base and altitude of the triangle, respectively, and $K$ and $m$ are the values applicable to the $j$th triangle.

In the triangle the magnetic field is closely equal to the constant value (11); hence the magnetic energy is closely

Magnetic energy in triangle

$$=\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)^2\int_0^{W_{nj}}Kx^m dx$$

Magnetic energy in triangle $\qquad (25)$

$$=\frac{\phi^2}{8\pi}\left(\frac{\omega}{c}\right)^2\left(\alpha_j\sigma_n+\sum_{k=1}^{n-1}\sigma_k\right)^2\frac{L_{nj}W_{nj}}{(m+1)}.$$

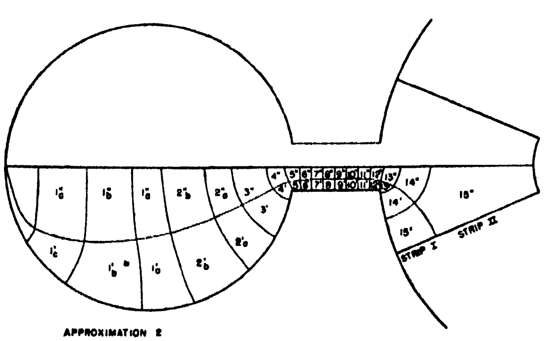

FIG. 5. Electric field in hole and slot type magnetron. Approximation 2.

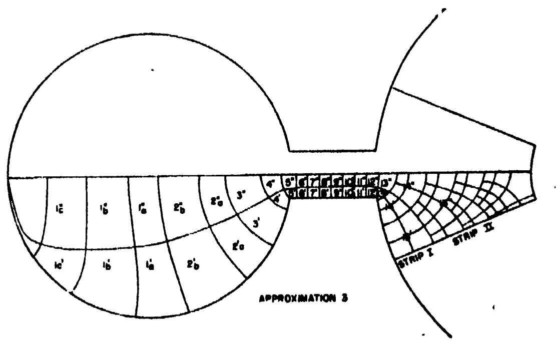

FIG. 6. Electric field in hole and slot type magnetron. Approximation 3.

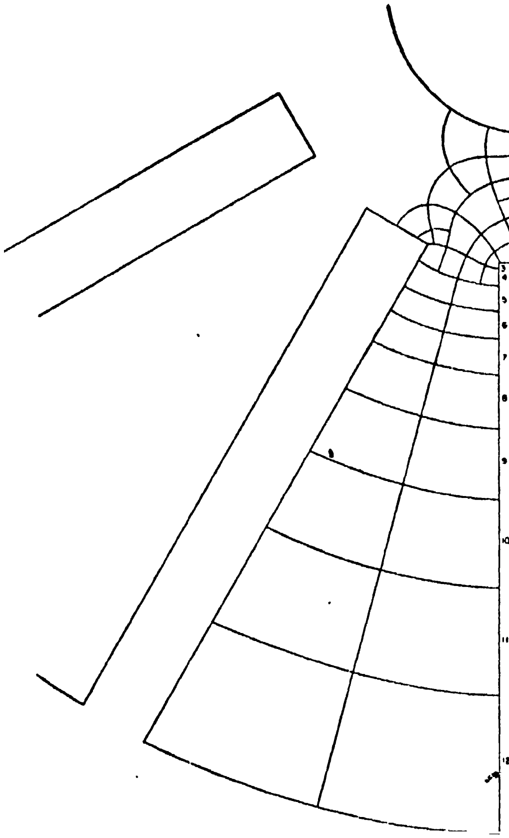

FIG. 7. Electric field in vane type magnetron.

### 5. APPLICATION TO A SPECIFIC PROBLEM. HOLE AND SLOT TYPE MAGNETRON

The procedure used to obtain the field in the cavity shown in Fig. 2 will now be outlined.[8] The approximation that was used for the electric field in order to get the step-by-step process started was a uniform electric field in the gap between two adjacent anode segments, the electric field being taken as zero everywhere else, Fig. 4. Data from this first approximation are now inserted in the right-hand sides of (17) and (18) as described in Section 3 to obtain corrected data for the plot which constitutes the second approximation. In so doing we note that $\sigma$ is zero in the anode-cathode region, and increases linearly through the gap to a value which remains constant in the well. It follows that $\int_0^{\bar{A}_{ij}}\sigma dA_j$ and hence the computed values of $L_{ij}\sigma_i/W_{ij}$ are constant in the anode-cathode region, and that in the well $L_{ij}\sigma_i/W_{ij}$ and $L_{nj}\sigma_n/W_{nj}$ are proportional, respectively, to $\bar{A}_{ij}$ and $A_{nj}/2$. The flux plot which constitutes the second approximation was begun at the inner (cathode) side of the gap, the work being carried both inward and outward from this point. We note that in the anode-cathode region this plot can be a lattice of curvilinear squares, which gives a field satisfying Laplace's equation since $L_{ij}\sigma_i/W_{ij}$ is constant in this region; also we note that the choice of the $\sigma_i$'s is a matter of convenience. The second approximation is shown in Fig. 5.[9]

Continuing the step-by-step process, data from this second approximation are now inserted in (17) and (18) to obtain data for a third approximation. In so doing each new value of $\sigma_i$ is taken as the average of the $\bar{\sigma}_{ij}$'s of the elementary areas in the $i$th tube. After the third approximation, Fig. 6, was obtained, it was found that the ratio of $\sigma_i$ to $W_{ij}\beta_{ij}/L_{ij}$ was constant for all the elementary areas to within the accuracy expected of the graphical process. This third approximation, Fig. 6, was therefore taken as the final result, the constant ratio being $(\omega/c)^2$. The frequency corresponding to the value so obtained for $\omega/c$ is $2.818\cdot 10^9$ c.p.s.; that obtained by equating electric and magnetic energies using (21) was $2.825\cdot 10^9$ c.p.s. The various tube dimensions were

| | |

The values of the $\sigma_i$'s for the final plot, Fig. 6, are shown in Table I.

### 6. APPLICATION TO A SPECIFIC PROBLEM. VANE TYPE MAGNETRON

If the shape of the electric field is known approximately, the work required to obtain a plot can be greatly reduced.[10] For example in the

---

[8] The work outlined in this section including that involved in constructing the flux plots shown in Figs. 5 and 6 was done by Mr. F. S. Holt.

[9] The labels shown in Figs. 5 and 6 are those that were used in making the plot. The strips are indicated by primes, the tubes are numbered, and subdivisions are indicated by letters or, if obvious, are not indicated. This notation differs from that used in the derivation of (7), (13), (17), and (18); but is convenient for actual construction.

[10] The work outlined in this section including that involved in constructing the flux plot Fig. 7 was done by Mr. F. E. Bothwell.

vane type magnetron, Fig. 7, the electric lines of force in most of the region between the vanes evidently approximate arcs of circles centered at the cathode; also in the anode cathode region, where the magnetic field is weak, the electric field approximates a solution of Laplace's equation. With these facts in mind Fig. 7 was drawn for the case where the cathode and all vanes but one are at the same voltage, no attempt being made to satisfy (7). Omitting the line of no work let us temporarily consider the field as occupying a single strip; then Eqs. (7) form a set of twelve homogeneous, linear, algebraic equations for the $\sigma_i$'s. These can be conveniently solved by successive substitutions by first placing all $\sigma_i$'s on the right-hand side of (7) equal to unity. The $\sigma_i$'s so obtained are inserted in the right-hand sides of (7) to give the next approximation, and so on. In each step the $k$ which replaces $(\omega/c)^2$ was given that value which would make the average of the computed $\sigma_i$'s equal to unity. This method of successive substitutions has the physical significance described in footnote 5; its convergence was rapid, and the results obtained are shown in Table II. When put equal to $(\omega/c)^2$ the last obtained value of $k$ corresponds to a wave-length of 2.6200 cm. The (probably) more exact value obtained by equating total electric and magnetic energies as described in Section 4 is 2.6456 cm.

Let us finally try to improve the accuracy of the plot by subdividing and proceeding as in Section 5. We therefore draw the line of no work that was omitted above; and, placing the $\sigma_i$'s of Step 5 in the right-hand side of (7), determine a new set of values $L_{ij}/W_{ij}$. These new values, however, duplicate the old values in all tubes except the first four, in which there is a discrepancy of one percent. Since $L_{ij}$ and $W_{ij}$ cannot be measured to within one percent, no alteration of the plot is indicated, and it is therefore taken as final. It is probable that the procedure used in this section on the vane type magnetron can be used to advantage on the hole and slot type magnetron considered in Section 5.

# A Magnetron Oscillator for Dielectric Heating

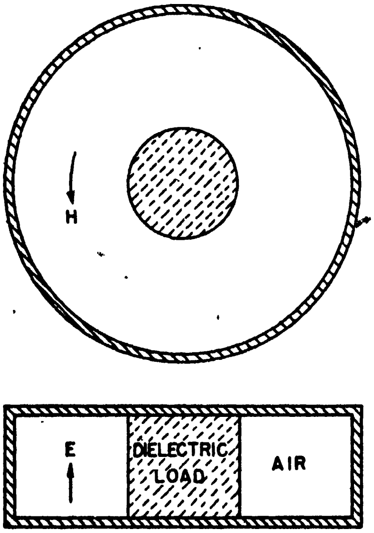
R. B. Nelson
*Research Laboratory, General Electric Company, Schenectady, New York*

(Received January 31, 1947)

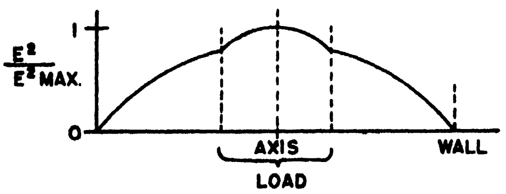
Magnetron oscillators can provide very high frequency power for dielectric heating. Factors determining the choice of frequency for particular jobs are discussed. The design of a magnetron having 5 kw continuous output at 1050 megacycles is described, and performance data on the tube are given.

## INTRODUCTION

THE method of heating non-conducting materials by dielectric loss in a high frequency electric field is becoming an important industrial process. Many of the materials heated by this method, such as plastics, are of such low loss that it is hard to heat them as rapidly as desired. The rate of heating increases with the electric field strength and, in practically all materials, with the frequency. Since the usable field is definitely limited by arcing between the electrodes, the only remaining way to speed up the heating process is to increase the frequency.



GEOMETRY OF CAVITY AND LOAD



RADIAL VARIATION OF FIELD

FIG. 1. Distribution of heating in cylindrical load. In a simple cylindrical cavity where the electric field is produced by radial currents in the walls, the r.m.s. field is a maximum at the center and decreases radially as a Bessel function. The rate of decrease depends upon the wave-length in the dielectric, giving the discontinuity in slope of the curve of $E^2$ plotted against radial distance. Rate of production of heat per unit volume is proportional to $E^2$.

Commercial dielectric heaters have been restricted to frequencies below about 40 megacycles by the limitations of available vacuum tubes. However, the recent development of magnetron oscillators has made available considerable power at frequencies up to some 10,000 megacycles. Using magnetrons for heating thus allows the choice of almost any desired frequency.

## CHOICE OF FREQUENCY

It must not be assumed that the highest frequencies are always best. While heating rates go up with frequency, a point is reached where non-uniformity of heating limits the usable frequency. Two effects contribute to non-uniformity. First, in the case of high loss materials such as most foods, there is the decreased heating toward the center of large objects because the power is absorbed by the surface layers before it can penetrate. Second, in the case of low loss materials such as plastics, the wave-length of the heating power limits the volume of material that may be heated uniformly. To apply power efficiently to low loss material, it is necessary to surround the material with reflecting walls so that the electromagnetic wave passing through it is not radiated and lost after one passage. The reflecting walls set up a standing wave in and around the load material. This wave has in general a three-dimensional space variation of electric field, with periodic maxima and minima.

Since the dielectric heating at any point is proportional to the square of the electric field strength, widely varying temperatures will be produced in the material if its dimensions are comparable with a wave-length. As an example of how the standing-wave pattern limits the usable frequency, consider a cylinder of load material located axially in a cylindrical resonant cavity, as shown in Fig. 1. Exciting the cavity in its lowest mode with axial electric field, the field is a maximum at the center and falls off radially as

$$E = E_{\max} J_0(6.28r/\lambda),$$

where $E$ is the electric field strength at radius $r$ from the axis, $E_{\max}$ is the field on the axis, and $\lambda$ is the wave-length in the material. If it is required to heat the edges of the load 90 percent as much as the center,

$$E^2/E_{\max}^2 = J_0^2(6.28r/\lambda) \geqq .90 \text{ at the edges,}$$

and solving the above equation for a load of radius $a$

$$a \leqq .0725\lambda.$$

If, for example, the load is a piece of phenolic plastic with dielectric constant 4.0 and radius 1.0 cm,

$$\lambda = \lambda_0/4.0^{\frac{1}{2}},$$

where $\lambda_0$ is the free space wave-length corresponding to the frequency used. Solving for $\lambda_0$

$$\lambda_0 \geqq 27.6 \text{ cm}.$$

Thus, the maximum frequency allowed in this case would be 1087 megacycles.

### OSCILLATOR DESIGN CONSIDERATIONS

On the basis of considerations such as the above example, it appeared that many dielectric heating processes could be done well at a frequency of about 1000 mc. Therefore, a magnetron oscillator was developed in the General Electric Research Laboratory to give 5 kw output at 1050 mc. In designing this oscillator, consideration had to be given to several special requirements of heating apparatus which differ from other uses of magnetrons.

The most important specific requirement is that the heating oscillator must be capable of operating into any load impedance, including the completely unloaded condition. This is caused by the non-uniformity of successive charges of load material, to the certainty of bad adjustment of matching transformers by unskilled operators, and the possibility of accidentally running the oscillator with no load at all. To meet these conditions, the anode should be capable of dissipating the entire input power to the tube. The output seal and transmission line to the load must stand very high voltages and currents associated with high standing wave ratios. The cathode should not be damaged by the excessive power it receives from back-bombardment by electrons, which is a function of the load impedance as well as the plate voltage and current.

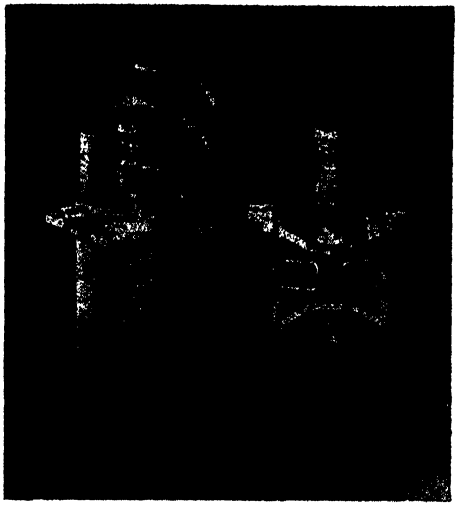


FIG. 2. Photograph of the 5-kw magnetron, showing the external appearance and also an axial section.

Although the multiple-cavity magnetron has many resonant modes, efficient oscillation occurs only in the "$\pi$" mode where each anode is 180° out of phase with those adjoining it. When this mode is overloaded, as may occur by poor load matching, the oscillator will tend to jump to another mode, which is usually completely unloaded, and may continue in the spurious mode, even if the mismatch is corrected, until it is turned off and restarted. The accepted cure for mode jumping is to strap the anodes together in two alternate sets with low impedance conductors. This raises the frequency of all modes except the "$\pi$" mode to a point where the oscillator does not readily excite them. The

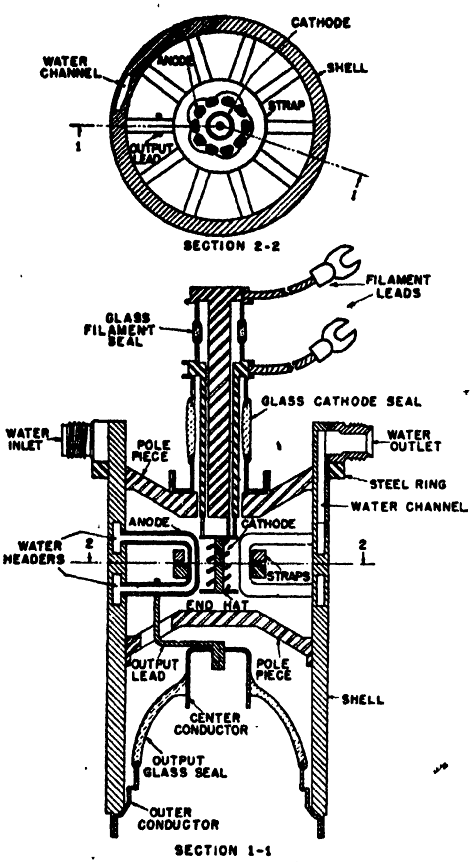

FIG. 3. Construction of water cooled magnetron. Sectional views showing the tubular anodes and water circulating channels. The O.D. of the copper shell is 3½″.

heating magnetron, as distinguished from the radar transmitter, runs continuously, so once it has jumped modes it does not have a chance to restart properly. Also the wide range of load impedances favors mode jumps. These factors necessitate very tight strapping. It is desirable that the next higher frequency mode be at least twice the frequency of the operating mode. In the oscillator to be described, this separation was attained by a new method of strapping.

### A 5-KW, 1050-MC MAGNETRON

The magnetron is shown in the photograph, Fig. 2, and constructional details in Fig. 3. It has 10 anodes, and so may be run at relatively low voltage and magnetic field. Rated operating conditions for the full 5 kw output are: plate voltage 5.0 kv, plate current 1.5 amp., magnetic field 1500 gauss. Water cooling was adopted for the anodes, and this allowed making the anodes of U-shaped pieces of copper tubing through which the water flows. Channels in the copper tube shell form headers for water distribution.

In addition to providing excellent cooling, the tubular anodes have a minimum of inter-anode capacity, thus allowing a large fraction of the capacitance of the resonant circuits to be provided by low impedance straps. The resulting tight strapping gives a frequency ratio of 1:2 between the operating mode and the next higher mode. The double ring straps are looped inside the anode U's. This allows the straps to be attached near the centers of the anode faces, eliminating unbalanced r-f voltages on the anodes. Also, the anodes shield the cathode and the rest of the tube from the fundamentally unbalanced double ring straps. The ten resonant circuits formed by the anode loops extending radially inward from the tube shell are electrically similar to conventional vane resonators.

The over-all size of the magnetron is determined by the output seal, which must be large to

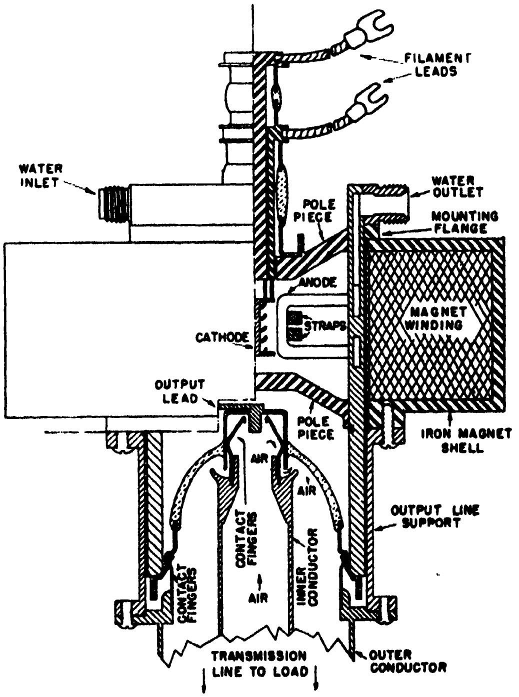

FIG. 4. Magnetron mounting and connections. The tube is slid downward into the cylindrical magnet, simultaneously plugging in to the coaxial output transmission line which is rigidly mounted on the magnet. The iron magnetic circuit is shown in heavy cross-hatching.

handle the power. In this cylindrical structure the seal occupies the entire diameter of the tube shell. The coaxial arrangement of the seal with the cathode and magnetic pole pieces allows the tube to be plugged into its magnet and output transmission line simultaneously. Figure 4 shows the method of mounting the tube. An electromagnet is used, consisting of a solenoidal coil with an iron shell whose ends line up with the iron pole pieces inside the tube. Air is blown through the center conductor of the output line to cool the seal, the inverted cup shape of the seal giving a good distribution of the cooling air as well as protecting the seal from breakage.

The power output is obtained by attaching a flat strap from the center conductor of the seal to one of the anodes. The exact point of attachment is selected to provide proper loading of the oscillator when the 52.5-ohm transmission line on the output has no standing wave.

The cathode is a simple spiral of pure tungsten wire with molybdenum end hats. It requires 600 watts heating power. In a magnetron having considerable electron bombardment of the cathode, it is desirable to use a very inefficient high wattage cathode, so that the back heating becomes a small fraction of the total heating power.

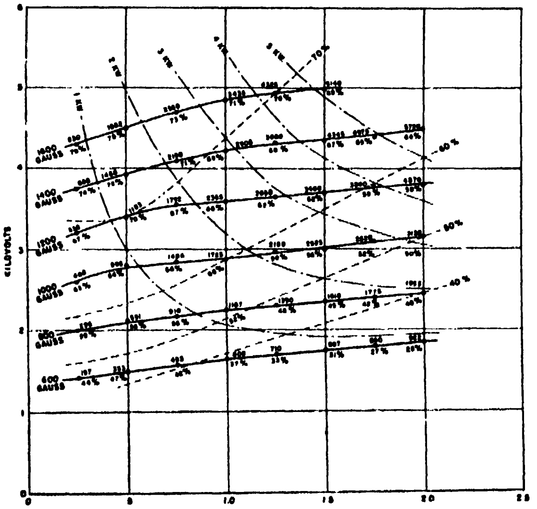

FIG. 5. Performance chart. Solid lines are contours of constant magnetic field, dashed lines are constant power, and dotted lines constant efficiency. Power, in watts, and efficiency measured are indicated on the experimental points. This chart is taken with a load matched to the transmission line.

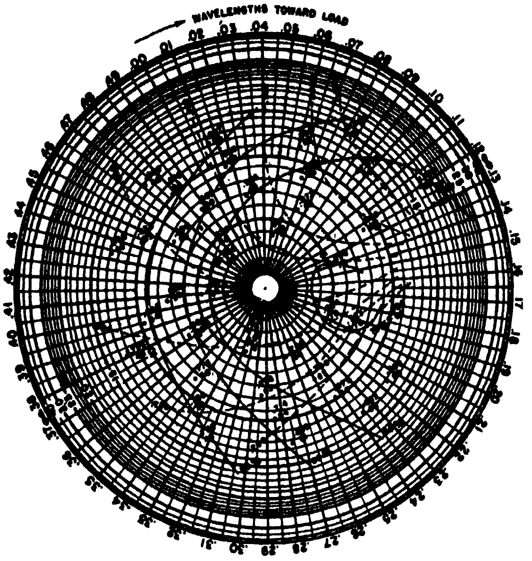

FIG. 6. Rieke diagram. The effect of load impedance on the efficiency and wave-length of the oscillator is best shown by this chart. The data were taken at fixed conditions of 1.0 amp. plate current and 1200 gauss magnetic field. Upper figures are wave-length (add 29.000 cm) and lower figures percentage efficiency. Constant efficiency and constant wave-length contours are shown by solid and dotted lines, respectively. The radial coordinate is voltage reflection coefficient, with the scale marked in standing wave ratio in decibels. The azimuthal coordinate is the phase angle of the reflection coefficient, with the scale marked in wave-lengths displacement of the standing wave minimum from an arbitrary zero.

## MAGNETRON OPERATING CHARACTERISTICS

The performance of the magnetron as an oscillator is graphically presented by several charts. Shown in Fig. 5 is the "performance chart" in which power output (upper numbers) and efficiency (lower numbers) are plotted against plate voltage and current. Lines of constant magnetic field are also shown.

Another important oscillator characteristic is shown in Fig. 6, the "Rieke diagram," in which efficiency and wave-length are plotted as a function of load impedance for constant current and magnetic field. The radial coordinate is standing wave ratio in the output line (in voltage) plotted on a scale proportional to reflection coefficient. The angular coordinate is the phase angle of the standing wave minimum. Thus the position of a point on the chart represents a complex load impedance, which might be transformed into resistance and reactance components by superposition of a Smith chart.

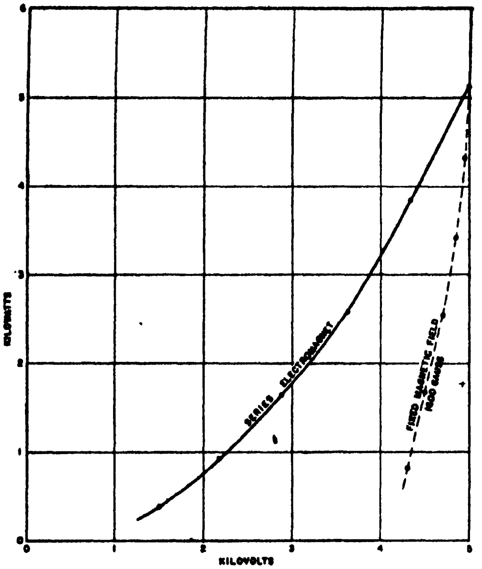

FIG. 7. Effect of plate voltage on output power. With a constant magnetic field as obtained from a permanent magnet, power output varies rapidly with plate voltage, following the dotted curve. An electromagnet excited by the magnetron plate current reduces this variation.

It is apparent from Fig. 5 that the plate current changes very rapidly with plate voltage at constant magnetic field. That is, the variational resistance for plate modulation is around 250 ohms. This is a good situation if one desires to use amplitude modulation, as the modulating power is low. However, in dielectric heating, a constant r-f output is desired, and account must be taken of variations in line voltage. It is obvious from the curves that a small variation in line voltage and hence in plate voltage will produce a large change in plate current and in output power. Figure 7 shows this relation, neglecting the regulation of the plate supply rectifier.

A method of greatly reducing the effect of line voltage fluctuations and, incidentally, plate supply ripple, is to run the tube's electromagnet in series with the low voltage end of the plate supply. This gives a magnetic field directly proportional to the plate current. Since the plate voltage is almost directly proportional to the magnetic field, the plate current will in turn be proportional to plate voltage. The resultant ohmic plate resistance characteristic produces the variation of r-f power with plate supply voltage shown by the solid curve in Fig. 7.

The relationship between d.c. plate current, plate voltage, and magnetic field also affects the way in which the magnetron output depends on the load impedance. The data plotted in Fig. 6 were taken under the easily reproducible conditions of constant current and magnetic field, letting the voltage find its own value. The voltage varies much less at constant current than the current would at constant voltage.

In practical operation we do not have either a constant current or constant voltage power supply, and the regulation characteristics of the supply affect the relationship of magnetron power output and load impedance. It is obvious that this is a very important relationship for heating applications.

With the magnetic field supplied by a series electromagnet, some of the effects of power supply regulation are simulated, and r-f power output tends to be stabilized. For a constant voltage power supply and series magnet, the variation of output power with load for a pure resistive load is plotted in Fig. 8. For comparison, there is also shown the relations obtained with constant voltage power supply, and with constant current.

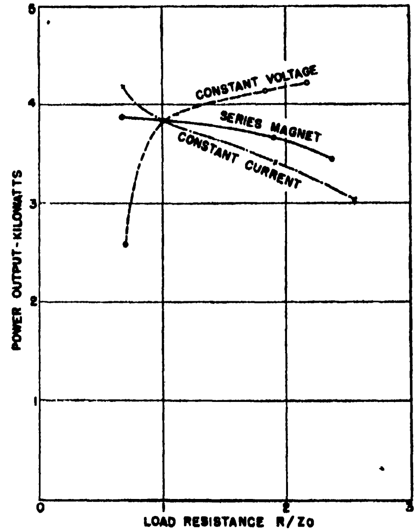

FIG. 8. Effect on output power of varying pure resistance loads. For loads which present a pure resistive impedance to the magnetron, the power delivered is plotted as a function of the ratio of load resistance $R$ to the characteristic impedance $Z_0$ of the transmission line. At constant magnetic field, the power increases with load resistance if the magnetron plate voltage is held constant, but decreases if the current is constant. Using a series electromagnet with constant voltage supply, the better characteristic shown by the solid line is obtained.

It has been found that if plate voltage is applied to the magnetron with no magnetic field but with the magnet in series, the tube will start in a very high frequency mode of oscillation, drawing plate current so that the voltage never rises enough to start the desired mode of circuit oscillation. To prevent this, it is necessary to have a field of at least 600 gauss present before plate voltage is applied. A rectifier across the magnet as shown in Fig. 9 supplies this starting current, and normally stops supplying current when the magnetron current builds up a voltage drop across the magnet coil greater than the output voltage of the rectifier.

The magnet supply rectifier can be made to do another useful job as a fine control for plate current and output power. In the plate supply rectifier, continuous voltage control is expensive, but a few taps for step control are cheap. Now at any given plate voltage, the magnetron is approximately a constant-magnetic-field device, independent of plate current. If the plate current supplies part of the magnetic field and the rest comes from the magnet rectifier, any increase in rectifier current will tend to increase the magnetic field and thus will cause a corresponding decrease in magnetron current. In this way continuous adjustment of output power is obtained by regulating the 100-watt magnet rectifier. Figure 9 shows the Variac connection used for control.

## R-F LOADING EQUIPMENT

The problem of carrying the 1050 mc power from the magnetron and coupling it into a load is one which has almost as many answers as there are varieties of material to be heated. The power is taken from the oscillator on a stub-supported coaxial line, the start of which is shown in Fig. 4. A line size of 3⅛" O.D. with 1¼" center conductor has been adopted as adequate for this power level and frequency. For most loads, a large step-up in impedance is necessary to match the line to the load. This usually takes the form of a resonant cavity tuned to the operating frequency and coupled to the transmission line by a loop or antenna.

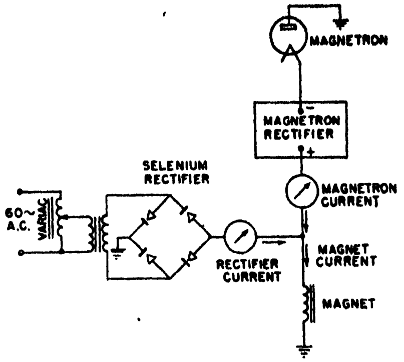

FIG. 9. Current supply for electromagnet. An auxiliary d.c. supply for the magnet is necessary to assure proper starting. This variable-voltage rectifier may be used to control the magnetron power output.

## ACKNOWLEDGMENTS

The author wishes to thank Dr. A. W. Hull for his continued interest and advice in carrying out this development. Mr. T. C. Swartz, Miss H. C. Hertha, and Mr. P. J. Scavullo have contributed largely to its progress.

# An Approximate Solution of the Differential Equation of the Ultracentrifuge

W. J. ARCHIBALD
*Dalhousie University, Halifax, Nova Scotia*

(Received November 13, 1946)

In determining molecular weights with the ultracentrifuge by the equilibrium method, it is necessary to drive the rotor at relatively high speeds for very long periods of time. It would be a real advantage to be able to deduce molecular weights from the distribution of concentration within a cell placed in a rotor without waiting for equilibrium. The solution of a certain differential equation gives the theoretical distribution within the cell at any time, and a comparison of the experimentally determined concentrations with those deduced from theory should yield molecular weights without waiting for equilibrium. The exact solution of this differential equation is known, but it is not suitable for numerical work. The present paper presents an approximate solution from which numerical results can be obtained with ease.

ONE of the most important methods of measuring high molecular weights is by the use of the ultracentrifuge as developed by Svedberg and Beams. A dilute solution of the substance whose molecular weight is to be determined is placed in a small cell, with radial sides and cylindrical ends, near the periphery of the rotor, and under the influence of the centrifugal force the distribution of concentration changes from an initial uniform distribution to an exponential one. When this final equilibrium state has been reached the concentration "$c$," at any point in the cell, is given by the expression

$$c = c_0 \exp\left[\frac{M(1-V\rho)\omega^2(r^2-r_0^2)}{2RT}\right], \tag{1}$$

where "$M$" is the molecular weight of the dissolved substance, "$V$" its partial specific volume, $\rho$ the density of the solvent, $\omega$ the angular velocity of rotation, and "$r$" the distance of any point in the cell from the axis of rotation. "$C_0$" is the concentration at the point "$r_0$." "$R$" is the gas constant per mole and "$T$" the absolute temperature. The equilibrium state is reached when the tendency for solute particles to settle to the outer part of the cell because of the centrifugal force is exactly equal to the tendency for them to diffuse inwards because of the concentration gradient. It is obvious that Eq. (1) gives "$M$" in terms of quantities that can be measured, although the experiment is one that can only be performed successfully with faultless optical and mechanical equipment.

The time required for the attainment of the equilibrium state is often very long—sometimes the centrifuge must run for many days, or even weeks, at constant speed and at a constant temperature. If the time of a run could be shortened this method of molecular weight determination would be much more useful. The experimental difficulties would be greatly reduced and the number of runs made with any centrifuge would be increased. This latter consideration is an important one in view of the many substances that could be studied by this method. If the distribution of concentration within the cell at any time after the start of an experiment could be deduced theoretically, a comparison of the measured and computed distribution might enable "$M$" to be found without waiting for equilibrium. The function $c(r, t)$, which gives the concentration at any point at any time, would be required for this purpose and this is obtained by solving the following differential equation:

$$\frac{1}{r}\frac{\partial}{\partial r}\left\{\left(D\frac{\partial c}{\partial r}-\omega^2 rsc\right)r\right\}=\frac{\partial c}{\partial t}. \tag{2}$$

In (2), "$D$" is the diffusion constant of the solute and "$s$" the sedimentation constant, i.e., the velocity of settling of the dissolved substance in unit gravitational field. The quantities "$D$" and "$s$" are related to each other. It is possible to show that

$$D/s = RT/M(1-V\rho). \tag{3}$$

A proof of this relation is given in a previous paper by the author.[1] The differential Eq. (2) was

---

[1] W. J. Archibald, Phys. Rev. 53, 746 (1938).

first derived by Lamm.[2] A simple derivation is to be found in reference 1.

A treatment of Eq. (2) which is free of any mathematical approximations has been given and is to be found in two places in the literature.[3,4] While the solution given is exact and can be employed for purposes of computation, yet the cost in time of getting numerical results is so great that little use has been found for it. The expression obtained for $c(r,t)$ is simple in form and would be most serviceable if the mathematical functions which it contains could be looked up in tables. However such tables are not available and the task of compiling them would be a major project in applied mathematics. It is the purpose of this paper to derive another expression for $c(r,t)$ which, while not exact, is felt to be good enough for many purposes, and which contains functions that are tabulated.

In dealing with Eq. (2) it is more convenient to use "$z$" and "$\tau$" rather than "$r$" and "$t$" as the independent variables, where

$$z=\frac{\omega^2 s}{2D}r^2=\frac{M(1-V\rho)\omega^2}{2RT}r^2 \quad \text{and} \quad \tau=2\omega^2 st. \tag{4}$$

As $r_1 \leq r \leq r_2$ where $r_1$ and $r_2$ are the inner and outer limits of the cell, respectively, then $a \leq z \leq b$ where

$$\begin{Bmatrix} a \\ b \end{Bmatrix}=\frac{M(1-V\rho)\omega^2}{2RT}\begin{Bmatrix} r_1^2 \\ r_2^2 \end{Bmatrix}.$$

In terms of these variables we find

$$\frac{c(z,\tau)}{c_0}=\frac{b-a}{e^b-e^a}e^z+\sum_{n=1}^{\infty}\frac{\int_a^b e^{-z}M(\alpha_n,1,z)dz}{\int_a^b e^{-z}\{M(\alpha_n,1,z)\}^2dz} \times M(\alpha_n,1,z)e^{(\alpha_n-1)\tau}, \tag{5}$$

where $M(\alpha,\gamma,z)$ is a solution of the differential equation

$$\frac{d^2M}{dz^2}+\left(\frac{\gamma}{z}-1\right)\frac{dM}{dz}-\frac{\alpha}{z}M=0 \tag{6}$$

and the $\alpha_n$'s are the "eigenvalues" of the parameter $\alpha$. The $\alpha_n$'s are those particular values of $\alpha$ which give the functions $M(\alpha_n,1,z)$ the property that

$$\frac{d}{dz}M(\alpha_n,1,z)=M(\alpha_n,1,z) \tag{7}$$

for $z=a$ and $z=b$. "$c_0$" is the initial uniform concentration. (The reader is asked to consult reference 3 or 4 for a detailed proof of (5) and a full explanation of the results stated here.) $M(\alpha_n,1,z)$ is an abbreviation for

$$F(\alpha_n,1,z)-\frac{F(\alpha_n,2,a)}{W(\alpha_n,2,a)}W(\alpha_n,1,z), \tag{8}$$

where $F(\alpha_n,\gamma,z)$ and $W(\alpha_n,\gamma,z)$ are the two independent solutions of (6) which are to be found written out in full.[3,4] It is the difficulty of obtaining numerical values for the $F$ and $W$ functions which limits the usefulness of Eq. (5).

It will be our purpose to see if it is possible to derive some expression for the functions $M(\alpha_n,1,z)$, other than that given in (8), and which contains only well-known functions. This alternative expression will of necessity be an approximation and a careful study of the magnitude of the different quantities involved will be required to make the approximation a good one. A further purpose will be to discover a simple method for determining the eigenvalues $\alpha_n$.

In (5) the first term, in $e^z$, gives $c/c_0$ for the equilibrium state. In an actual experiment it is not desirable to have the final concentration vary too widely throughout the cell. If one were to accept as a reasonable set of conditions that finally the concentration at $r_2$ be three times that at $r_1$ then

$$e^b/e^a \simeq 3, \quad \text{or} \quad (b-a)\simeq 1.1.$$

This serves to show the narrow limits within which the variable "$z$" is confined. Furthermore, since

$$b/a=r_1^2/r_2^2,$$

we have

$$a=(b-a)\frac{r_1^2}{r_2^2-r_1^2}\simeq 1.1\frac{r_1^2}{r_2^2-r_1^2}.$$

The cells used are usually small and one might

---

[2] Lamm, Ark. Mat. Astron. Fysik. 21B, No. 2 (1929).
[3] W. J. Archibald, Phys. Rev. 54, 371 (1938).
[4] W. J. Archibald, Ann. N. Y. Acad. Sc. 43, 211 (1942).

choose as typical values the following: $r_2=5.0$ cm and $r_1=4.5$ cm. This gives $a\simeq 4.7$. As a result of these considerations we are entitled to treat the variable "$z$" as being moderately large (of the order of 5.0) and as being confined within a short range of values. The results of a computation on a typical experiment[3,4] show that $5.0\leq z\leq 6.2$ and these figures are probably typical of most cases in which the equilibrium method is used.

A further point of interest has to do with the quantities $\alpha_n$. The exact theory gives $\alpha=1$ as one of the eigenvalues. This $\alpha$, of course, gives rise to the first term in (5). All the other $\alpha$'s have large negative values. In the computations referred to above it was found that $\alpha_1=-38.7$. $\alpha_2$ was not determined, but the indications were that it was less than $-100$.

The first term in (5) presents no difficulty: but the terms in the summation part of the expression are bothersome. Thus we will confine our attention to these terms. This means that we must study Eq. (6) (with $\gamma=1$), remembering that $\alpha$ is very large and negative and that "$z$" is moderately large and of restricted variation. In (6) let

$$M=e^{z/2}z^{-\frac{1}{2}}V. \tag{9}$$

The equation for "$V$" then becomes

$$\frac{d^2V}{dz^2}+\left\{-\frac{1}{4}+\frac{1}{4z^2}-\frac{(\alpha-\frac{1}{2})}{z}\right\}V=0. \tag{10}$$

The considerations given above suggest that it is permissible to drop the term $1/4z^2$. This term is very small in comparison with $-(\alpha-\frac{1}{2})/z$ and is even quite small in comparison with $\frac{1}{4}$. Then (10) becomes

$$\frac{d^2V}{dz^2}+\left\{-\frac{1}{4}-\frac{(\alpha-\frac{1}{2})}{z}\right\}V=0.$$

This is still an inconvenient equation to deal with but it can be further simplified by replacing the term in braces by

$$\left\{-\frac{1}{4}\frac{(a+b)}{2}-(\alpha-\tfrac{1}{2})\right\}\frac{1}{z}=\frac{\sigma^2}{z}. \tag{11}$$

This term is a very close approximation to $-\frac{1}{4}-(\alpha-\frac{1}{2})/z$ when $z\simeq 5$, $\alpha$ is large and $b-a$ is of the order of unity. As an example we may use the numerical data from reference 3 or 4. Putting $\alpha=-38.7$, $a=5$, and $b=6.2$ with $5.0\leq z\leq 6.2$ we obtain the results given in Table I. It will be observed that the maximum difference between the two quantities is less than 0.5 percent.

TABLE I.

| $z$ | $f(z)$ | $f(z)$ approx. |
|---|---|---|
| 5.0 | 7.59 | 7.56 |
| 5.2 | 7.29 | 7.27 |
| 5.4 | 7.01 | 7.00 |
| 5.6 | 6.75 | 6.75 |
| 5.8 | 6.51 | 6.52 |
| 6.0 | 6.28 | 6.30 |
| 6.2 | 6.07 | 6.10 |

$$f(z)=-\tfrac{1}{4}-\frac{(\alpha-\frac{1}{2})}{z}$$

$$f(z)\text{ approx.}=\left\{-\tfrac{1}{4}\frac{(a+b)}{2}-(\alpha-\tfrac{1}{2})\right\}\frac{1}{z}$$

With $\alpha=-38.7$, $a=5.0$, and $b=6.2$.

Thus if one uses

$$\frac{d^2V}{dz^2}+\frac{\sigma^2}{z}V=0, \tag{12}$$

as the differential equation for the function "$V$" it seems reasonable to suppose that (9) will give a close representation of the function "$M$" for "$z$" between "$a$" and "$b$."

Now Eq. (12) has for its most general solution

$$V(z)=z^{\frac{1}{2}}\{AJ_1(2\sigma z^{\frac{1}{2}})+BN_1(2\sigma z^{\frac{1}{2}})\}, \tag{13}$$

where $J_1$ and $N_1$ are Bessel functions of the first and second kind, respectively, and $A$ and $B$ are arbitrary constants to be determined by the conditions of the problem. Combining (9) and (13) we have

$$M(\alpha,z)=e^{z/2}\{AJ_1(2\sigma z^{\frac{1}{2}})+BN_1(2\sigma z^{\frac{1}{2}})\}. \tag{14}$$

It must be emphasized that this expression can only be made to approximate $M(\alpha, 1, z)$ (by the proper choice of $A$ and $B$) for large values of $\alpha$ and for $z$ between $a$ and $b$. For any other range of variables it will undoubtedly be wide of the mark. Even subject to these restrictions there is no reason to suppose that $e^{z/2}J_1(2\sigma z^{\frac{1}{2}})$ is an approximation to $F(\alpha, 1, z)$ or $e^{z/2}N_1(2\sigma z^{\frac{1}{2}})$ to $W(\alpha, 1, z)$. All we are entitled to expect is that a linear combination of $F(\alpha, 1, z)$ and $W(\alpha, 1, z)$ can be replaced by some linear combination of the functions $e^{z/2}J_1(2\sigma z^{\frac{1}{2}})$ and $e^{z/2}N_1(2\sigma z^{\frac{1}{2}})$.

We will now adopt for the function $M(\alpha_n, 1, z)$, which occurs in Eq. (5), the form given in (14). However it is still necessary to discover what values of $\alpha_n$ to use. (It must be remembered that $\alpha$ is contained in the quantity $\sigma$.) It will be recalled that the function $M(\alpha, z)$ must be such that

$$dM/dz = M \tag{15}$$

for $z=a$ and $z=b$. This equation will be found to hold only when the $\alpha$'s are properly chosen. Let

$$Z_1(2\sigma z^{\frac{1}{2}}) = AJ_1(2\sigma z^{\frac{1}{2}}) + BN_1(2\sigma z^{\frac{1}{2}})$$

and in order to be specific let $N_1(2\sigma z^{\frac{1}{2}})$ be the Neumann function whose properties are well known. Then

$$M(\alpha, z) = e^{z/2} Z_1(2\sigma z^{\frac{1}{2}}). \tag{16}$$

Substituting (16) in (15) one gets

$$\frac{dZ_1}{d(2\sigma z^{\frac{1}{2}})} - \frac{z^{\frac{1}{2}}}{2\sigma} Z_1 = 0. \tag{17}$$

(In the following the argument of $Z$, $J$, and $N$ will be omitted.) But

$$\frac{dZ_1}{d(2\sigma z^{\frac{1}{2}})} = Z_0 - \frac{1}{2\sigma z^{\frac{1}{2}}} Z_1.$$

Therefore, (17) becomes

$$Z_0 - Z_1 \tan\zeta = 0, \tag{18}$$

where

$$\tan\zeta = \frac{1}{2\sigma}\left(\frac{1}{z^{\frac{1}{2}}} + z^{\frac{1}{2}}\right). \tag{19}$$

In terms of the $J$ and $N$ functions (18) becomes

$$A(J_0 - J_1 \tan\zeta) + B(N_0 - N_1 \tan\zeta) = 0. \tag{20}$$

At this point it is useful to make a further approximation. We have carried the Bessel and Neumann functions as far as it is convenient—to carry them further leads to complicated expressions. However the argument $2\sigma z^{\frac{1}{2}}$ is so large that they may be replaced by their asymptotic representations. The quantity $2\sigma z^{\frac{1}{2}}$ will usually have values in excess of 20 and in this range we may use the following:

$$\left.\begin{aligned} J_0 &= (\pi\sigma z^{\frac{1}{2}})^{-\frac{1}{2}} \cos(2\sigma z^{\frac{1}{2}} - \pi/4), \\ N_0 &= (\pi\sigma z^{\frac{1}{2}})^{-\frac{1}{2}} \sin(2\sigma z^{\frac{1}{2}} - \pi/4), \\ J_1 &= (\pi\sigma z^{\frac{1}{2}})^{-\frac{1}{2}} \cos(2\sigma z^{\frac{1}{2}} - 3\pi/4), \\ N_1 &= (\pi\sigma z^{\frac{1}{2}})^{-\frac{1}{2}} \sin(2\sigma z^{\frac{1}{2}} - 3\pi/4). \end{aligned}\right\} \tag{21}$$

Substituting these expressions in (20), and simplifying, one obtains

$$A(\cos\epsilon - \tan\zeta \sin\epsilon) + B(\sin\epsilon + \tan\zeta \cos\epsilon) = 0,$$

where $\epsilon = 2\sigma z^{\frac{1}{2}} - \pi/4$. Dividing through by $\cos\epsilon$ this becomes

$$A(1 - \tan\zeta \tan\epsilon) + B(\tan\zeta + \tan\epsilon) = 0$$

or

$$A + B\tan(\zeta + \epsilon) = 0. \tag{22}$$

Now $\zeta$ and $\epsilon$ are both functions of $z$ and equation (22) must hold for $z=a$ and $z=b$. Therefore, we get the two equations

$$\left.\begin{aligned} A + B\tan\{\zeta(a) + \epsilon(a)\} &= 0 \\ A + B\tan\{\zeta(b) + \epsilon(b)\} &= 0 \end{aligned}\right\}. \tag{23}$$

These equations can only have roots other than the trivial ones $A = B = 0$ if

$$\tan\{\zeta(a) + \epsilon(a)\} = \tan\{\zeta(b) + \epsilon(b)\}. \tag{24}$$

Equation (24) can be satisfied if

$$\{\zeta(b) + \epsilon(b)\} - \{\zeta(a) + \epsilon(a)\} = n\pi, \quad n = 0, 1, 2, \cdots \tag{25}$$

Introducing the functions $\zeta$ and $\epsilon$ explicitly (25) becomes

$$x = n\pi + \tan^{-1}\left\{\frac{(b^{\frac{1}{2}} - a^{\frac{1}{2}})}{x}\left(\frac{1+a}{a^{\frac{1}{2}}}\right)\right\} - \tan^{-1}\left\{\frac{(b^{\frac{1}{2}} - a^{\frac{1}{2}})}{x}\left(\frac{1+b}{b^{\frac{1}{2}}}\right)\right\}. \tag{26}$$

where $x = 2\sigma(b^{\frac{1}{2}} - a^{\frac{1}{2}})$. The permissible values of $\alpha$ are determined by finding the values of $x$ for which this equation is satisfied ($x$ is a function of $\alpha$). Before looking at (26) in detail it is obvious that when $n=0$ its solution is $x=0$. This means $\sigma=0$ or

$$\alpha = \tfrac{1}{2} - \tfrac{1}{8}(a+b).$$

This will give a small negative value for $\alpha$. Remembering that out treatment cannot be expected to be correct when $\alpha$ has a small absolute value it will be realized that this is the approximation to the eigenvalue $\alpha=1$. However the term in (5) arising from this eigenvalue (*viz.*, the term in $e^z$) is simple and there is no point in doing otherwise than taking it as it stands.

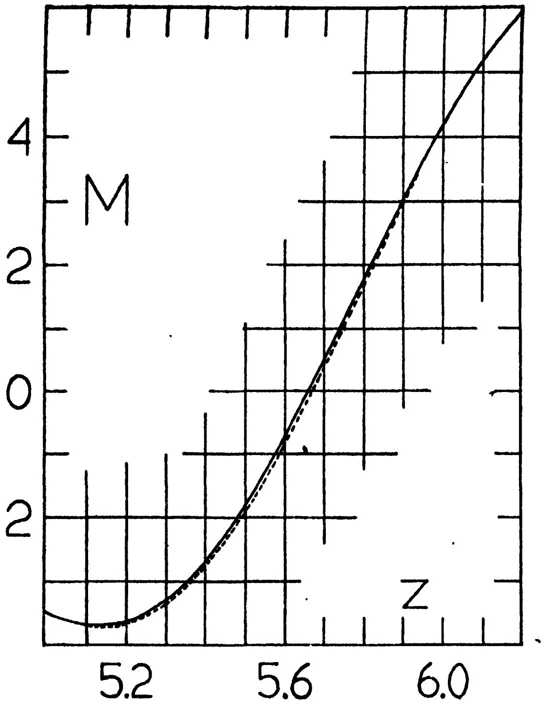

Fig. 1. The full line is the function $M(-38.7, 1, z)$ and the dotted line the function $-0.4205M(-38.77, z)$.

Since $b-a\simeq 1$, we have

$$(b^{\frac{1}{2}}-a^{\frac{1}{2}})\simeq\frac{1}{b^{\frac{1}{2}}+a^{\frac{1}{2}}}\simeq\frac{1}{2b^{\frac{1}{2}}}.$$

Therefore,

$$\frac{(b^{\frac{1}{2}}-a^{\frac{1}{2}})}{x}\frac{(1+b)}{b^{\frac{1}{2}}}\simeq\left(\frac{0.5}{x}\right)\frac{1+b}{b}\simeq\frac{0.5}{x}.$$

When $n=1, 2, \cdots$ in (26) an actual computation using representative figures shows that $x\simeq n\pi$. Thus the arguments of the inverse tan functions will be small, and these terms will be very small in comparison with $n\pi$. This being the case we will replace $x$ by $n\pi$ in the inverse tan functions and expand them retaining only the first term of the expansions. This gives

$$x=n\pi+\frac{(b^{\frac{1}{2}}-a^{\frac{1}{2}})}{n\pi}\left\{\frac{1+a}{a^{\frac{1}{2}}}-\frac{1+b}{b^{\frac{1}{2}}}\right\}$$

or

$$\sigma_n=\frac{n\pi}{2(b^{\frac{1}{2}}-a^{\frac{1}{2}})}+\frac{1}{2n\pi}\left\{\frac{1+a}{a^{\frac{1}{2}}}-\frac{1+b}{b^{\frac{1}{2}}}\right\}. \qquad (27)$$

It is interesting to see how accurately this formula gives $\alpha_1$ (i.e., $n=1$) for the problem referred to above in which $a=5.0$ and $b=6.2$. A simple computation gives $\sigma_1=6.154$ or $\alpha_1=-38.77$. The correct value is $\alpha_1=-38.70$. Thus it is seen that for large absolute values of $\alpha$ the approximation is a very good one. Using the exact theory, several weeks of computing were required to get $\alpha_1$ and the labor involved in getting $\alpha_2$ seemed prohibitive. Formula (27) gives a result, correct to within 0.2 percent in this case, with only a few minutes required for the computation. When $n=2$, we have $\sigma_2=12.36$ and $\alpha_2=-154.6$. This checks with the exact theory as to order of magnitude and is probably quite accurate because for such large values of $\alpha$ the approximations are especially valid. This eigenvalue and the ones which follow it are so large that rapid convergence of the summation in (5) is assured even for small values of $\tau$.

Returning to a consideration of Eq. (14) we see that it should now be written

$$M(\alpha_n, z)=A_n e^{z/2}\{J_1(2\sigma_n z^{\frac{1}{2}})+K_n N_1(2\sigma_n z^{\frac{1}{2}})\}, \qquad (28)$$

where

$$K_n=B_n/A_n=-\cot\{\zeta_n(a)+\epsilon_n(a)\}. \qquad (29)$$

Since it is not usual to find the $J_1$ and $N_1$ functions tabulated for such large values of the argument as occur in this problem it seems best to replace them by their asymptotic representations in $M(\alpha_n, z)$. Then (28) becomes

$$M(\alpha_n, z)=e^{z/2}z^{-\frac{1}{4}}\{\cos(2\sigma_n z^{\frac{1}{2}}-3\pi/4)$$
$$+K_n\sin(2\sigma_n z^{\frac{1}{2}}-3\pi/4)\}. \qquad (30)$$

It will be noted that the $A_n$ as well as some other constants which occur as multiplying factors have been dropped. That this is permissible is at once evident from Eq. (5). $M(\alpha_n, 1, z)$, or its approximation $M(\alpha_n, z)$, is found twice in the numerator and twice in the denominator and any constant multiplying factor will cancel. Hence $M(\alpha_n, z)$ as written in (30) will replace $M(\alpha_n, 1, z)$ as given by the exact theory, and the $\alpha_n$'s will be given by (27) and (11).

A noteworthy feature of the function $M(\alpha_n, z)$ is its simplicity and the ease with which numerical results can be obtained from it. Its validity is best illustrated by comparing the curve obtained from it with that obtained from the exact function $M(\alpha_n, 1, z)$. This latter function is tabulated for $5.0 \leq z \leq 6.2$ and $\alpha = -38.7$.[4] In Fig. (1) the two functions $M(-38.7, 1, z)$ and $-0.4205M(-38.77, z)$ are plotted for purposes of comparison. (It is to be observed that the two $M$ functions are not identical—one is a multiple of the other.) No attempt has been made to find the best multiplying factor: the factor $-0.4205$ is the one that makes the two functions identical at $z = 5.0$, the extreme end of the range. The usefulness of the approximation seems well attested within the range of values for which it was devised.

The evaluation of the integrals which occur in Eq. (5) does not seem of importance. Since $M(\alpha_n, z)$ must be computed in any case the simplest procedure is to evaluate these integrals by numerical integration.

Two sets of values of $c/c_0$ for several values of $\tau$ are to be found in Table II. In the first column of each group are the results given by the approximate functions and in the second column those given by the exact functions. These latter values are obtained from reference 4, for the problem considered there. In computing the values of $c/c_0$ from the exact solution the terms in $\alpha_2, \alpha_3, \cdots$ etc., were not used. This did not seem to introduce a serious error into the results because it was felt that these higher terms were insignificant even for such a small value of $\tau$ as .015. However, no proof of this could be given and it is reassuring to discover from the approximate solution that this omission is justified. If the term in $\alpha_2$ is included the numerical values most seriously affected are only changed by a few units in the third figure beyond the decimal. (It should be stated that the values given in Table II for the approximate solution do not include the terms in $\alpha_2, \alpha_3, \cdots$. They were omitted purposely in order to have the same conditions in both sets of calculations.) The greatest differences between the two sets of figures occur in the section headed $\tau = .015$. (This corresponds to a time equal to about 1/7 of that required to reach full equilibrium.) But even here the approximation is within 1.2 percent of being correct over most of the range of $z$. For larger values of $\tau$ the differences are much less.

TABLE II. $c(z, \tau)/c_0$.

| | $\tau = .015$ | | $\tau = .03$ | | $\tau = .05$ | | $\tau = .10$ | |
|---|---|---|---|---|---|---|---|---|
| $z$ | *A* | *B* | *A* | *B* | *A* | *B* | *A* | *B* |
| 5.0 | .726 | .717 | .632 | .627 | .569 | .567 | .524 | .524 |
| 5.1 | .795 | .784 | .695 | .689 | .627 | .625 | | |
| 5.2 | .853 | .841 | .754 | .747 | .687 | .684 | .640 | .639 |
| 5.3 | .900 | .889 | .809 | .804 | .748 | .746 | | |
| 5.4 | .938 | .926 | .863 | .857 | .813 | .810 | .778 | .777 |
| 5.5 | .968 | .956 | .916 | .910 | .882 | .879 | | |
| 5.6 | .994 | .983 | .971 | .965 | .955 | .953 | .944 | .944 |
| 5.7 | 1.021 | 1.013 | 1.030 | 1.026 | 1.037 | 1.035 | | |
| 5.8 | 1.051 | 1.050 | 1.096 | 1.095 | 1.126 | 1.126 | 1.148 | 1.148 |

| 6.0 | 1.157 | 1.165 | 1.269 | 1.273 | 1.344 | 1.346 | 1.398 | 1.398 |
| 6.1 | 1.241 | 1.254 | 1.382 | 1.389 | 1.476 | 1.479 | | |
| 6.2 | 1.358 | 1.374 | 1.519 | 1.528 | 1.628 | 1.632 | 1.705 | 1.705 |

Columns *A* contain the approximate values and columns *B* the exact values of the function $c(z, \tau)/c_0$.

To obtain a set of curves from the exact solution would take an experienced computer several weeks: using the functions derived in this paper the same curves could be obtained in six or eight hours.

# The Motion of a Conical Coil Spring

I. EPSTEIN*
*Department of Physics, University of Cincinnati, Cincinnati, Ohio*

(Received November 22, 1946)

The elongations and natural frequencies of conically-shaped coil springs are derived theoretically for several dynamic boundary conditions. Frequencies are verified experimentally on nickel and piano wire springs, attesting the reliability of the computations.

## 1. EQUATION OF MOTION

THE dissimilarities in the analytic expressions for the oscillatory motions of conically-shaped springs on one hand and cylindrical ones on the other, arise as results of the variability of mass per unit length in the direction of motion and of the inconstancy of the spring "constant" in the case of the conical type. If a constant mass per unit length of wire, $m$, is assumed, the total mass of a single complete turn of wire can be stated as a function of the diameter of the turn, or as a function of the diameter of the largest turn and the linear distance from it. Let it be required to find the mass of a complete turn of wire at an average distance $x$ from a coil of diameter $D_0$ (Fig. 1). The circumference of the turn in question is $\pi(D_0-2ax)$, where $a$ is the tangent of the half-angle at the vertex of the cone. Hence, its mass is $m$ times this value. The "inertial force" (mass times acceleration) of a single turn of wire is then, $\pi(D_0-2ax)m\partial^2E/\partial t^2$, where $E$ is the displacement of the turn (elongation of the spring), measured from its unstretched position. The inertial force of an element $dx$ must be equated to the net force necessary to give the element displacement $E$. The formula for the deflection of a single turn of wire (as measured by one 360° revolution of the coil around the longitudinal axis of the cone) of loop diameter $D$ and wire thickness $d$, under a load of $P$ pounds, is $f=8D^3P/Gd^4$, where $f$ is the deflection in inches, $D$ and $d$ are measured in inches, and $G$ is the torsional modulus of elasticity of the wire used.[1] Since the spring constant $K$ is defined as the force per unit deflection, the conical spring "constant" is $K=Gd^4/8D^3$, and the force on an element of wire due to spring tension is:

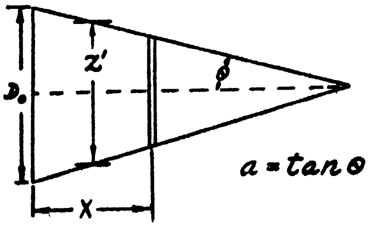

FIG. 1. Schematic diagram of spring (longitudinal section).

$$F=\frac{\partial}{\partial x}\left[K\frac{\partial E}{\partial x}\right]dx=\frac{\partial}{\partial x}\left[\frac{Gd^4}{8D^3}\frac{\partial E}{\partial x}\right]dx.$$

It is advantageous to use as independent variable the diameter of a turn of wire, defined by the equation $Z=D=D_0-2ax$. Thus, equating the inertial force to the tension force, the equation takes the form:

$$\frac{2\pi mZ^4}{a^2Gd^4}\frac{\partial^2E}{\partial t^2}=\frac{\partial^2E}{\partial Z^2}-\frac{3}{Z}\frac{\partial E}{\partial Z}. \tag{1}$$

A solution of the form $E(Z,t)=w(Z)\cdot T(t)$ is assumed, and substitutions are made back into Eq. (1). The variables $Z$ and $t$ may be separated and two ordinary differential equations arise. For the equation in $t$ we get:

$$d^2T/dt^2+\lambda^2T=0. \tag{2}$$

The general solution of this equation is $T=T_0\cos(\lambda t+\delta)$, where $\lambda=2\pi f$, where $f_j$ are the natural frequencies of the oscillatory system to be determined by boundary conditions operating on the ordinary differential equation in $Z$. For the equation in $Z$ we get:

$$\frac{-2\pi m\lambda^2}{a^2Gd^4}=\frac{1}{Z^4w}\frac{d^2w}{dZ^2}-\frac{3}{Z^5w}\frac{dw}{dZ}. \tag{3}$$

---

* Graduate student.

[1] *National Metals Handbook* (American Society for Steel Training, Cleveland, 1933), p. 990.

For ease in computation to be done later, the following changes are made at this point. $Z$ is changed so that $z=Z/D_0$. Thus, the range of the independent variable, rather than being from 0 to $D_0$, will now be from 0 to 1. Further, let $a^2Gd^4/2\pi mD_0^6$ be denoted by a single bulk constant $c$. Equation (3) then reduces to:

$$\frac{d^2w}{dz^2}-\frac{3}{z}\frac{dw}{dz}+\frac{\lambda^2z^4w}{c}=0. \tag{4}$$

Series solutions of Eq. (4) may be identified with solutions in Bessel functions of orders $\frac{2}{3}$ and $-\frac{2}{3}$ of the form:

$$W(y)=(y/2)^{\frac{2}{3}}\{AJ_{-2/3}(y)+BJ_{2/3}(y)\}, \tag{5}$$

where $y=\lambda z^3/3\sqrt{c}$. Finally, the general solution of Eq. (1), in terms of the independent variable $z$, is:

$$E(z,t)=(\Lambda/2)^{\frac{2}{3}}z^2\{AJ_{-2/3}(\Lambda z^3)+BJ_{2/3}(\Lambda z^3)\}\cos(\lambda t+\delta), \tag{6}$$

where $\lambda/3\sqrt{c}$ has been replaced by $\Lambda$. An investigation will now be conducted into the particular solutions of this equation to be used to satisfy specific boundary conditions.

## 2. SPECIAL BOUNDARY CONDITIONS

### I. Both Extremities Fixed

The particular solutions of Eq. (6) which satisfy the boundary conditions $E(0,t)=E(1,t)=0$, are:

$$E(z,t)=(\Lambda/2)^{\frac{2}{3}}z^2BJ_{2/3}(\Lambda z_3)\cos(\lambda t+\delta). \tag{7}$$

By taking $\delta=0$, we assume that the motion starts from rest, that is, $\partial E/\partial t=0$ at $t=0$. In order to satisfy the boundary condition at the base, it is necessary that $E(1,t)$ in Eq. (7) be zero for all $t$. This can be accomplished by limiting the values of $\Lambda$ to those which are roots of the equation $J_{2/3}(\Lambda)=0$. The first two roots of this equation are $\Lambda_1=3.38$ and $\Lambda_2=6.53$, while other roots may be deduced by adding $\pi$ successively to each former root.[2] Since $\Lambda_j=\lambda_j/3c^{\frac{1}{2}}$, and $\lambda_j=2\pi f_j$, then $f_j$ (the natural frequencies of the system under assigned boundary conditions) will be $f_j=3c^{\frac{1}{2}}\Lambda_j/2\pi$, where the $\Lambda_j$ are roots of $J_{2/3}(\Lambda)=0$. The constant $c$ may be determined in one of three ways. First, by the defining formula for $c$: $c=a^2Gd^4/2\pi mD_0^6$, using quantities which are deemed reliable for $a$, $G$, $d$, and $m$. Another method is to analyze the static case for an experimental determination of $Gd^4$ and using values for the other quantities to the best of one's knowledge. A third method is to solve for $\sqrt{c}$ using one experimentally determined natural frequency. Once determined in this manner, $c$ will retain the same value regardless of boundary conditions or initial distortions. It is best to arrive at a suitable value of $c$ by using all three methods simultaneously, and arriving at consistent values for all of the constants included in $c$.

TABLE I.

| | Root | $\Lambda_j$ | $f_j$(c/sec.) | $f_j$(experimentally) |
|---|---|---|---|---|
| Ni | 1st | 3.38 | 2.59 | 2.58 |
| | 2nd | 6.53 | 5.21 | |
| Piano wire | 1st | 3.38 | 2.53 | 2.55 |
| | 2nd | 6.53 | 5.08 | |

In experiments performed in conjunction with this problem, two springs (one of nickel and one of piano wire) were employed. By the methods just outlined, the value of $c$ adopted for the nickel coil was 2.75 and for the piano wire coil, 2.65. Thus, for the nickel coil,

$$f_j=\frac{3(2.75)^{\frac{1}{2}}\Lambda_j}{6.28}=\frac{\Lambda_j}{1.26},$$

and for the piano wire coil,

$$f_j=\frac{3(2.65)^{\frac{1}{2}}\Lambda_j}{6.28}=\frac{\Lambda_j}{1.29}.$$

Table I shows the results of this case.

### IIA. Vertex Fixed, Base Free

In this case, the boundary conditions to be met are that $E(0,t)=0$, and $\partial E/\partial x$ be zero at $z=1$. As in the previous case, in order to fulfill the condition at the vertex, $A$, (Eq. (6)), must be made identically zero. Thus, for a particular solution, we choose:

$$E(z,t)=(\Lambda/2)^{\frac{2}{3}}z^2BJ_{2/3}(\Lambda z^3)\cos(\lambda t). \tag{8}$$

---

[2] Dinnik, Archiv d. Math. und Phys. [3], 18, 337–338 (1911).

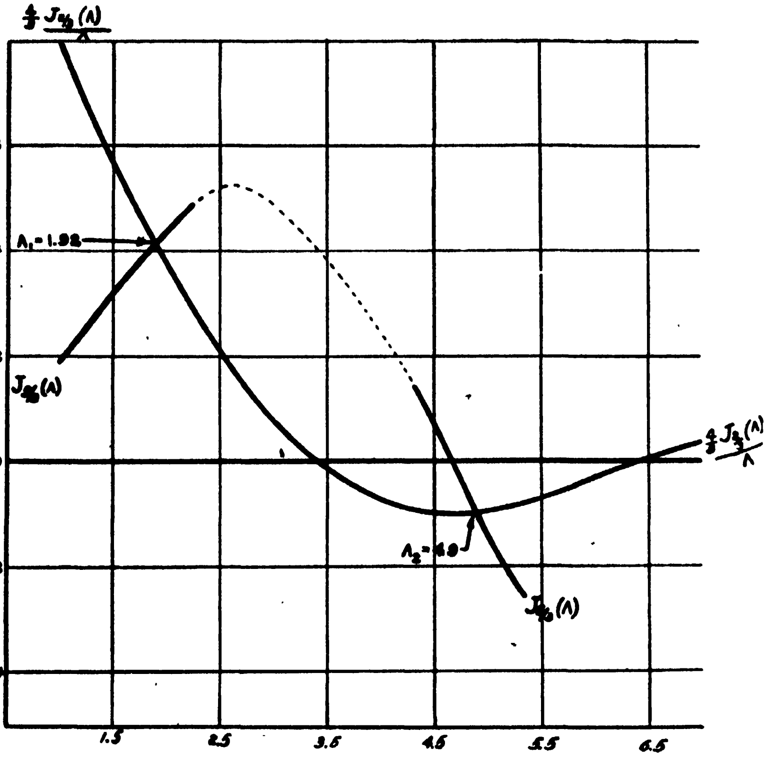

FIG. 2. Graphical solution for first two roots, $\Lambda_1$ and $\Lambda_2$ of Eq. (9).

$\partial E/\partial x$ must be zero for $z=1$, that is,

$$(\Lambda z^3)J_{2/3}'(\Lambda z^3) = -\tfrac{2}{3}J_{2/3}(\Lambda z^3) \quad \text{for } z=1.$$

Hence, the equivalent expression to be satisfied is:

$$J_{5/3}(\Lambda) = \frac{4}{3}\frac{J_{2/3}(\Lambda)}{(\Lambda)}. \tag{9}$$

The roots of this equation will determine the values of $\Lambda$ which will satisfy the boundary conditions at the base of the spring. Equation (9) may be solved graphically from tabulated values of $J_{5/3}(\Lambda)$ and of $4/3[J_{2/3}(\Lambda)/(\Lambda)]$. By inspection of Fig. 2, Eq. (9) is satisfied when $\Lambda = 1.92$, 4.9, $\cdots$,. Using the formulas developed in Section I, the natural frequencies may be computed. Table II shows the results of this case.

### IIB. Base Fixed, Vertex Free

In this case, the boundary conditions to be met are that $E(1, t) = 0$, and that $\partial E/\partial x$ be zero at $z=0$. It is advantageous at this point to write the general solution of Eq. (4) in the form:

$$W(y) = (y/2)^{\frac{1}{2}}\{AJ_{-2/3}(y) + BJ_{2/3}(y)\},$$

and noting that $y=0$ when $z=0$, $y=\Lambda$ when $z=1$. Now, from the definition of $J_{-2/3}(y)$, it is evident that

$$\lim_{y\to 0}[(y/2)^{\frac{1}{2}}J_{-2/3}(y)] = \frac{1}{\pi(-2/3)},$$

where $\pi(n) = \Gamma(n+1)$. Thus, when $y=0$, $E(z, t) = E(0, t) \neq 0$, as is required by boundary conditions, and the solution is not trivial. Inclusion of $J_{2/3}(y)$ in the solution is unnecessary to meet boundary conditions and $B$ can be taken as zero, thus reducing our solution to:

$$E(y, t) = (y/2)^{\frac{1}{2}}AJ_{-2/3}(y)\cos(\lambda t), \tag{10}$$

TABLE II.

| | Root | $\Lambda_i$ | $f_i$(c/sec.) | $f_i$(experimentally) |
|---|---|---|---|---|
| Ni | 1st | 1.92 | 1.53 | 1.53 |
| | 2nd | 4.9 | 3.9 | |
| | 3rd | 8.1 | 6.4 | |
| Piano wire | 1st | 1.92 | 1.49 | 1.51 |
| | 2nd | 4.9 | 3.8 | |
| | 3rd | 8.1 | 6.3 | |

or, in terms of $z$:

$$E(z, t) = [(\Lambda/2)^{\frac{1}{3}}A]z^2 J_{-2/3}(\Lambda z^3)\cos(\lambda t). \quad (11)$$

We now aim to satisfy the condition that $\partial E/\partial x$ be zero at $z=0$, using Eq. (11) as the particular solution of Eq. (1). This requires the following relationship to be satisfied:

$$3z(\Lambda z^3)J_{-2/3}'(\Lambda z^3) = -2zJ_{-2/3}(\Lambda z^3) \quad \text{for } z=0,$$

or the equivalent form:

$$3z[(-2/3)J_{-2/3}(\Lambda z^3) - \Lambda z^3 J_{1/3}(\Lambda z^3)] = -2zJ_{-2/3}(\Lambda z^3).$$

Terms in $J_{-2/3}(\Lambda z^3)$ are mutually annihilated and the following relationship remains to be satisfied:

$$-3\Lambda z^4 J_{1/3}(\Lambda z^3) = 0 \quad \text{for } z=0. \quad (12)$$

But this is true for $z=0$, hence, Eq. (11) satisfies the boundary condition at the vertex.

To satisfy the boundary condition at the base, $E(1, t) = 0$, the choice of $\Lambda$ must be restricted to roots of the equation $J_{-2/3}(\Lambda) = 0$. Hence, the boundary conditions of this case are satisfied by the particular solution (11) where $\Lambda_f$ are roots of $J_{-2/3}(\Lambda) = 0$. The first three roots of this equation are $\Lambda_1 = 1.25$, $\Lambda_2 = 4.43$, and $\Lambda_3 = 7.58$, while other roots may be deduced by adding $\pi$ successively to each former root.[2] After converting these roots to fundamental frequencies, the results of this case may be stated in tabular form (Table III).

Table III.

| | Root | $\Lambda_f$ | $f_f$(c/sec.) | $f_f$(experimentally) |
|---|---|---|---|---|
| Ni | 1st | 1.25 | 1.00 | 1.04 |
| | 2nd | 4.43 | 3.52 | |
| | 3rd | 7.58 | 6.04 | |
| Piano wire | 1st | 1.25 | .96 | .92 |
| | 2nd | 4.43 | 3.44 | |
| | 3rd | 7.58 | 5.88 | |

### IIIA. Weight Attached to Base, Vertex Fixed

The boundary conditions in this case are that $E(z, t)$ be zero at $z=0$ and that $K\partial E/\partial x = M\partial^2 E/\partial t^2$ at $z=1$, where $K = Gd^4/8z^3$, the spring "constant" in this problem, and $M$ the mass of the attached weight.

In order to satisfy the boundary condition at the vertex, $A$ in the general solution of Eq. (1) must be taken as zero. Hence,

$$(\Lambda/2)^{\frac{1}{3}}Bz^2 J_{2/3}(\Lambda z^3)\cos(\lambda t) \quad (13)$$

satisfies the physical conditions imposed at the point of support. To fulfill the boundary condition at $z=1$ (point of attachment of weight), the following equality must hold:

$$\frac{aGd^4}{4}\{4J_{2/3}(\Lambda) - 3\Lambda J_{5/3}(\Lambda)\} = 9Mc\Lambda^2 J_{2/3}(\Lambda),$$

or, writing this equation in a form more easily accessible to computation,

$$\left\{1 - \left[\frac{9Mc}{aGd^4}\right]\Lambda^2\right\} \cdot \frac{4}{3}\frac{J_{2/3}(\Lambda)}{(\Lambda)} = J_{5/3}(\Lambda). \quad (14)$$

Thus, the particular solution of Eq. (1) which satisfies the conditions of this case is Eq. (13) wherein $\Lambda_f$ are roots of Eq. (14). The defining equation for $\Lambda_f$, (14), and hence, for the fundamental frequencies of this system, may be solved by graphical means. The right member in Eq. (9) tabulated for Case IIA, is present here again. The function to the left of the equals sign in Eq. (14) is then built up as a tabulated function of $\Lambda$ and is plotted on the same sheet as $J_{5/3}(\Lambda)$. The intersection of these curves gives the roots $\Lambda_f$. Three different weights (60, 80, and 110 grams) are used in each case. For the coils used here, it was found that $aGd^4 = 5.22$ for the nickel coil, and for the piano wire coil, a corresponding value of $aGd^4 = 3.72$. Figure 3 gives, by inspection, the roots of Eq. (14) necessary for the fulfillment of the boundary conditions of this case. These roots are then converted into natural frequencies, yielding the following summary (Table IV).

### IIIB. Weight Attached to Vertex, Base Fixed

The boundary conditions in this case are that $E(z, t)$ be zero at $z=1$, and that $-K\partial E/\partial x = M\partial^2 E/\partial t^2$ at $z=0$, where $K = Gd^4/8z^3$, the spring "constant" in this problem, and $M$ the mass of the attached weights.

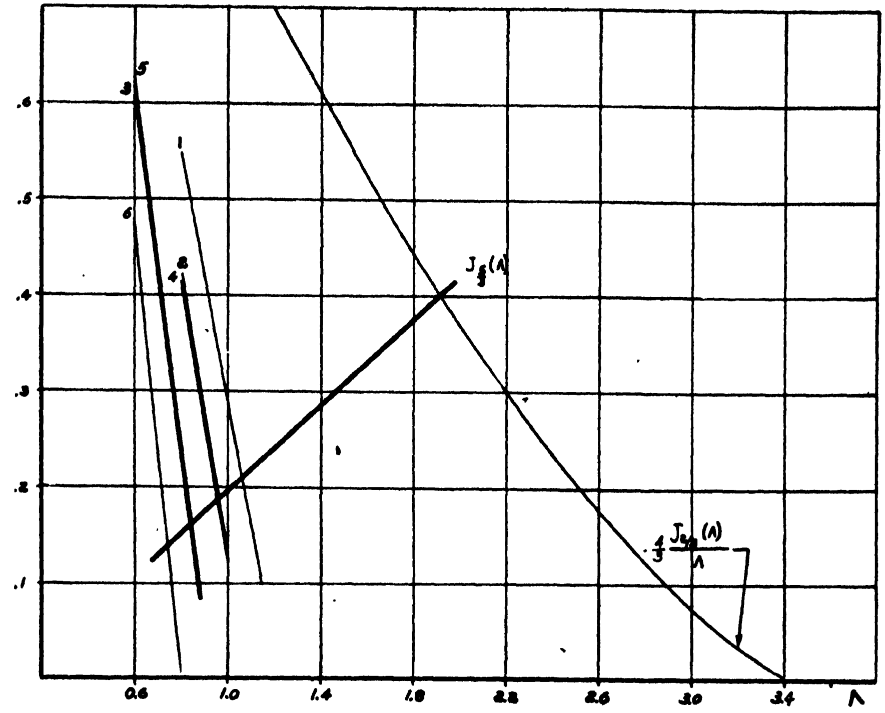

FIG. 3. Graphical solution of Eq. (14) for six values of $9Mc/aGd^4$.

To fulfill the boundary conditions of this problem, it is necessary to employ Bessel functions of orders $\frac{2}{3}$ *and* $-\frac{2}{3}$. The solution taken is the general one:

$$E(z,t)=(\Lambda/2)^{2/3}z^2$$
$$\times\{AJ_{-2/3}(\Lambda z^3)+BJ_{2/3}(\Lambda z^3)\}\cos(\lambda t). \quad (15)$$

The following two equalities must hold for the solution of this case:

$$\frac{aGd^4}{4z^2}(\Lambda/2)^{2/3}\{3A(\Lambda z^3)J_{-2/3}'(\Lambda z^3)+3B(\Lambda z^3)J_{2/3}'(\Lambda z^3)$$
$$+2AJ_{-2/3}(\Lambda z^3)+2BJ_{2/3}(\Lambda z^3)\}$$
$$=9Mc\Lambda^2(\Lambda/2)^{2/3}z^2\{AJ_{-2/3}(\Lambda z^3)+BJ_{2/3}(\Lambda z^3)\}, \quad (16)$$

for $z=0$, *and*

$$(\Lambda/2)^{2/3}z^2\{AJ_{-2/3}(\Lambda z^3)+BJ_{2/3}(\Lambda z^3)\}$$
$$\times\cos(\lambda t)=0 \quad (17)$$

for $z=1$. The condition of Eq. (17) reduces to:

$$AJ_{-2/3}(\Lambda)+BJ_{2/3}(\Lambda)=0. \quad (18)$$

In order to reduce Eq. (16) it is advisable to convert the derivatives of Bessel functions into related Bessel functions, and then to take limits of each term as $z\to 0$. Doing this, the condition to be met at the vertex becomes:

$$\left[\frac{aGd^4\Lambda^{2/3}}{(0.90275)4^{2/3}}\right]B_j=-\left[\frac{9Mc\Lambda^2 4^{2/3}}{(2.67893)\Lambda^{2/3}}\right]A_j. \quad (19)$$

Applying also condition (18), $A_j$ and $B_j$ can be eliminated, and the final ratio obtains:

$$\left\{-\left[\frac{aGd^4}{Mc}\right](59.4)\right\}\Lambda^{-2/3}=-\frac{J_{2/3}(\Lambda)}{J_{-2/3}(\Lambda)}, \quad (20)$$

where $M$ has been converted into grams. The values of $\Lambda_j$ which satisfy Eq. (20) are the ones which, when put into solution (15), will have both boundary conditions satisfied. Equation (20) may be solved graphically. $J_{2/3}(\Lambda)$ and

TABLE IV.

## IV. Two Intermediate Points Fixed

Next considered is the general case of the spring fastened at any two intermediate points. The

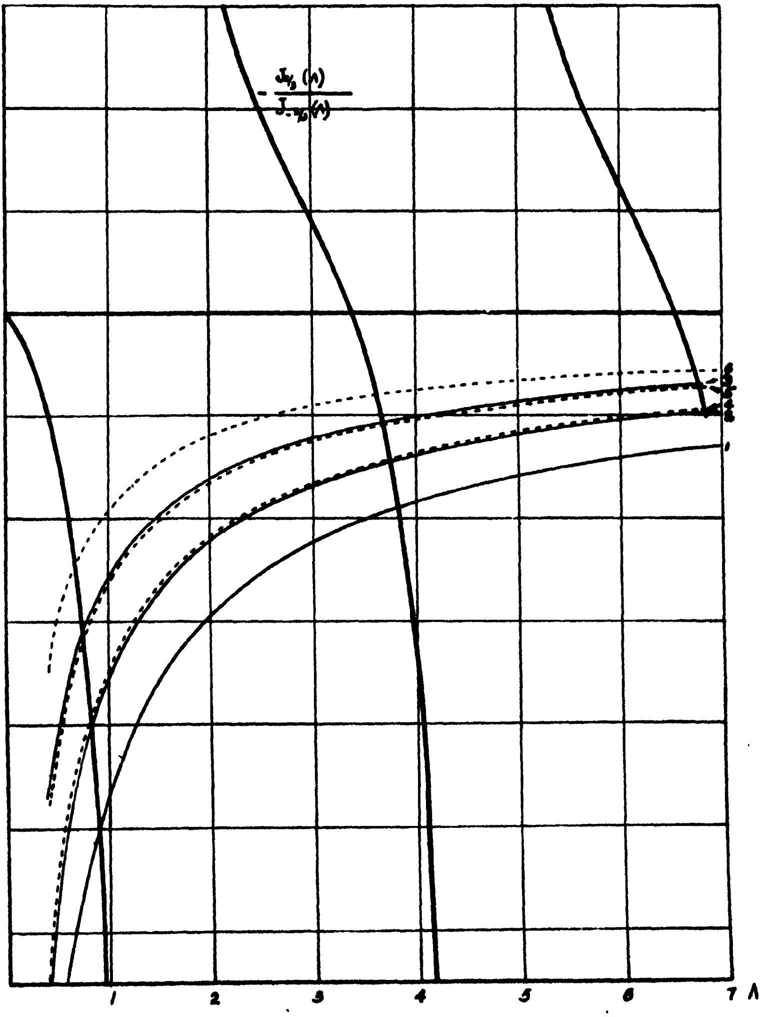

FIG. 4. Graphical solution of Eq. (20) for six values of $aGd^4/Mc$.

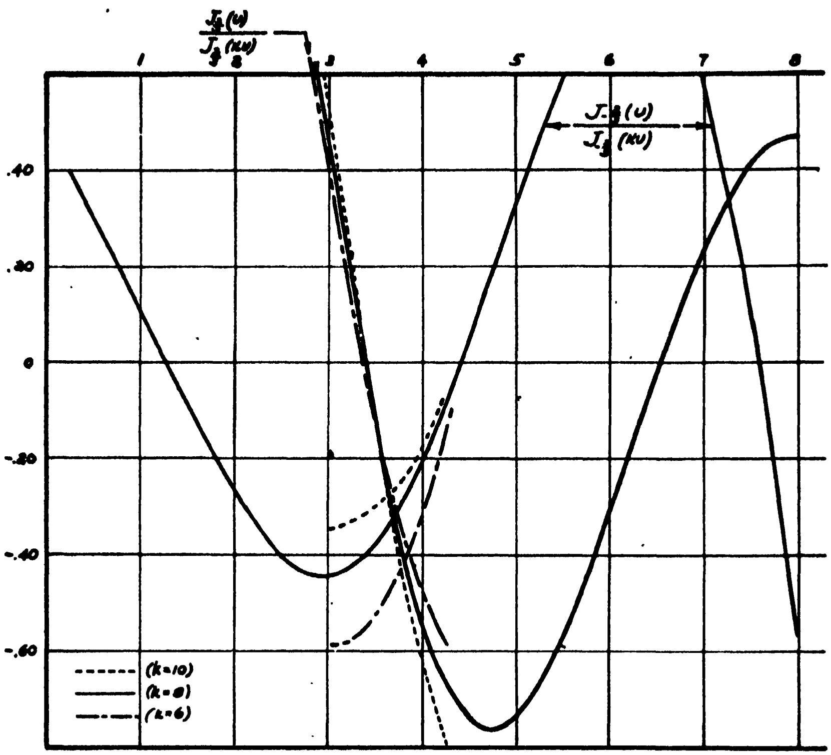

FIG. 5. Graphical solution of Eq. (24) when ratios of largest diameter of coil to smallest are as $1:10^{\frac{1}{3}}$, $1:2$, and $1:6^{\frac{1}{3}}$.

boundary conditions, stated mathematically, are that $E(z', t) = 0$ for $z' = a$ and for $z' = b$. There is no loss in generality if the widest upper boundary is taken to have the value 1. This can be done since in Eq. (1), $c$ is defined as $a^2Gd^4/2\pi mD_0^6$, where $D_0$ is the diameter of the widest turn of wire. This is, in effect, thinking of the upper bound as the base of the spring. Thus, the boundary conditions to be used are: $E(1, t) = 0 = E(b, t)$, where $0 < b < 1$. We take as a solution of Eq. (4) the general solution:

$$E(z,t) = (\Lambda/2)^{\frac{1}{3}} z^2 \{A J_{-2/3}(\Lambda z^3) + B J_{2/3}(\Lambda z^3)\} \times \cos(\lambda t). \qquad (21)$$

To satisfy boundary conditions at $z = 1$ and at $z = b$, the following equalities must be met simultaneously:

$$A J_{-2/3}(\Lambda) + B J_{2/3}(\Lambda) = 0, \qquad (22)$$

$$A J_{-2/3}(\Lambda b^3) + B J_{2/3}(\Lambda b^3) = 0. \qquad (23)$$

The solution of this pair of simultaneous equations depends upon the satisfaction of the following relationship:

$$\frac{J_{-2/3}(\Lambda)}{J_{-2/3}(\Lambda b^3)} = \frac{J_{2/3}(\Lambda)}{J_{2/3}(\Lambda b^3)}. \qquad (24)$$

Equation (24) may be solved graphically for specific values of $b^3$. Values of $J_n(k\Lambda_j)$ for $n = \frac{2}{3}$ and $-\frac{2}{3}$, and for $k = 6$, 8, and 10 are derived from tabulated values of $J_{-2/3}(x)$ and $J_{2/3}(x)$ by a shift of axis of the independent variable. It will be noted that this case degenerates into Case I when $k$ becomes infinite (that is, when the lower diameter is taken as zero). Figure 5 shows the solution of Eq. (24) for values of $b^3 = 6$, 8, and 10. It gives, by inspection, the values of $\Lambda_j$ which will satisfy Eq. (21) and both boundary conditions. $\Lambda_j$ may be translated into $f_j$ and in the usual way. Table VI below gives the results of this case.

## ACKNOWLEDGMENT

Special appreciation is due Professor D. A. Wells for having suggested this problem and for having offered many stimulating suggestions during its composition.

# An Introduction to the Mathematical Theory of Plasticity

W. PRAGER
*Brown University, Providence, Rhode Island*

(Received December 12, 1946)

The paper aims at introducing the reader to the principal theories of plasticity. Since a presentation of the general stress-strain relations used in these theories would require too much space, the discussion is restricted to the mechanical behavior of plastic materials under shear. Theories of plastic deformation (Hencky, Nadai) and theories of plastic flow (Saint Venant-Lévy-Mises, Prandtl-Reuss, Prager) are illustrated by the example of a prismatic bar under torsion.

## 1. INTRODUCTION

IN designing a structural member or a machine part the engineer, as a rule, uses formulas which are based on the theory of elasticity in a more or less rigorous manner. The highest stress predicted by these formulas is then compared with the maximum stress of the same type which the material can stand without failure. A so-called factor of safety is derived from this comparison. Now, in all but the very simplest cases the factor of safety obtained in this manner will differ considerably from the factor of safety defined as the ratio of the ultimate load to the design load. The reason for this is, of course, the fact that the stresses set up by the ultimate load will exceed the elastic limit of the material and that, consequently, the theory of elasticity is unable to predict these stresses. In order to obtain the second factor of safety, the only one with a physical meaning, the mechanical behavior of the material beyond the elastic limit must be taken into account. This behavior must also be taken into consideration in the study of manufacturing processes which aim at obtaining a favorable stress distribution under service conditions by setting up suitable initial stresses through previous plastic deformations. Another important field of application of the theory of plasticity is furnished by the phenomenon of creep. Under a constant load acting over a long period of time and at a high temperature a slow but steady increase of the deformation may take place. The problem of predicting the total deformation due to creep which may occur during the lifetime of a structure is of an obvious importance. In the cases mentioned so far, the plastic deformations must be rather small, as otherwise they would endanger the safety of the structure. This assumption of small deformations will no longer be justified in the study of technological processes like rolling or drawing. However, in an introduction to the theory of plasticity, it would certainly be unwise to try to cope at the same time with the difficulties arising from the consideration of finite deformations and from the unelastic behavior of the material. In the following it will, therefore, be assumed that the deformations, though greater than those possible within the elastic range, can still be treated as small. In order to show that such an assumption is reasonable, let us consider a bar of mild steel in simple tension. At the elastic limit the unit extension is of the order of one per mille. Now, we certainly are entitled to treat a unit extension of one percent still as small, but it is already far greater than any unit extension possible within the elastic range.

## 2. ELASTIC TORSION

The essential characteristic of the mechanical behavior of an elastic material is adequately expressed in Hooke's famous statement "*ut tensio sic vis.*" No similarly concise description of the mechanical behavior of plastic materials is possible, and a mathematical theory attempting to take into consideration all mechanical phenomena observed in the plastic range would not be practical. A workable mathematical theory must idealize the mechanical behavior of structural materials to a certain extent, and different idealizations are being used in the various fields of application. The fact that there exist almost as many theories of plasticity as writers on this subject is often a source of confusion to the student beginning to explore this field.

In the following, some of the more important theories of plasticity will be discussed briefly. Since a presentation of the general stress-strain relations used in the mathematical theory of plasticity would require too much space, the following discussion is restricted to the mechanical behavior of plastic materials under shear such as occurs at a generic point of a cylindrical or prismatic bar in torsion. Using a system of rectangular coordinates $x$, $y$, $z$, with the $z$ axis parallel to the generators of the cylindrical or prismatic surface of the bar, we let $\tau_x$ and $\tau_y$ denote the components of the shearing stress acting at a generic point of a cross section. We shall assume that all other stress components vanish and that $\tau_x$ and $\tau_y$ are independent of $z$.

The equation of equilibrium,[1]

$$\partial\tau_x/\partial x+\partial\tau_y/\partial y=0 \qquad (1)$$

is fulfilled if the stress components are derived from a stress function $\psi(x, y)$ in accordance with

$$\tau_x=\partial\psi/\partial y, \quad \tau_y=-\partial\psi/\partial x. \qquad (2)$$

The condition that the cylindrical or prismatic surface of the bar is free from stresses requires that the stress function $\psi$ has a constant value, for instance zero, along the boundary of the cross section of the bar.[1]

In order to obtain a differential equation for the stress function, we must consider the deformations of the bar and make use of the stress-strain relations. As in elastic torsion, the displacement components are assumed to be of the form

$$u=-yz\theta, \quad v=xz\theta, \quad w=\varphi(x, y, \theta), \qquad (3)$$

where $\theta$ denotes the angle of twist per unit length, and the function $\varphi$ represents the warping of an originally plane cross section of the bar.[2] The shear strains corresponding to the displacements (3) are[3]

$$\gamma_x=\partial\varphi/\partial x-y\theta, \quad \gamma_y=\partial\varphi/\partial y+x\theta. \qquad (4)$$

Up to this point, our discussion of the torsion problem applies equally well to elastic and plastic materials. Further progress, however, depends on the introduction of a stress-strain relation, and different materials require different stress-strain relations. For the purpose of the present discussion, the stress-strain relation of an *isotropic* material is best expressed as a relation between the vector $\boldsymbol{\tau}$ with the components $\tau_x$, $\tau_y$ and the vector $\boldsymbol{\gamma}$ with the components $\gamma_x$, $\gamma_y$, both vectors being considered as functions of time, as is the angle $\theta$. In addition to the vectors $\boldsymbol{\tau}$ and $\boldsymbol{\gamma}$, a stress-strain relation may therefore contain their derivatives with respect to time, $\partial\boldsymbol{\tau}/\partial t$, $\partial\boldsymbol{\gamma}/\partial t$, $\partial^2\boldsymbol{\tau}/\partial t^2$, etc. In expressing the stress-strain relation in vector form, we make certain that it is independent of the choice of the coordinate axes $x$, $y$, as it must be for an isotropic material.

For an elastic material, the stress-strain relation (Hooke's law) has the following particularly simple form

$$\boldsymbol{\tau}=G_0\boldsymbol{\gamma}, \qquad (5)$$

where $G_0$ is the shear modulus, a characteristic constant of the material. Introducing (2) and (4) into the scalar equations equivalent to (5), we obtain

$$\begin{aligned}\partial\psi/\partial y&=G_0(\partial\varphi/\partial x-y\theta),\\ -\partial\psi/\partial x&=G_0(\partial\varphi/\partial y+x\theta).\end{aligned} \qquad (6)$$

Elimination of the warping function $\varphi$ from Eqs. (6) furnishes the following differential equation for the stress function:

$$\partial^2\psi/\partial x^2+\partial^2\psi/\partial y^2=-2G_0\theta, \qquad (7)$$

where $G_0$ and $\theta$ may be considered as given constants. Together with the condition that $\psi=0$ on the boundary of the cross section, Eq. (7) completely defines the stress function $\psi$.

As L. Prandtl[4] has pointed out, the function $\psi$ satisfying (7) and vanishing along the boundary can be obtained by experiment. Let us consider a thin membrane, for instance a soap film, which is uniformly stretched over an opening in a rigid plane plate. The edge of the opening is given the shape of the contour of the cross section for which we desire to solve the boundary value problem formulated above. Furthermore, the membrane is fastened to the edge of the opening.

---

[1] See, for instance, S. Timoshenko, *Theory of Elasticity* (McGraw-Hill Book Company, Inc., New York, 1934) p. 230.

[2] J. Mandel, Ann. Ponts Chaussées **116**, 1–33 (1946) assumes $w=\theta\varphi(x, y)$. Such proportionality between warping and angle of twist can hardly be expected in the plastic range.

[3] See, for instance, S. Timoshenko, reference 1, p. 233.

[4] L. Prandtl, Jahresber. Deutsch. Math.-Ver. **13**, 31–36 (1904).

If we now have a small excess pressure $p$ on one side of the plate, the membrane will be deformed and it can easily be shown that the deflections $\omega$ of the membrane out of its original plane will satisfy the differential equation

$$\partial^2\omega/\partial x^2+\partial^2\omega/\partial y^2=-p/T, \qquad (8)$$

where $T$ is the uniform surface tension in the membrane. Along the edge of the opening we have $\omega=0$. Choosing the value of $p/T$ in a suitable manner, we can therefore obtain the surface $z=\psi(x, y)$ by experiment. Equations (2) show that the magnitude of the vector $\boldsymbol{\tau}$ is represented by the slope of the deformed membrane, and that the vector $\boldsymbol{\tau}$ is tangential to the contour lines of the deformed membrane.[5]

### 3. STRESS-STRAIN RELATIONS FOR PLASTIC MATERIALS UNDER SHEAR

In its initial phase, engineering research in plasticity was concerned with the limits of the elastic range rather than the phenomena occurring beyond this range. The condition that a given state of stress and strain is on the boundary of the elastic domain is expressed mathematically by the vanishing of a certain expression in the components of stress and strain (*yield condition*). For isotropic materials, this expression must be invariant with respect to rotation of the coordinate axes. Since Hooke's law holds up to the boundary of the elastic domain, all strain components which might appear in the yield condition can be expressed in terms of stress components. The yield conditions for an isotropic material then stipulates the vanishing of a certain stress invariant. In the torsion problem, where the state of stress at a point is defined by the vector $\boldsymbol{\tau}$, the only yield condition of this kind is

$$|\boldsymbol{\tau}|-k=0, \qquad (9)$$

where $|\boldsymbol{\tau}|$ denotes the *intensity of stress*, i.e., the magnitude of the vector $\boldsymbol{\tau}$, and $k$ the yield stress in pure shear.

The yield condition (9) establishes the limit up to which the stress distribution can be obtained from the theory of elasticity. To carry the stress analysis beyond this point, we must explore the stress-strain relations in the plastic range. It was already pointed out above that, for the torsion problem, a stress-strain relation reduces to a relation between the vectors $\boldsymbol{\tau}$ and $\boldsymbol{\gamma}$ and their derivatives with respect to time. We shall restrict the following discussion to stress-strain relations which do not involve time derivatives of an order higher than the first. Moreover, we shall neglect all viscosity effects. This means that we shall only admit stress-strain relations which are homogeneous in the time rates of stress and strain. In spite of these restrictions which are suggested by the results of experiments on metals such as steel, copper, and aluminum, we still retain considerable freedom in fitting stress-strain relations to experimental evidence.

With each *homogenous* state of stress and strain in a plastic body there is associated a certain *permanent strain*, i.e., the residual strain after the stress is reduced to zero by unloading the body. That part of the strain which disappears upon unloading is called the *elastic strain*. In the case of the torsion problem, we shall denote the elastic and permanent strains by $\boldsymbol{\gamma}'$ and $\boldsymbol{\gamma}''$, respectively. Experience shows that the elastic strain is related to the stress by Hooke's law:

$$\boldsymbol{\tau}=G_0\boldsymbol{\gamma}'. \qquad (10)$$

In establishing stress-strain relations for plastic materials, we must distinguish between *loading* and *unloading*. An infinitesimal change of the state of stress and strain in a plastic material is said to constitute loading if it involves a change of the permanent strain. On the other hand, during an infinitesimal change of stress and strain which constitutes unloading the permanent strain remains constant. In the case of the torsion problem, we have $\partial\boldsymbol{\gamma}/\partial t=\partial\boldsymbol{\gamma}'/\partial t$ for unloading, and Eq. (10) suggests

$$\partial\boldsymbol{\tau}/\partial t=G_0\partial\boldsymbol{\gamma}/\partial t \qquad (11)$$

as the stress-strain relation for unloading. Equation (11) is used in all theories of plasticity as the stress-strain relation for unloading; these theories therefore differ only in the stress-strain relations for loading. Moreover, even for loading the elastic strain is supposed to be related to the stress by Hooke's law, so that the task of establishing a stress-strain relation for a plastic

---

[5] For a comprehensive survey of the elastic torsion problem see T. J. Higgins, J. App. Phys. 10, 248–259 (1942).

material consists essentially in defining the manner in which the permanent strain, or its rate of change, depend on the stress. For the torsion problem, in particular, we must define the manner in which $\gamma''$ or $\partial\gamma''/\partial t$ depend on $\boldsymbol{\tau}$.

Let us first consider the case where $\gamma''$ is made to depend on $\boldsymbol{\tau}$ (*theories of plastic deformation*). The isotropy of the material requires then that these two vectors have the same direction. This may be expressed by the equation

$$G_0\gamma''=(\lambda-1)\boldsymbol{\tau}, \tag{12}$$

where $\lambda$ is a scalar factor of proportionality which, as a rule, will be a function of the coordinates $x$, $y$, and the time. To obtain a proper relation between $\gamma''$ and $\boldsymbol{\tau}$ we must supplement Eq. (12) by a relation between the intensities $|\gamma''|$ and $|\boldsymbol{\tau}|$:

$$|\boldsymbol{\tau}|=G_0f(|\gamma''|). \tag{13}$$

In the following, Eq. (13) will be called the *flow condition.* The flow condition enables us to eliminate the factor of proportionality, $\lambda$, from Eq. (12). In the following, we shall consider two kinds of flow conditions:

(a) *for perfectly plastic materials:* $G_0f=k=\text{const.}$,

(b) *for materials with strain-hardening:* for the small permanent strains to which this discussion is restricted, $f$ is a monotonically increasing function of its argument; it is then convenient to write the inverse of (13) in the form

$$G_0|\gamma''|=|\boldsymbol{\tau}|[g(|\boldsymbol{\tau}|/G_0)-1]. \tag{14}$$

The elastic strain is given by Eq. (10), the permanent strain by (12) and (13). Combining Eqs. (10) and (12), we obtain the following relation for the total strain $\gamma=\gamma'+\gamma''$:

$$G_0\gamma=\lambda\boldsymbol{\tau}. \tag{15}$$

In the case of a perfectly plastic material Eq. (15) together with the flow condition $|\boldsymbol{\tau}|=k$ constitute the stress-strain relations for loading. This stress-strain relation must, of course, be supplemented by Hooke's law, Eq. (5), which is supposed to be valid as long as $|\boldsymbol{\tau}|<k$. Stress-strain relations of this type were first discussed by H. Hencky.[6] In the case of a material with strain-hardening the form (14) of the flow condition enables us to eliminate $\lambda$ from Eq. (15). Since both $\gamma'$ and $\gamma''$ have the direction of $\boldsymbol{\tau}$, we have

$$G_0|\gamma''|=G_0[|\gamma|-|\gamma'|]=G_0|\gamma|-|\boldsymbol{\tau}|.$$

Equating the last member of this continued equation to the right-hand side of (14), we find

$$G_0|\gamma|=|\boldsymbol{\tau}|g(|\boldsymbol{\tau}|/G_0).$$

Comparing this to the equation obtained by taking absolute values on both sides of (15), we find

$$\lambda=g(|\boldsymbol{\tau}|/G_0).$$

The stress-strain relation for the loading of a material with strain-hardening therefore takes the form

$$G_0\gamma=\boldsymbol{\tau}g(|\boldsymbol{\tau}|/G_0). \tag{16}$$

Setting $G_0/g=G$, we may write (16) in the form $\boldsymbol{\tau}=G\gamma$, where $G$ is a function of $|\boldsymbol{\tau}|/G_0$. This stress-strain relation which, of course, applies to loading only, has the form of Hooke's law, but the shear modulus $G$, the so-called *secant modulus*, depends on the intensity of stress. The relation $\boldsymbol{\tau}=G\gamma$ covers the elastic as well as the plastic range, if $G$ is made to equal $G_0$ for $|\boldsymbol{\tau}|<k$. The practical stress analysis is simplified, however, if a single analytic function $G(|\boldsymbol{\tau}|/G_0)$ is used for both the elastic and the plastic range. To obtain good results one must, of course, choose a function which departs but little from the initial value $G_0$ as long as $|\boldsymbol{\tau}|<k$. On account of its mathematical simplicity, this type of stress-strain relation which was introduced by A. Nadai[7] is widely used in the modern literature;[8] it gives a continuous transition from the elastic to the plastic state.

The stress-strain relations of Hencky and Nadai are sometimes criticized because they let the stress depend on the instantaneous strain only and not on the history of straining as might

Sokolovsky, J. Appl. Mech. **13**, A1–A10 (1946).

be expected for plastic materials. We shall return to this criticism after discussing some rival theories of plasticity.

Let us now consider the case where $\partial\boldsymbol{\gamma}''/\partial t$ is made to depend on $\boldsymbol{\tau}$ (*theories of plastic flow*). The isotropy of the material requires that these two vectors have the same direction, and we may write

$$G_0\partial\boldsymbol{\gamma}''/\partial t=\mu\boldsymbol{\tau}, \tag{17}$$

where $\mu$ is a factor or proportionality similar to the factor $\lambda$ appearing in (12). Combining Eqs. (10) and (17), we obtain the following relation for the total strain $\boldsymbol{\gamma}=\boldsymbol{\gamma}'+\boldsymbol{\gamma}''$:

$$G_0\partial\boldsymbol{\gamma}/\partial t=\partial\boldsymbol{\tau}/\partial t+\mu\boldsymbol{\tau}. \tag{18}$$

For a perfectly plastic material with the flow condition $|\boldsymbol{\tau}|=k$ or $\boldsymbol{\tau}\cdot\boldsymbol{\tau}=k^2$, we have $\boldsymbol{\tau}\cdot\partial\boldsymbol{\tau}/\partial t=0$. Scalar multiplication of each side of Eq. (18) by $\boldsymbol{\tau}$ yields therefore

$$\mu=G_0\boldsymbol{\tau}\cdot\partial\boldsymbol{\gamma}/k^2\partial t=G_0\dot{W}/k^2, \tag{19}$$

where $\dot{W}=\boldsymbol{\tau}\cdot\partial\boldsymbol{\gamma}/\partial t$ denotes the rate at which work is done. Substituting (19) into (18) we obtain

$$G_0\partial\boldsymbol{\gamma}/\partial t=\partial\boldsymbol{\tau}/\partial t+G_0\dot{W}\boldsymbol{\tau}/k^2 \text{ with } |\boldsymbol{\tau}|=k. \tag{20}$$

This stress-strain relation for loading must, of course, be supplemented by Hooke's law, Eq. (5), which is supposed to be valid as long as $|\boldsymbol{\tau}|<k$. Stress-strain relations of this type were first discussed by L. Prandtl[9] and E. Reuss.[10]

As has already been indicated above, the sharp distinction between the elastic and plastic ranges with separate stress-strain relations complicates any stress analysis considerably. It therefore seems desirable to modify Eq. (20) so as to obtain a gradual transition from the elastic to the plastic state and take account of strain-hardening at the same time. As the present author[11] has shown, this can be accomplished without difficulty. In fact, let us drop the condition $|\boldsymbol{\tau}|=k$ in (20). Scalar multiplication of each side of this equation by $\boldsymbol{\tau}$ then furnishes

$$G_0\dot{W}=\tfrac{1}{2}\dot{S}+G_0\dot{W}S/k^2, \tag{21}$$

where $S=\boldsymbol{\tau}\cdot\boldsymbol{\tau}=|\boldsymbol{\tau}|^2$ is a measure of the intensity of stress and the dot denotes differentiation with respect to time. Solving (21) for $\dot{W}$ and substituting into (20), we obtain

$$G_0\frac{\partial\boldsymbol{\gamma}}{\partial t}=\frac{\partial\boldsymbol{\tau}}{\partial t}+\frac{\dot{S}/k^2}{2(1-S/k^2)}\boldsymbol{\tau}. \tag{22}$$

Let us apply this stress-strain relation to the case of pure shear, where $\tau_y=\gamma_y=0$. Equation (22) then takes the form

$$G_0\dot{\gamma}_x=\dot{\tau}_x+\frac{\tau_x\dot{\tau}_x/k^2}{1-\tau_x{}^2/k^2}\tau_x=\frac{\dot{\tau}_x}{1-\tau_x{}^2/k^2}. \tag{23}$$

With the initial condition $\tau_x=0$ for $\gamma_x=0$, integration of (23) furnishes

$$\tau_x=k\tanh(G_0\gamma_x/k).$$

The graph of $\tau_x$ *vs.* $\gamma_x$ has the initial slope $G_0$ and the asymptote $\tau_x=k$. The stress-strain relation (23) thus provides a continuous transition from elastic behavior governed by Hooke's law to the flow of a perfectly plastic material.

Equation (23) is easily modified so as to include strain-hardening. To this end we write

$$G_0\frac{\partial\boldsymbol{\gamma}}{\partial t}=\frac{\partial\boldsymbol{\tau}}{\partial t}+\frac{1}{2}\left(\frac{G_0}{G^*}-1\right)\frac{\dot{S}}{S}\boldsymbol{\tau}, \tag{24}$$

where $G^*$ denotes the so-called *tangent modulus* which depends on the stress intensity $S$. Indeed, specializing as in (23), we obtain

$$G_0\dot{\gamma}_x=\dot{\tau}_x+\left(\frac{G_0}{G^*}-1\right)\frac{\tau_x\dot{\tau}_x}{\tau_x{}^2}\tau_x=\frac{G_0}{G^*}\dot{\tau}_x$$

or

$$d\tau_x/d\gamma_x=G.^*$$

From a graph of $\tau_x$ *vs.* $\gamma_x$ the tangent modulus $G^*$ can be found as a function of $\tau_x{}^2$; the quantity $G^*$ appearing in (24) is the same function of $S$. The stress-strain relation (24) was suggested in 1942 by H. J. Laning in an unpublished manuscript; more general stress-strain relations of this type are discussed by G. H. Handelman, C. C. Lin, and W. Prager.[12]

The first term on the right-hand side of Eq. (18) represents the rate of change of the elastic

strain. For perfectly plastic materials, it has sometimes been suggested to neglect the elastic strains at the side of the often much larger permanent strains. Equation (18) then takes the form

$$\partial\gamma/\partial t=\mu'\boldsymbol{\tau} \text{ with } |\boldsymbol{\tau}|=k. \tag{25}$$

Stress-strain relations of this type were the first to be used in the theory of plasticity, in the two-dimensional case by B. de Saint Venant,[13] and in the three-dimensional case by M. Lévy[14] and R. v. Mises.[15] As will be shown below, serious objections can be raised against the neglection of elastic strains.[16] In view of this fact, the amount of effort which has been spent on developing this particular theory of plasticity is surprising.[17]

## 4. PLASTIC TORSION

In applying the stress-strain relations of the preceding section to the torsion problem, let us first consider perfectly plastic materials. These possess a clearly defined yield point below which they obey Hooke's law (Hencky, Prandtl-Reuss) or are rigid (Saint Venant-Lévy-Mises); in the plastic range they flow under constant $|\boldsymbol{\tau}|$. Once the applied torque is sufficiently large to produce yielding, the cross section can be divided into elastic (or rigid) and plastic regions. In the latter we have $|\boldsymbol{\tau}|=k$ or, in terms of the stress function,

$$(\partial\psi/\partial x)^2+(\partial\psi/\partial y)^2=k^2. \tag{26}$$

As the applied torque increases the plastic regions expand until, finally, they cover the entire cross section.

Let us first consider this final stage of the torsion test. Here Eq. (26) is satisfied throughout the cross section. The left-hand side of this equation is the square of the slope of the tangent plane of the surface $z=\psi(x, y)$ with respect to the plane $z=0$. According to (26) the surface $z=\psi(x, y)$ therefore is a surface of constant slope. We can produce such a surface experimentally by heaping sand on a horizontal tray which has the shape of the cross section. Indeed, the slope of such a sand hill has a constant value corresponding to the angle of friction, and the boundary condition $\psi=0$ is enforced by the shape of the tray. For a bar of quadratic cross section, for instance, the surface $z=\psi(x, y)$ is a pyramid, for a rectangular cross section it has the form of a roof and for a circular cross section the form of a cone.

In the case of a perfectly plastic material, and for a torque which produces plastic flow throughout the entire test specimen, the stress distribution can thus be obtained without reference to any specific relation between stresses and strains. This fact is usually expressed by stating that, under these circumstances, the stress distribution in torsion is statically *determinate.*[18]

So far, we have assumed that the torque is sufficiently large to produce plastic flow throughout the entire test specimen. For smaller torques only part of the material will become plastic. According to the theories of Hencky and Prandtl-Reuss, the stress function $\psi$ will satisfy Eq. (7) [with $(\partial\psi/\partial x)^2+(\partial\psi/\partial y)^2<k^2$] in the elastic region of the cross section and Eq. (26) in the plastic region. Continuity of the stress vector $\boldsymbol{\tau}$ at the boundary between elastic and plastic regions requires continuity of the first derivatives of $\psi$. The complete problem for the stress function has therefore the following form: *to determine a function $\psi(x,y)$ with continuous first derivatives, which vanishes along the contour of the cross section and satisfies Eq. (7) with $(\partial\psi/\partial x)^2+(\partial\psi/\partial y)^2<k^2$ in part of the cross section and Eq. (26) in the rest.*[19] As Nadai[18] has pointed out, Prandtl's membrane analogy can easily be modified so as to enable us to solve this problem by experiment. Let us consider the square cross section as an example. A membrane is then stretched uniformly over a square opening in a rigid plate and fastened to the edge of this opening. Over the opening we erect a pyramidal surface of the slope which corresponds to the yield stress $k$. If now the membrane is deformed by slowly increasing pres-

[17] Excellent surveys of the Saint Venant-Mises theory of plasticity have been given by H. Geiringer, *Fondements mathématiques de la théorie des corps plastiques isotropes* (Gauthier-Villars, Paris, 1937), and S. G. Mikhlin in the chapter entitled "The mathematical theory of plasticity" of the book *Some New Methods in the Mechanics of Continuous Media* (Russian), (Izd. A. N. USSR, 1938), pp. 157–216.

[18] This was first pointed out by A. Nadai, Zeits. f. angew. Math. Mech. **3**, 442–454 (1923).

[19] For an ingenious manner of constructing particular solutions of this problem by an inverse method see V. V. Sokolovsky, Prikladnaia Mat. Mekh. **6**, 241–246 (1942).

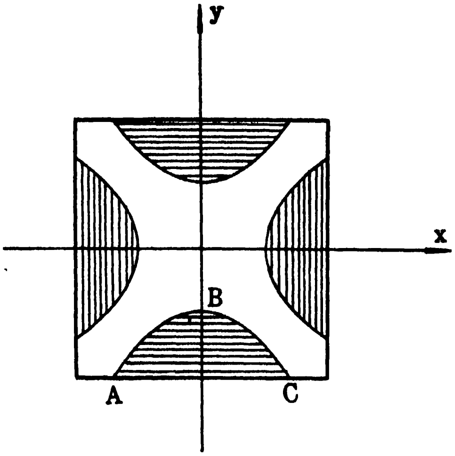

FIG. 1. Elastic and plastic regions in the cross section of a prismatic bar under torsion.

sure on one side of the plate, it will at first assume a shape which corresponds to the stress function in the elastic case. As the pressure increases, however, the membrane will partly be pressed against the pyramidal surface. Where this is the case, the membrane represents the plastic stress function satisfying Eq. (26). Where the membrane is not in contact with the pyramidal surface it represents the elastic stress function satisfying Eq. (7).

Having determined the stresses by means of this so-called soap film—sand hill analogy, we can determine the strains. Let us first apply the theory of Hencky, again considering a square cross section as an example. In Fig. 1, let the shaded areas be the plastic regions as obtained from the soap film—sand hill analogy and the unshaded cruciform area the elastic region. Since the stress function, and hence the stresses, are determined by the analogy, the strains in the elastic region can be found by applying Hooke's law. As Eqs. (4) show, this means that, in the elastic region, the warping function $\varphi$ can be determined to within an immaterial constant. To show how the warping function in the plastic region is found, we consider the shaded area $ABC$ in Fig. 1. Here $\tau_x = k$, $\tau_y = 0$, and the $y$ component of Hencky's stress-strain relation (15) gives

$$\gamma_y = \partial\varphi/\partial y + x\theta = 0, \qquad (27)$$

while the $x$ component does not furnish any information on account of the presence of the unknown factor $\lambda$. Integration of (27) furnishes

$$\varphi = -xy\theta + f(x). \qquad (28)$$

Along the arc $ABC$ the warping function $\varphi$ is known from the elastic solution, and this enables us to determine the function $f(x)$ in (28).

Next, let us apply the theory of Prandtl and Reuss to the same problem. The soap film—sand hill analogy shows that, for any given torque, this theory furnishes the same stress distribution as that of Hencky. Moreover, it can be shown that the warping function, too, is the same for both theories.[20] Indeed, let us consider a generic point $P$ of the cross section. As the torque is increased, the boundary between the elastic and plastic regions sweeps across the section of the bar. Once $P$ has been engulfed in the plastic region, the stress $\boldsymbol{\tau}$ at this point remains constant. For instance, if $P$ is engulfed in the shaded area $ABC$ of Fig. 1, the stress at $P$ will have the constant components $\tau_x = k$, $\tau_y = 0$. Accordingly, $\partial\boldsymbol{\tau}/\partial t$ is zero, and the $y$ component of the stress-strain relation (18) of the Prandtl-Reuss theory furnishes $\dot{\gamma}_x = 0$, while the $x$ component does not give any information on account of the presence of the unknown factor $\mu$. The strain component $\gamma_x$ therefore retains whatever value it has at the instant when the boundary between the elastic and plastic regions sweeps across $P$. On account of the continuity of the stress vector, however, the stress components at $P$ just before this point is engulfed into the plastic region must be $\tau_x = k$, $\tau_y = 0$. At this instant we therefore have $\gamma_y = 0$ at $P$, by Hooke's law. Since from this instant on $\dot{\gamma}_y = 0$ at $P$, we have $\gamma_y = 0$ at a generic point $P$ inside the shaded area $ABC$ of Fig. 1. From this and the identity of the stress distributions for the two theories follows the identity of the warping functions.

The theories of Hencky and Prandtl-Reuss are thus seen to furnish two identical predictions in the case of the torsion problem. This result must not be unduly generalized, however. As a rule, the predictions furnished by the two theories

---

[20] This was first pointed out by the present author in H. Geiringer and W. Prager, "Mechanik isotroper Koerper im plastischen Zustand," Ergebnisse d. exakt. Nat. wiss. 13, 310–363 (1934), p. 331.

differ; conditions under which they agree were investigated by A. A. Ilyushin.[21]

As regards the theory of Saint Venant-Lévy-Mises, it does not give a solution of the torsion problem except in the case where the torque is sufficiently large to produce plastic flow throughout the entire test specimen. Indeed, the stress distribution in the plastic part being the same as was studied above, Eq. (25) gives

$$\dot{\gamma}_y = \partial\dot{\varphi}/\partial y + x\dot{\theta} = 0$$

or

$$\dot{\varphi} = -xy\dot{\theta} + f(x) \tag{29}$$

for a point in the shaded region $ABC$ in Fig. 1. Since the cruciform unshaded region now is supposed to be rigid, we have $\dot{\varphi}=0$ along the arc $ABC$. This condition enables us to determine $f(x)$, and hence $\dot{\varphi}$, inside the shaded area $ABC$ provided that its boundary, the arc $ABC$, is known. *The theory of Saint Venant-Lévy-Mises does not furnish any condition, however, from which this boundary between the rigid and plastic regions could be determined. Moreover, the stress distribution in the rigid part is indeterminate.*

Let us review the results obtained so far. The Saint-Venant-Lévy-Mises theory is applicable only if the torque is large enough to produce plastic flow throughout the entire bar. For smaller torques the theories of Hencky and Prandtl-Reuss furnish identical results. In all but the very simplest cases, however, the theoretical determination of the boundary between the elastic and plastic regions encounters practically unsurmountable mathematical difficulties.[22] These difficulties are avoided by the theories of Nadai and Prager which stipulate a continuous transition from the elastic to the plastic state.

Let us first apply Nadai's theory to the torsion problem. In terms of the stress function the intensity of stress, on which the shear modulus depends, is given by

$$|\tau| = \left[\left(\frac{\partial\psi}{\partial x}\right)^2 + \left(\frac{\partial\psi}{\partial y}\right)^2\right]^{\frac{1}{2}} = |\text{grad}\psi|.$$

The stress-strain relation $\tau = G\gamma$ therefore gives

$$\frac{1}{G}\frac{\partial\psi}{\partial y} = \frac{\partial\varphi}{\partial x} - y\theta, \qquad -\frac{1}{G}\frac{\partial\psi}{\partial x} = \frac{\partial\varphi}{\partial y} + x\theta.$$

Elimination of $\varphi$ between these equations furnishes

$$\frac{\partial}{\partial x}\left(\frac{1}{G}\frac{\partial\psi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{1}{G}\frac{\partial\psi}{\partial y}\right) = -2\theta \tag{30}$$

which equation replaces Eq. (7). Here $G$ is a function of $|\text{grad}\,\psi|$, and the stress function $\psi$ vanishes on the contour of the cross section. Equation (30) is non-linear, and somewhat reminiscent of equations which are encountered in connection with steady two-dimensional flows of compressible fluids. Integration methods developed in fluid dynamics might therefore prove useful; so far, however, the boundary value problem formulated in connection with Eq. (30) has been solved only in a few special cases.[23]

Finally, let us apply the stress-strain relation (24) to the torsion problem. To this end, we set

$$\int_0^S \frac{1}{2}\left(\frac{G_0}{G^*(s)} - 1\right)\frac{ds}{s} = -\log A(S).$$

This enables us to write Eq. (24) in the form

$$G_0\frac{\partial\gamma}{\partial t} = A\frac{\partial}{\partial t}(\tau/A). \tag{31}$$

Introducing the warping function and the stress function into the two scalar equations equivalent to (31) and eliminating the warping function between them we obtain[24]

$$\frac{\partial}{\partial x}\left[A\frac{\partial}{\partial t}\left(\frac{1}{A}\frac{\partial\psi}{\partial x}\right)\right] + \frac{\partial}{\partial y}\left[A\frac{\partial}{\partial t}\left(\frac{1}{A}\frac{\partial\psi}{\partial y}\right)\right] = -2G_0\frac{\partial\theta}{\partial t}. \tag{32}$$

This equation contains the time rates of change

---

[21] A. A. Ilyushin, Prikladnaia Mat. Mekh. 9, 207–218 (1945).

[22] For a numerical treatment of this problem by relaxation methods see D. G. Christopherson, Trans. A.S.M.E. 62, A1–A4, and F. S. Shaw, Austral. Counc. Aeronaut. Rep. ACA-11 (1944). See also R. V. Southwell, *Relaxation methods in theoretical physics* (Oxford Press, 1946).

[23] The as yet unpublished Ph.D. thesis of G. H. Handelman (Brown University, 1946) is concerned with the application of this theory to thin-walled sections. See also L. A. Galin, Prikladnaia Mat. Mekh. 8, 307–322 (1944).

[24] This equation was first established in W. Prager, "Theory of plasticity," (mimeographed lecture notes) Brown University, Providence, Rhode Island, 1942, p. 112.

of $\psi$ and $\theta$ in a homogeneous manner. Accordingly, the time scale is irrelevant and the angle of twist $\theta$ may be taken as measure for the time. Thus,

$$\frac{\partial}{\partial x}\left[A\frac{\partial}{\partial\theta}\left(\frac{1}{A}\frac{\partial\psi}{\partial x}\right)\right]+\frac{\partial}{\partial y}\left[A\frac{\partial}{\partial\theta}\left(\frac{1}{A}\frac{\partial\psi}{\partial y}\right)\right]=-2G_0. \quad (33)$$

Considered as an equation for $\psi(x, y, \theta)$, Eq. (33) is non-linear. It is worth noting, however, that this equation is linear in $\partial\psi/\partial\theta$ with coefficients which depend on $\psi$. This remark suggests the possibility of integrating (33) approximately by solving a number of linear problems for $\partial\psi/\partial\theta$ with coefficients which depend on the function $\psi$ built up from the previously obtained values of $\partial\psi/\partial\theta$. Physically speaking, this procedure amounts to producing the desired angle of twist in a series of small steps, and assuming that during each step the tangent modulus at any point of the cross section retains the value which corresponds to the stress intensity existing at the beginning of this step at the point under consideration.

For perfectly plastic materials, the theories of plastic deformation and of plastic flow furnished the same solution of the torsion problem; except for the circular cross section these theories will yield different results, however, when strain-hardening is taken into account. Torsion of a cylindrical bar of non-circular cross section may therefore afford an opportunity of deciding experimentally between these two theories.

# On the Theory of Noise in Radio Receivers with Square Law Detectors[*]

MARK KAC
*Department of Mathematics, Cornell University, Ithaca, New York*

AND

A. J. F. SIEGERT[**]
*Radiation Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received September 13, 1946)

For the video output $V$ of a receiver, consisting of an i-f stage, a quadratic detector, and a video amplifier, the probability density $P(V)$ has been obtained for noise alone and for noise and signal. The results are expressed in terms of eigenvalues and eigenfunctions of the integral equation

$$\int_0^\infty K(t)\rho(s-t)f(t)dt=\lambda f(s),$$

where $\rho(\tau)$ is the i-f correlation function (i.e., the Fourier transform of the i-f power spectrum) and $K(t)$ is the response function of the video amplifier (i.e., the Fourier transform of the video amplitude spectrum). Two special cases are discussed in which the integral equation can be solved explicitly. Approximations for general amplifiers are given in the limiting cases of wide and narrow videos. Some applications of the method to other problems are shown in Sections 7B and 9.

## I. THE RECEIVER MODEL

THE response of a linear circuit to noise has been investigated by several authors. The probability densities and correlation coefficients of the noise outputs of some types of detectors are also known.[1] To find the probability density of the noise voltage output of the next stage

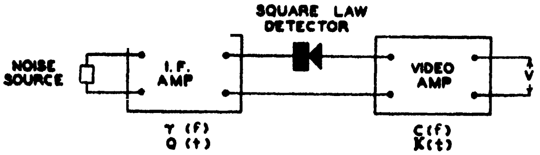

FIG. 1. The receiver model.

(video or audio amplifier) is a problem of a different type, since after the detector, the noise voltage is no longer Gaussianly distributed.

In this paper we have, therefore, calculated the probability density $P(V)$ of the noise voltage $V$ at the end terminals of a receiver consisting of an intermediate-frequency amplifier, a quadratic detector and a video (or audio) amplifier (Fig. 1). The response of both amplifiers is assumed to be linear and characterized by the steady-state response function $\gamma(f)$ and $C(f)$, respectively, or the response functions $Q(t)$ and $K(t)$, such that the output voltages of the amplifiers are $\gamma(f)e^{2\pi ift}$ and $C(f)e^{2\pi ift}$, respectively, if the input voltage is $e^{2\pi ift}$. If, therefore, the video input voltage is $v(t)$, the video output voltage $V$ is given by

$$V(t)=\int_{-\infty}^{\infty}dfC(f)e^{2\pi ift}\int_{-\infty}^{\infty}dt'e^{-2\pi ift'}v(t')$$
$$=\int_{-\infty}^{\infty}dt'K(t-t')v(t') \qquad (1.11)$$

where

$$K(\tau)=\int_{-\infty}^{\infty}dfC(f)e^{2\pi if\tau}. \qquad (1.12)$$

Since $V(t)$ can depend only on the values which $v(t')$ assumes at times $t'\leqq t$, it follows that $K(\tau)=0$ for $\tau<0$, which means that all poles of $C(f)$ lie above the real axis. Since $K$ must be real, we have $C(-f)=C^*(f)$. Both conditions are fulfilled for passive networks. We shall normalize $K$ by

$$\int_0^{\infty}K(t)dt=1.$$

In writing i-f voltages $V_{\text{I.F.}}^{(i)}$ and $V_{\text{I.F.}}^{(o)}$ for input and output it is generally convenient to consider them as modulated carriers, i.e., we write

$$V_{\text{I.F.}}^{(i)}=Re\{u(t)e^{2\pi if_0t}\}$$
$$=x(t)\cos 2\pi f_0t+y(t)\sin 2\pi f_0t,$$

where

$$u(t)=x(t)-iy(t),$$

and $f_0$ is the carrier frequency. The i-f output voltage is then

$$V_{\text{I.F.}}^{(o)}=Re\left\{\int_{-\infty}^{\infty}dfe^{2\pi ift}\gamma(f)\right.$$
$$\left.\times\int_{-\infty}^{\infty}dt'e^{-2\pi ift'}u(t')e^{2\pi if_0t'}\right\}$$
$$=Re\left\{e^{2\pi if_0t}\int_{-\infty}^{\infty}dt'u(t')\right.$$
$$\left.\times\int_{-\infty}^{\infty}dfe^{2\pi i(f-f_0)(t-t')}\gamma(f)\right\}$$
$$=Re\{U(t)e^{2\pi if_0t}\}$$

where

$$U(t)=\int_{-\infty}^{\infty}dt'Q(t-t')u(t'),$$

and

$$Q(\tau)=\int_{-\infty}^{\infty}dfe^{2\pi i(f-f_0)\tau}\gamma(f)=\int_{-\infty}^{\infty}df'e^{2\pi if'\tau}\gamma(f'+f_0).$$

We shall normalize $\gamma$ and $Q$ by demanding that

$$\int_{-\infty}^{\infty}Q^2(\tau)d\tau=1;$$

then we have

$$\int_{-\infty}^{\infty}Q^2(\tau)d\tau=\iiint_{-\infty}^{\infty}d\tau df'df''e^{2\pi i(f'+f'')\tau}\gamma(f'+f_0)$$
$$\times\gamma(f''+f_0)=1,$$

or

$$\int_{-\infty}^{\infty}df'\gamma(f_0+f')\gamma(f_0-f')=1.$$

The calculations are appreciably simplified by assuming a symmetrical pass band* for the i-f amplifier, i.e.,

$$\gamma(f_0+f')=\gamma^*(f_0-f'). \qquad (1.20)$$

We also put $|\gamma(f_0+f)|=B(f)$. Inserting this in the normalization equation we have

$$\int_{-\infty}^{\infty}|\gamma^2(f)|df=1,$$

i.e., the power spectrum is normalized. The sym-

---

* See, however, footnote 3, Section IV.

metry of $\gamma$ implies that $Q$ is real and $V_{\text{I.F.}}^{(o)}$ can now be written as

$$V_{\text{I.F.}}^{(o)}=X(t)\cos 2\pi f_0 t+Y(t)\sin 2\pi f_0 t \qquad (1.21)$$

with

$$\begin{aligned} X(t)&=\int_{-\infty}^{\infty}dt'Q(t-t')x(t') \\ Y(t)&=\int_{-\infty}^{\infty}dt'Q(t-t')y(t'). \end{aligned} \qquad (1.22)$$

$Q(\tau)$ must of course vanish for $\tau<0$.

The detector is assumed to yield the output

$$X^2(t)+Y^2(t), \qquad (1.31)$$

if the input voltage is

$$X(t)\cos 2\pi f_0 t+Y(t)\sin 2\pi f_0 t. \qquad (1.32)$$

In order that this be a reasonable model of an actual detector it is necessary to assume

$$\left|\frac{x'(t)}{x(t)}\right|\ll f_0 \quad\text{and}\quad \left|\frac{y'(t)}{y(t)}\right|\ll f_0,$$

which implies that the width of the pass band of the i-f amplifier is small compared to the intermediate frequency $f_0$.

## II. REPRESENTATION OF NOISE

The i-f output noise voltage (omitting the irrelevant d.c. component) is represented[2] as

$$V_{\text{I.F.}}^{(o)}=\frac{\sqrt{N}}{\sqrt{T}}\sum_{k=1}^{\infty}|\gamma(f_k')| \times(X_k'\cos 2\pi f_k't+Y_k'\sin 2\pi f_k't) \qquad (2.11)$$

with

$$f_k'=k/T,$$

where $X_1'$, $Y_1'$, $X_2'$, $Y_2'\cdots$ are independent normally distributed random variables each having the probability density

$$\pi^{-\frac{1}{2}}\exp(-u^2).$$

The representation holds only for the time interval $0<t<T$, but this is adequate if $T$ is chosen large compared to the time during which observations are made. We shall later let $T\rightarrow\infty$. The properties of $\gamma(f)$ were discussed above and $N$ denotes the input noise power per unit frequency.

According to (1.31) and (1.32), the detector output voltage arising from this i-f input voltage is given by

$$X^2(t)+Y^2(t)=V_D^{(o)},$$

where

$$\begin{aligned} X(t)&=\frac{\sqrt{N}}{\sqrt{T}}\sum_{k=1}^{\infty}|\gamma(f_k')|[X_k'\cos 2\pi(f_k'-f_0)t \\ &\qquad +Y_k'\sin 2\pi(f_k'-f_0)t] \\ Y(t)&=\frac{\sqrt{N}}{\sqrt{T}}\sum_{k=1}^{\infty}|\gamma(f_k')|[-X_k'\sin 2\pi(f_k'-f_0) \\ &\qquad +Y_k'\cos 2\pi(f_k'-f_0)t]. \end{aligned} \qquad (2.12)$$

Making use of (1.20) and the fact that the band width of the i-f amplifier is small compared to the intermediate frequency $f_0$, we may write

$$\begin{aligned} X(t)&=\frac{\sqrt{N}}{\sqrt{T}}\sum_{-\infty}^{\infty}B(f_k)(X_k\cos 2\pi f_k t+Y_k\sin 2\pi f_k t), \\ Y(t)&=\frac{\sqrt{N}}{\sqrt{T}}\sum_{-\infty}^{\infty}B(f_k) \\ &\qquad \times(-X_k\sin 2\pi f_k t+Y_k\cos 2\pi f_k t), \end{aligned} \qquad (2.13)$$

where

$$\begin{aligned} &f_k=k/T, \quad B(f_k)=|\gamma(f_k+f_0)|, \\ &X_k=X'_{k+k_0} \quad\text{and}\quad Y_k=Y'_{k+k_0} \end{aligned} \qquad (2.14)$$

with $k_0=Tf_0$, assumed to be an integer.

The video output voltage $V(t)$ is given by (1.11) as

$$\begin{aligned} V(t)&=\int_{-\infty}^{\infty}K(t-t')[X^2(t')+Y^2(t')]dt' \\ &=\int_0^{\infty}K(u)[X^2(t-u)+Y^2(t-u)]du. \end{aligned} \qquad (2.15)$$

In the derivation of Chapter 3 we shall consider the probability distribution of the slightly modified quantity

$$V_T(t)=\int_0^T K(u)[X^2(t-u)+Y^2(t-u)]du, \qquad (2.16)$$

and then pass to the limit as $T\rightarrow\infty$.

## III. "WHITE NOISE"

The i-f output $X(t)\cos 2\pi f_0 t+Y(t)\sin 2\pi f_0 t$ with $X(t)$, $Y(t)$ given by (2.13) can be described

---

[2] S. O. Rice, "Mathematical analysis of random noise," Bell Sys. Tech. J. 23, 282 (1944), see p. 328.

as caused by the "white noise"

$$x(t)\cos 2\pi f_0 t + y(t)\sin 2\pi f_0 t,$$

where $x(t)$ and $y(t)$ are given by

$$x(t)=\frac{\sqrt{N}}{\sqrt{T}}\sum_{k=-L}^{L}(X_k\cos 2\pi f_k t+Y_k\sin 2\pi f_k t)$$

$$v(t)=\frac{\sqrt{N}}{\sqrt{T}}\sum_{k=-L}^{L}(-X_k\sin 2\pi f_k t+Y_k\cos 2\pi f_k t),$$

where $L$ is a number so large that the frequencies $f_0 \pm L/T$ lie outside of the pass band of the i-f amplifier. This "white noise" is the input thermal and shot noise which actually is known to have a constant power spectrum up to very high frequencies.

In the derivation of the next section it will be advantageous to represent $x(t)$ and $y(t)$ in a different orthogonal system, and we will now show that the expansion coefficients in any other complete orthogonal system are Gaussianly distributed and independent of each other, if $L$ is sufficiently large, i.e., if the power spectrum is constant up to sufficiently high frequencies.

Let $\phi_j(t)$ be an orthonormal, complete set in the interval $(0, T)$. Expanding $x(t)$ in this system we have

$$x(t)=\sum_{1}^{\infty} u_j\phi_j(t), \tag{3.1}$$

where

$$u_j=\left(\frac{N}{T}\right)^{\frac{1}{2}}\sum_{k=-L}^{L}\left(X_k\int_0^T \phi_j(t)\cos 2\pi f_k t dt + Y_k\int_0^T \phi_j(t)\sin 2\pi f_k t dt\right). \tag{3.2}$$

The coefficients $u_j$ are thus linear combinations of the Gaussian variables $X_k$, $Y_k$ and are, therefore, Gaussianly distributed. To prove independence of linear combinations of independent Gaussian variables, it is necessary only to show that $\langle u_l u_j\rangle = 0$ for $l \neq j$. Using the statistical properties of $X_k$ and $Y_k$, we have

$$\langle u_l u_j\rangle_{\mathrm{Av}}=\frac{1}{2}\frac{N}{T}\int_0^T\int_0^T dsdt\phi_l(t)\phi_j(s) \times\sum_{-L}^{L}\cos 2\pi f_k(s-t). \tag{3.3}$$

For sufficiently large $L$

$$\frac{1}{T}\sum_{-L}^{L}\cos 2\pi f_k(s-t)$$

can be replaced by $\delta(s-t)$ and, therefore,

$$\langle u_l u_j\rangle_{\mathrm{Av}}\rightarrow\frac{N}{2}\delta_{jl}. \tag{3.4}$$

In the same way we can show, for the coefficients $v_j$ of $y(t)$, that

$$\langle v_l v_j\rangle_{\mathrm{Av}}\rightarrow\frac{N}{2}\delta_{lj} \tag{3.5}$$

and

$$\langle u_k v_l\rangle_{\mathrm{Av}}\rightarrow 0. \tag{3.6}$$

## IV. DERIVATION OF PROBABILITY DENSITY FOR NOISE ALONE

To derive the probability density $P(V)$ we use the above representation for the incoming "white noise" writing the i-f input voltage[3] as

$$V_{\mathrm{I.F.}}^{(i)}=x(t)\cos 2\pi f_0 t+y(t)\sin 2\pi f_0 t, \tag{4.11}$$

with

$$x(t)=\textstyle\sum_j u_j\phi_j(t)$$

and

$$y(t)=\textstyle\sum_j v_j\phi_j(t). \tag{4.12}$$

Choosing $N$ as unit of power we have

$$\langle u_k u_l\rangle_{\mathrm{Av}}=\langle v_k v_l\rangle_{\mathrm{Av}}=\tfrac{1}{2}\delta_{lk}. \tag{4.13}$$

The i-f output voltate $V_{\mathrm{I.F.}}^{(o)}$ is given by

$$V_{\mathrm{I.F.}}^{(o)}=X(t)\cos 2\pi f_0 t+Y(t)\sin 2\pi f_0 t, \tag{4.14}$$

where

$$X(t)=\int_{-\infty}^{\infty}Q(t-\tau)x(\tau)d\tau,$$
$$Y(t)=\int_{-\infty}^{\infty}Q(t-\tau)y(\tau)d\tau. \tag{4.15}$$

---

[3] The authors are aware that the results of this section can be obtained in a more elegant way by using the representation (4.12) for $V_{\mathrm{I.F.}}^{(i)}$ rather than for the components $x(t)$ and $y(t)$, and by defining the quadratic detector by

$$V_D^{(o)}=[V_{\mathrm{I.F.}}^{(o)}]^2$$

rather than by Eq. (4.31), provided that the I.F. and video band widths are small compared with $f_0$ [cf. Phys. Rev. 70, 449, C6 (1946)]. The simplifying assumption of symmetrical I.F. pass band can then be easily dispensed with. The method presented here was chosen to keep the continuity with the existing literature.

The correlation coefficient

$$\rho(\tau)=\langle X(t)X(t+\tau)\rangle_{\text{Av}}/\langle X^2(t)\rangle_{\text{Av}} \tag{4.21}$$

can be expressed in terms of the function $Q$ as follows:

$$\begin{aligned}\langle X(t)X(t+\tau)\rangle_{\text{Av}}&=\int\int_{-\infty}^{\infty} Q(t-\tau_1)Q(t+\tau-\tau_2)\\&\qquad\times\langle X(\tau_1)X(\tau_2)\rangle_{\text{Av}}d\tau_1d\tau_2\\&=\frac{1}{2}\int_{-\infty}^{\infty}Q(t-\tau_1)Q(t+\tau-\tau_1)d\tau_1\\&=\frac{1}{2}\int_{-\infty}^{\infty}Q(\theta)Q(\theta+\tau)d\theta,\end{aligned} \tag{4.22}$$

$$\langle X^2(t)\rangle_{\text{Av}}=\frac{1}{2}\int_{-\infty}^{\infty}Q^2(\theta)d\theta=\tfrac{1}{2}, \tag{4.23}$$

and therefore

$$\rho(\tau)=\int_{-\infty}^{\infty}Q(\theta)Q(\theta+\tau)d\theta. \tag{4.24}$$

We note that

$$\begin{aligned}&\int_{-\infty}^{\infty}e^{2\pi if\tau}\rho(\tau)d\tau\\&=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}Q(\theta)Q(\theta+\tau)e^{2\pi if\tau}d\theta d\tau\\&=\int\int\int\int_{-\infty}^{\infty}df'df''\gamma(f'+f_0)\gamma(f''+f_0)\\&\qquad\times e^{2\pi i[f'\theta+f''(\theta+\tau)+f\tau]}d\theta d\tau\\&=\int\int_{-\infty}^{\infty}df'df''\gamma(f'+f_0)\gamma(f''+f_0)\\&\qquad\times\delta(f'+f'')\delta(f''+f)\\&=\gamma(f+f_0)\gamma(f_0-f)=|\gamma^2(f+f_0)|\end{aligned} \tag{4.25}$$

which is a special case of the Wiener-Khintchine relation.

The detector output voltage $V_D^{(o)}$ is, therefore,

$$\begin{aligned}V_D^{(o)}&=X^2(t)+Y^2(t)\\&=\int\int_{-\infty}^{\infty}Q(t-\tau_1)Q(t-\tau_2)\\&\qquad\times[x(\tau_1)x(\tau_2)+y(\tau_1)y(\tau_2)]d\tau_1d\tau_2,\end{aligned} \tag{4.31}$$

and the output of the video amplifier

$$\begin{aligned}V(t)&=\int_{-\infty}^{\infty}K(t-\theta)[X^2(\theta)+Y^2(\theta)]d\theta\\&=\int_{-\infty}^{\infty}K(t-\theta)d\theta\int\int_{-\infty}^{\infty}Q(\theta-\tau_1)Q(\theta-\tau_2)\\&\qquad\times[x(\tau_1)x(\tau_2)+y(\tau_1)y(\tau_2)]d\tau_1d\tau_2.\end{aligned} \tag{4.32}$$

Changing variables to

$$\theta'=t-\theta,\quad \tau_1'=t-\tau_1,\quad \tau_2'=t-\tau_2, \tag{4.33}$$

we have

$$\begin{aligned}V(t)=\int_{-\infty}^{\infty}&K(\theta')d\theta'\int\int_{-\infty}^{\infty}Q(\tau_1'-\theta')Q(\tau_2'-\theta')\\&\times[x(t-\tau_1')x(t-\gamma_2')\\&\qquad+y(t-\tau_1')y(t-\tau_2')]d\tau_1'd\tau_2'.\end{aligned} \tag{4.34}$$

If the i-f input noise voltage is a homogeneous random function $x(t-\tau)$ and $y(t-\tau)$ are given by

$$\begin{aligned}x(t-\tau)&=\textstyle\sum_j u_j'\phi_j(\tau),\\y(t-\tau)&=\textstyle\sum_j v_j'\phi_j(\tau),\end{aligned} \tag{4.35}$$

where $u_j'$ and $v_j'$ are random variables with the same properties as $u_j$ and $v_j$, and we have—omitting the primes—

$$\begin{aligned}V(t)&=\int_{-\infty}^{\infty}K(\theta)d\theta\int\int_{-\infty}^{\infty}Q(\tau_1-\theta)Q(\tau_2-\theta)\\&\qquad\times\textstyle\sum_{ij}(u_iu_j+v_iv_j)\phi_i(\tau_1)\phi_j(\tau_2)d\tau_1d\tau_2\end{aligned} \tag{4.36}$$

$$\begin{aligned}&=\textstyle\sum_{ij}(u_iu_j+v_iv_j)\\&\qquad\times\int\int_{-\infty}^{\infty}\Lambda(\tau_1,\tau_2)\phi_i(\tau_1)\phi_j(\tau_2)d\tau_1d\tau_2\end{aligned} \tag{4.37}$$

with

$$\Lambda(\tau_1,\tau_2)=\int_{-\infty}^{\infty}K(\theta)d\theta Q(\tau_1-\theta)Q(\tau_2-\theta). \tag{4.38}$$

We note that $t$ does not appear anymore on the r.h.s., that means that $V(t)$ is a homogeneous random function. This is caused by the fact that the input noise is itself a homogeneous random function.

The essential step in our calculation is now to choose as the function $\phi_i(\tau)$ the normalized eigenfunctions of the integral equation

$$\int_{-\infty}^{\infty} \Lambda(\tau_1, \tau_2)\phi(\tau_2)d\tau_2 = \lambda\phi(\tau_1). \qquad (4.41)$$

Then $V(t)$ is expressed as

$$V = \sum_i (u_i^2 + v_i^2)\lambda_i, \qquad (4.42)$$

where the quantities $\lambda_i$ are the eigenvalues of the integral equation. The quantities

$$u_i^2 + v_i^2 = Z_i \qquad (4.43)$$

are independent and their probability densities $W(Z_i)$ are given by

$$W(Z_i) = \begin{cases} e^{-Z_i} & \text{if } Z_i > 0, \\ 0 & \text{if } Z_i < 0, \end{cases} \qquad (4.44)$$

because $u_i$ and $v_i$ are independent Gaussian variables of spread $\frac{1}{2}$. The probability distribution of the sum representing $V$ is therefore

$$\begin{aligned} P(V)dV &= dV \int_0^{\infty} \cdots \int_0^{\infty} \delta(V - \sum_i \lambda_i Z_i) \prod_k W(Z_k) dZ_k \\ &= dV \frac{1}{2\pi} \int_{-\infty}^{\infty} d\xi e^{-iV\xi} \int_0^{\infty} \cdots \int_0^{\infty} \prod_k e^{-Z_k(1-i\lambda_k\xi)} dZ_k \\ &= dV \frac{1}{2\pi} \int_{-\infty}^{\infty} d\xi e^{-iV\xi} \frac{1}{\prod_k (1 - i\lambda_k \xi)}. \end{aligned} \qquad (4.45)$$

For $V>0$ the path of integration is closed in the lower half plane and contracted around all poles $\xi_s = -i/\lambda_s$ with $\lambda_s > 0$ and *vice versa*. We thus obtain

$$P(V) = \frac{1}{2\pi} \sum_s{}^{+} \oint^{(1/i\lambda_s, -)} \frac{d\xi}{(-i\lambda_s)\left(\xi - \frac{1}{i\lambda_s}\right)} \frac{e^{-iV\xi}}{\prod'_{k\neq s}(1 - i\lambda_k\xi)} = \sum_s{}^{+} \frac{e^{(-V/\lambda_s)}}{\lambda_s \prod'_{k\neq s}\left(1 - \frac{\lambda_k}{\lambda_s}\right)} \quad \text{for } V>0 \qquad (4.46)$$

where $\sum_s{}^{+}$ means summation over all values of $s$ for which $\lambda_s > 0$. For $V<0$ we obtain

$$P(V) = \frac{1}{2\pi} \sum_n{}^{(-)} \oint \frac{d\xi}{(-i\lambda_n)\left(\xi - \frac{1}{i\lambda_n}\right)} \frac{e^{-iV\xi}}{\prod'_{k\neq n}(1 - i\lambda_k\xi)} = \sum_n{}^{(-)} \frac{e^{(-V/\lambda_n)}}{\lambda_n \prod'_{k\neq n}\left(1 - \frac{\lambda_k}{\lambda_n}\right)} \qquad (4.47)$$

where $\sum_n{}^{(-)}$ indicates summation over all $n$ for which $\lambda_n < 0$. The product is extended always over all $k$ with exception of $k = n$.

It is sometimes more convenient to have the integral equation in a different form, involving the functions $K$ and $\rho$ rather than $K$ and $Q$. This form is obtained by introducing the new unknown

$$f(\theta) = \int_{-\infty}^{\infty} Q(\tau_2 - \theta)\phi(\tau_2)d\tau_2, \qquad (4.51)$$

so that

$$\int_{-\infty}^{\infty} d\theta K(\theta) Q(\tau_1 - \theta) f(\theta) = \lambda\phi(\tau_1). \qquad (4.52)$$

Multiplying both sides with $Q(\tau_1 - \theta')$ and integrating over $\tau_1$ we obtain

$$\int_{-\infty}^{\infty} K(\theta)d\theta \int_{-\infty}^{\infty} d\tau_1 Q(\tau_1 - \theta') \times Q(\tau_1 - \theta) f(\theta) = \lambda f(\theta'). \qquad (4.53)$$

We can now write

$$\int_{-\infty}^{\infty} Q(\tau_1 - \theta')Q(\tau_1 - \theta)d\tau_1 = \int_{-\infty}^{\infty} d\tau Q(\tau)Q(\tau + \theta' - \theta) = \rho(\theta' - \theta), \qquad (4.54)$$

and have the integral equation in the form

$$\int_{-\infty}^{\infty} K(\theta)\rho(\theta' - \theta) f(\theta) d\theta = \lambda f(\theta'),$$

or, since $K(\theta)=0$ for $\theta<0$,

$$\int_0^\infty K(\theta)\rho(\theta'-\theta)f(\theta)d\theta=\lambda f(\theta'). \quad (4.55)$$

Finally, by writing $(K(\theta))^{\frac{1}{2}}f(\theta)=\Phi(\theta)$ we can bring the equation into the form which will be derived directly in Section 6:

$$\int_0^\infty [K(\theta')]^{\frac{1}{2}}\rho(\theta'-\theta)[K(\theta)]^{\frac{1}{2}}\Phi(\theta)d\theta=\lambda\Phi(\theta'). \quad (4.56)$$

By means of the expression

$$V=\sum \lambda_j Z_j, \quad (4.61)$$

we can easily verify formulas for the moments. For the first two moments we have for instance

$$\langle V\rangle_{\text{Av}}=\sum \lambda_j\langle Z_j\rangle_{\text{Av}}=\sum \lambda_j=\int_0^\infty K(s)ds=1, \quad (4.62)$$

$$\begin{aligned}\langle V^2\rangle_{\text{Av}}&=\sum \lambda_j^2\langle Z_j^2\rangle_{\text{Av}}+\sum_{j\neq k}\lambda_j\lambda_k\langle Z_jZ_k\rangle_{\text{Av}}\\&=\sum_1^\infty \lambda_j^2+(\sum\lambda_j)^2 \qquad (4.63)\\&=1+\sum\lambda_j^2.\end{aligned}$$

For the fluctuation

$$\sigma^2=\langle V^2\rangle_{\text{Av}}-\langle V\rangle_{\text{Av}}^2. \quad (4.64)$$

We thus obtain

$$\sigma^2=\sum\lambda_j^2=\int_0^\infty\int_0^\infty K(s)K(t)\rho^2(s-t)dsdt, \quad (4.65)$$

this being the trace of the first iterated kernel.

## V. DERIVATION OF THE PROBABILITY DENSITY FOR SIGNAL AND NOISE

For the case of signal and noise only one derivation will be given here, since the direct derivation runs parallel to the analogous derivation for noise alone. The i-f input voltage $V_{\text{I.F.}}^{(i)}$ is in this case given by

$$V_{\text{I.F.}}^{(i)}=[x(t)+\alpha(t)]\cos 2\pi f_0t+[y(t)+\beta(t)]\sin 2\pi f_0t, \quad (5.11)$$

where $x(t)$, $y(t)$ are the input white noise amplitudes, and $\alpha(t)$, $\beta(t)$ are the input signal amplitudes. The i-f output voltage is then given by

$$V_{\text{I.F.}}^{(o)}=[X(t)+p(t)]\cos 2\pi f_0t+[Y(t)+q(t)]\sin 2\pi f_0t, \quad (5.12)$$

where $X$ and $Y$ are defined as above and

$$p(t)=\int_{-\infty}^\infty Q(t-\tau)\alpha(\tau)d\tau \quad\text{and}\quad q(t)=\int_{-\infty}^\infty Q(t-\tau)\beta(\tau)d\tau \quad (5.13)$$

are the signal amplitudes after the i-f amplifier. The detector output voltage is then

$$V_D^{(o)}=[X(t)+p(t)]^2+[Y(t)+q(t)]^2 \quad (5.14)$$

and the output of the video amplifier is

$$\begin{aligned}V(t)&=\int_{-\infty}^\infty K(t-\theta)d\theta\{[X(\theta)+p(\theta)]^2+[Y(\theta+q(\theta)]^2\}\\&=\int_{-\infty}^\infty K(t-\theta)d\theta\iint_{-\infty}^\infty Q(\theta-\tau_1)Q(\theta-\tau_2)\{[X(\tau_1)+\alpha(\tau_1)][x(\tau_2)+\alpha(\tau_2)]\\&\qquad+[y(\tau_1)+\beta(\tau_1)][y(\tau_2)+\beta(\tau_2)]\}d\tau_1d\tau_2. \quad (5.15)\end{aligned}$$

Changing variables to

$$\theta'=t-\theta,\ \tau_1'=t-\tau_1,\ \tau_2'=t-\tau_2, \quad (5.16)$$

we obtain

$$V(t)=\int_{-\infty}^{\infty}K(\theta')d\theta'\iint_{-\infty}^{\infty}Q(\tau_1'-\theta')Q(\tau_2'-\theta')\{[x(t-\tau_1')+\alpha(t-\tau_1')][x(t-\tau_2')+\alpha(t-\tau_2')]$$
$$+[y(t-\tau_1')+\beta(t-\tau_1')][y(t-\tau_2')+\beta(t-\tau_2')]\}d\tau_1'd\tau_2'$$
$$=\int_{-\infty}^{\infty}\Lambda(\tau_1,\tau_2)d\tau_1d\tau_2\{[x(t-\tau_1)+\alpha(t-\tau_1)][x(t-\tau_2)+\alpha(t-\tau_2)]$$
$$+[y(t-\tau_1)+\beta(t-\tau_1)][y(t-\tau_2)+\beta(t-\tau_2)]\}. \quad (5.17)$$

We now expand noise and signal amplitudes in terms of the eigen functions $\phi_j$ of $\Lambda$, writing

$$\begin{aligned} x(t-\tau)&=\textstyle\sum_j u_j\phi_j(\tau), & \alpha(t-\tau)&=\textstyle\sum_j \alpha_j(t)\phi_j(\tau),\\ y(t-\tau)&=\textstyle\sum_j v_j\phi_j(\tau), & \beta(t-\tau)&=\textstyle\sum_j \beta_j(t)\phi_j(\tau),\end{aligned} \quad (5.18)$$

and obtain

$$V(t)=\textstyle\sum_j\lambda_j\{[u_j+\alpha_j(t)]^2+[v_j+\beta_j(t)]^2\}. \quad (5.19)$$

The probability density of the variables $u_j$ and $v_j$ are $\pi^{-\frac{1}{2}}\exp(-u_j^2)$ and $\pi^{-\frac{1}{2}}\exp(-v_j^2)$, respectively, and the characteristic function for $V(t)$ is, therefore, given by

$$\langle e^{i\xi V}\rangle_{\text{Av}}=\int\overset{\infty}{\underset{-\infty}{\cdots}}\int\exp\{i\xi\textstyle\sum_j\lambda_j[(u_j+\alpha_j)^2+(v_j+\beta_j)^2]\}\displaystyle\prod_j\frac{\exp[-(u_j^2+v_j^2)]}{\pi}du_jdv_j$$

$$=\prod_j\frac{1}{\pi}\iint_{-\infty}^{\infty}du_jdv_j\exp\{-[(u_j^2+v_j^2)(1-i\xi\lambda_j)-2i\xi\lambda_j(u_j\alpha_j+v_j\beta_j)]+i\xi\lambda_j(\alpha_j^2+\beta_j^2)\}$$

$$=\prod_j\frac{1}{\pi}\iint_{-\infty}^{\infty}du_jdv_j\exp\left\{\left(-u_j(1-i\xi\lambda_j)^{\frac{1}{2}}-\frac{i\xi\lambda_j\alpha_j}{(1-i\xi\lambda_j)^{\frac{1}{2}}}\right)^2-\left(v_j(1-i\xi\lambda_j)^{\frac{1}{2}}-\frac{i\xi\lambda_j\beta_j}{(1-i\xi\lambda_j)^{\frac{1}{2}}}\right)^2\right\}$$
$$\times\exp\left[-\frac{\lambda_j^2\xi^2(\alpha_j^2+\beta_j^2)}{1-i\xi\lambda_j}+i\xi\lambda_j(\alpha_j^2+\beta_j^2)\right], \quad (5.21)$$

$$\langle e^{i\xi V}\rangle_{\text{Av}}=\prod_j\frac{\exp[i\xi\lambda_j(\alpha_j^2+\beta_j^2)/(1-i\xi\lambda_j)]}{1-i\xi\lambda_j}. \quad (5.22)$$

The Fourier inversion integral of this expression which represents the probability density cannot be evaluated in closed form.

We shall check this expression by deriving the known [4] probability density for the voltage after a quadratic detector. This distribution is obtained in the limit of infinitely wide video band width, which implies that

$$\int_0^{\infty}K(\theta)\psi(\theta)d\theta=\psi(0) \quad (5.31)$$

for any function $\psi(\theta)$. Then $\Lambda(\tau_1\tau_2)$ becomes simply the product $Q(\tau_1)Q(\tau_2)$ and the integral equation reduces to

$$Q(\tau_1)\int_{-\infty}^{\infty}Q(\tau_2)\phi(\tau_2)d\tau_2=\lambda\phi(\tau_1). \quad (5.32)$$

The only eigenfunction of this integral equation is of the form $CQ(\tau_1)$ where $C$ is a constant, and from

---

[4] S. A. Goudsmit, RL 43-21; K. A. Norton and V. D. Landon, Proc. I.R.E. **30**, 425, Sept. 42; J. C. Slater, RL V-23; D. G. Fink, Report T8; D. O. North, RCA Tech. Rep. PTR6C.

$\int_{-\infty}^{\infty}Q^2(\tau)d\tau=1$ we have $C=1$ and $\lambda=1$. The characteristic function, therefore, reduces to

$$\frac{\exp i\xi(\alpha^2+\beta^2)/(1-i\xi)}{1-i\xi},$$

where

$$\begin{aligned}\alpha&=\int_{-\infty}^{\infty}\alpha(t-\tau)Q(\tau)d\tau=\int_{-\infty}^{\infty}\alpha(\tau')Q(\tau-\tau')d\tau'=p(t),\\ \beta&=\int_{-\infty}^{\infty}\beta(t-\tau)Q(\tau)d\tau=\int_{-\infty}^{\infty}\beta(\tau')Q(t-\tau')d\tau'=q(t).\end{aligned}\tag{5.33}$$

Calling the signal after the detector $s^2=s^2(t)$ we have

$$s^2(t)=p^2(t)+q^2(t)=\alpha^2+\beta^2,\tag{5.34}$$

and

$$\begin{aligned}P(V)&=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{\exp(-i\xi V+i\xi s^2/(i-i\xi))}{(1-i\xi)}d\xi\\ &=\frac{1}{2\pi}\oint^{-i,-}\frac{\exp(-i\xi V+i\xi s^2/(1-i\xi))}{1-i\xi}d\xi\end{aligned}\tag{5.35}$$

for $V>0$ and zero otherwise. With $u=1-i\xi$ this becomes

$$\begin{aligned}P(V)&=\exp(-V-s^2)\frac{1}{2\pi i}\int^{0,+}\exp[Vu+s^2/u]du/u\\ &=\exp(-V-s^2)J_0(2is\sqrt{V})\text{ for }V>0\text{ and}\end{aligned}\tag{5.36}$$

zero otherwise, where $J_0$ is the Bessel function of order 0. This result is in agreement with the earlier results.

## VI. DIRECT DERIVATION FOR NOISE ALONE

In order to give a direct derivation of the results obtained in Section 4, we investigate the probability density of the function

$$V(t)=\int_0^T K(u)[x^2(t-u)+y^2(t-u)]du\tag{6.11}$$*

and let, at an appropriate instant, $T$ approach infinity. For the sake of simplicity, we shall restrict ourselves to the case $K(u)>0$. We divide the interval $(0, T)$ into a large number $n$ of equal subintervals and consider the expression

$$\begin{aligned}&\frac{T}{n}\sum_{j=1}^{n}[x^2(t-u_j)+y^2(t-u_j)]K(u_j);\\ &\frac{j-1}{n}T<u_j<\frac{j}{n}T.\end{aligned}\tag{6.12}$$

The characteristic function of the joint probability density of

$$x_1=x(t-u_1),\quad x_2=x(t-u_2),\quad\cdots,\quad x_n=x(t-u_n)$$

defined as the average

$$\left\langle\exp\left[i\sum_1^n\xi_jx(t-u_j)\right]\right\rangle_{\mathrm{Av}}$$

is easily found to be

$$\exp\left[-\frac{1}{4}\sum_{j,k=1}^{n}\rho_T(u_j-u_k)\xi_j\xi_k\right]\tag{6.13}$$

where the correlation coefficients $\rho_T$ for the finite interval $T$ are defined as

$$\rho_T(t)=\frac{1}{T}\sum_{-\infty}^{\infty}A(f_k)\cos 2\pi f_kt,\tag{6.14}$$

and

$$A(f)=B^2(f)=|\gamma^2(f\pm f_0)|.\tag{6.15}$$

---

* For convenience, $x$ and $y$ are used in this section to denote the quantities formerly denoted by $X$ and $Y$.

Thus the joint probability density of

$$x_1,\ x_2,\ x_3,\ \cdots,\ x_n$$

is given by the formula

$$\frac{1}{(2\pi)^n}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\exp\left\{-i\sum_1^n \xi_j x_j\right\}$$

$$\times\exp\left\{-\frac{1}{4}\sum_1^n \rho_T(u_j-u_k)\xi_j\xi_k\right\}d\xi_1\cdots d\xi_n$$

$$=\frac{1}{(\sqrt{\pi})^n}\frac{1}{\sqrt{D}}\exp\left\{-\sum_1^n \alpha_{jk}x_jx_k\right\},\quad (6.16)$$

where the matrix $[\alpha_{jk}]$ is the inverse of the correlation matrix $[\rho_T(u_j-u_k)]$ and $D$ the determinant of the correlation matrix.

We next find the characteristic function of

$$\frac{T}{n}\sum_1^n K(u_j)x^2(t-u_j),$$

i.e., the average

$$\left\langle\exp\left\{\frac{i\xi T}{n}\sum_1^n K(u_j)x^2(t-u_j)\right\}\right\rangle_{\text{Av}}.$$

We have

$$\left\langle\exp\left\{\frac{i\xi T}{n}\sum_1^n K(u_j)x^2(t-u_j)\right\}\right\rangle_{\text{Av}}$$

$$=\frac{1}{(\sqrt{\pi})^n}\frac{1}{\sqrt{D}}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\exp\left\{\frac{i\xi T}{n}\sum_1^n K(u_j)x_j^2\right\}$$

$$\times\exp\left\{-\sum_1^n \alpha_{jk}x_jx_k\right\}dx_1\cdots dx_n.\quad (6.21)$$

Since $K(u_j)>0$ we can introduce the new variables

$$x_j'=[K(u_j)]^{\frac{1}{2}}x_j.\quad (6.22)$$

Obtaining

$$\left\langle\exp\left\{\frac{i\xi T}{n}\sum_1^n K(u_j)x^2(t-u_j)\right\}\right\rangle_{\text{Av}}$$

$$=\frac{1}{(\sqrt{\pi})^n}\frac{1}{\sqrt{\ }}\frac{1}{\prod_1^n[K(u_j)]^{\frac{1}{2}}}$$

$$\times\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\exp\left\{\frac{i\xi T}{n}\sum_1^n x_j'^2\right\}$$

$$\times\exp\left\{-\sum_1^n \beta_{jk}x_j'x_k'\right\}dx_1'\cdots dx_n',\quad (6.23)$$

where

$$\beta_{jk}=\frac{\alpha_{jk}}{[K(u_j)]^{\frac{1}{2}}[K(u_k)]^{\frac{1}{2}}}.\quad (6.24)$$

Let $\mu_1^{(n)},\ \mu_2^{(n)},\ \cdots,\ \mu_n^{(n)}$ be the eigenvalues of the matrix $[\beta_{jk}]$; then changing the coordinates in the last integral to "principal axes" of the "ellipsoid"

$$\sum_1^n \beta_{jk}x_j'x_k'=1\quad (6.25)$$

and noting that $\sum x_j'^2$ remains invariant under the transformation, we get easily

$$\left\langle\exp\left\{\frac{i\xi T}{n}\sum_1^n K(u_j)x^2(t-u_j)\right\}\right\rangle_{\text{Av}}$$

$$\frac{1}{\sqrt{D}\prod_1^n[K(u_j)]^{\frac{1}{2}}}\frac{1}{\prod_1^n\left(\mu_j^{(n)}-\frac{i\xi T}{n}\right)^{\frac{1}{2}}}\quad (6.26)$$

Since we have assumed that $A(f)$ is an even function we can show without much difficulty that

$$\sum_1^n K(u_j)x^2(t-u_j)\quad\text{and}\quad\sum_1^n K(u_j)y^2(t-u_j)$$

are independent in the statistical sense of the word. Thus the characteristic function of

$$\frac{T}{n}\sum_1^n K(u_j)\{x^2(t-u_j)+y^2(t-u_j)\}\quad (6.27)$$

is

$$\frac{1}{D\prod_1^n K(u_j)\prod_1^n\left(\mu_j^{(n)}-\frac{i\xi T}{n}\right)}$$

we now observe that the matrix $[\beta_{jk}]$ is the inverse of the matrix

$$[(K(u_j))^{\frac{1}{2}}\rho_T(u_j-u_k)(K(u_k))^{\frac{1}{2}}]\quad (6.28)$$

and that the determinant of (6.28) is

$$D\prod_1^n K(u_j).$$

Denoting by $\lambda_1^{(n)},\ \lambda_2^{(n)},\ \cdots,\ \lambda_n^{(n)}$, the eigenvalues of matrix (6.28) we see that the $\mu$'s are the inverses of the $\lambda$'s and that

$$D\prod_1^n K(u_j)=\lambda_1^{(n)}\cdot\lambda_2^{(n)}\cdots\lambda_n^{(n)}.$$

These facts imply that the characteristic function of (6.27) is

$$1\Big/\prod_{1}^{n}\left(1-\frac{iT}{n}\lambda_j^{(n)}\xi\right). \tag{6.29}$$

It follows from Hilbert's treatment of integral equations that the eigenvalues of matrix (6.28) when multiplied by $T/n$ approach, as $n$ approaches infinity, the eigenvalues of the integral equation

$$\int_0^T [K(s)]^{\frac{1}{2}}\rho_T(s-t)[K(t)]^{\frac{1}{2}}f(t)dt=\lambda f(s), \tag{6.31}$$

provided these eigenvalues are simple. Since the distribution of (6.27) approaches that of $V(t)$ we deduce that the characteristic function of $V(t)$ is given by the formula

$$1\Big/\prod_{1}^{\infty}(1-i\lambda_j^{(T)}\xi), \tag{6.32}$$

where $\lambda_1^{(T)}$, $\lambda_2^{(T)}$, $\cdots$, are the eigenvalues of the integral equation (6.31). For large $T$ we can replace the integral equation (6.31) by

$$\int_0^\infty [K(s)]^{\frac{1}{2}}\rho(s-t)[K(t)]^{\frac{1}{2}}f(t)dt=\lambda f(s), \tag{6.33}$$

and the characteristic function of $V(t)$ by

$$1/\prod_j(1-i\lambda_j\xi), \tag{6.34}$$

where $\lambda_1$, $\lambda_2$, $\lambda_3$, $\cdots$ are now the eigenvalues of the integral equation (6.34) which we again assume to be simple. The probability density $P(V)$ of $V$ can now be expressed by means of the inversion formula

$$P(V)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{e^{-iV\xi}}{\prod_j(1-i\lambda_j\xi)}d\xi. \tag{6.35}$$

At the end of Section 4, the integration has been carried out by the method of residues. The justification of the formal integration is not quite simple since one must investigate the behavior of the entire function

$$\phi(Z)=\prod_{1}^{\infty}(1-i\lambda_j Z)$$

for large $|Z|$.[5] However, it can be considerably simplified if one assumes that for some $\nu(0<\nu<1)$ the series

$$\sum_{1}^{\infty}\lambda_j^{\nu}$$

converges. On the other hand it is easy to see that the exact probability density $P(V)$ is the limit, as $n$ approaches infinity, of $P_n(V)$ where

$$P_n(V)=\sum_{s=1}^{n}\frac{\exp(-V/\lambda_s)}{\lambda_s\prod_{1}^{n}{}'(1-\lambda_j/\lambda_s)};\quad V>0. \tag{6.36}$$

$P_n(V)=0$; $V<0$ since with the assumption $K(u)>0$ negative eigenvalues cannot occur. In fact, the characteristic function corresponding to $P_n(V)$ which is seen to be

$$\prod_{1}^{n}\frac{1}{1-i\xi\lambda_j}$$

approaches the characteristic function associated with $P(V)$ thus $P_n(V)$ approaches $P(V)$.

## VII. EXPLICIT SOLUTIONS IN SOME SPECIAL CASES

### 1. Single-Tuned I.F. with Simple Low Pass Video

For the special case of a single tuned i-f amplifier with the video amplifier acting as a simple low pass filter the integral equation can be solved explicitly and the eigenvalues can be expressed in terms of roots of Bessel functions. For one special ratio of video band width to i-f band width it is even possible to obtain $P(V)$ in closed form. For other ratios it is not too difficult to sum the series for $P(V)$ numerically.

The correlation function $\rho(t)$ is in this case

$$\rho(t)=e^{-\alpha|t|} \tag{7.11}$$

which is equivalent to writing

$$A(f)=\frac{\text{Const.}}{1+(2\pi f/\alpha)^2}. \tag{7.12}$$

---

[5] We note that $\phi(Z)=D(iZ)$ where $D(\mu)$ is the Fredholm Determinant of the above integral equation. It is noteworthy that this relationship between the characteristic function of $P(V)$ and the Fredholm Determinant persists, even in the general case in which $K(t)$ is not assumed positive (in which case the simple product representation need not hold, since $\Sigma\lambda$ need not converge). In the general case one must take the Fredholm Determinant of the kernel $K(t)\rho(s-t)$.

For the video we assume

$$K(u)=\begin{cases}0 & , u>0\\ \beta\exp(-\beta u), & u<0\end{cases} \qquad (7.13)$$

i.e.,

$$C(f)=\frac{1}{1+2\pi i f/\beta}. \qquad (7.14)$$

The integral equation (6.33) now assumes the form

$$\beta\int_0^\infty e^{-\alpha|s-t|}e^{-(\beta/2)(s+t)}f(t)dt=\lambda f(s). \qquad (7.15)$$

Putting

$$\psi(t)=\exp\left(\frac{\beta}{2}t\right)f(t) \qquad (7.16)$$

we have

$$\int_0^\infty \exp(-\alpha|s-t|)\exp(-\beta t)\psi(t)dt=\frac{\lambda}{\beta}\psi(s). \qquad (7.17)$$

This integral equation is solved by[6]

$$\psi(s)=J_{2\alpha/\beta}\left[2\left(\frac{2\alpha}{\beta\lambda}\right)^{\frac{1}{2}}e^{-\beta s/2}\right] \qquad (7.18)$$

and the eigenvalues are determined by

$$J_{(2\alpha/\beta)-1}[2(2\alpha/\beta\lambda)^{\frac{1}{2}}]=0. \qquad (7.19)$$

Thus the eigenvalues of our integral equation are expressible in terms of roots of Bessel functions and are seen to be simple. It is interesting to note that if $2\alpha/\beta=\frac{3}{2}$ we can express $P(V)$ in terms of one of the theta functions. In fact, if $2\alpha/\beta=\frac{3}{2}$, Eq. (7.19) assumes the form

$$J_{\frac{1}{2}}[(6/\lambda)^{\frac{1}{2}}]=0 \qquad (7.21)$$

and since

$$J_{\frac{1}{2}}(x)=\left(\frac{2}{\pi}\right)^{\frac{1}{2}}\frac{\sin x}{\sqrt{x}} \qquad (7.22)$$

we see that

$$\lambda_n=\frac{6}{\pi^2}\frac{1}{n^2}\quad (n=1,2,\cdots) \qquad (7.23)$$

and formula (6.36) for $V>0$ becomes

$$P(V)=\frac{\pi^2}{6}\sum_{s=1}^{\infty}\frac{s^2\exp(-\pi^2s^2V/6)}{\prod_j'(1-(s^2/j^2))}. \qquad (7.24)$$

It can be shown quite easily that

$$\prod_j'\left(1-\frac{s^2}{j^2}\right)=-\frac{\cos\pi s}{2} \qquad (7.25)$$

and therefore,

$$P(V)=\frac{\pi^2}{3}\sum_{s=1}^{\infty}(-1)^{s+1}s^2\exp(-\pi^2s^2V/6). \qquad (7.26)$$

Introducing the theta-function notation

$$\theta(q;0)=1-2q+2q^4-2q^9+\cdots \qquad (7.27)$$

we have

$$q\theta'(q;0)=-2\sum_{s=1}^{\infty}(-1)^{s+1}s^2q^{s^2} \qquad (7.28)$$

and finally

$$P(V)=-\frac{\pi^2}{6}\exp\left(\frac{\pi^2V}{6}\right)\theta'(e^{-\pi^2V/6};0). \qquad (7.29)$$

For other values of the ratio $\alpha/\beta$ we can calculate values of $P(V)$ and plot the corresponding graphs.

### 2. The Noise Power, Averaged over a Finite Time Interval

In some problems it is of interest to know the distribution of the average

$$M=\frac{1}{\tau}\int_0^\tau I^2(t)dt. \qquad (7.31)$$

The derivation of Section 4 is clearly applicable to this case if we put

$$K(u)=\begin{cases}1/\tau, & 0<u<\tau\\ 0 & \text{elsewhere.}\end{cases} \qquad (7.32)$$

The probability density is given by (4.46) replacing $V$ by $M$ except that the $\lambda$'s are now eigenvalues of the integral equation

$$\frac{1}{\tau}\int_0^\tau \rho(s-t)f(t)dt=\lambda f(s). \qquad (7.33)$$

In the simple case

$$\rho(t)=e^{-\alpha|t|} \qquad (7.34)$$

the eigenvalues can be shown to be given by the formula

$$\lambda_m=\frac{2}{g}\frac{1}{1+y_m^2}. \qquad (7.35)$$

---

[6] For the solution and discussion of the integral equation see M. L. Juncosa "An integral equation related to Bessel functions," Duke Math. J. 12, 465–471 (1945).

where $y_m$ is the $m$th (positive) root of the equation

$$\tan gy = -2y/(1-y^2) \tag{7.36}$$

and $g = \alpha\tau$.

## VIII. APPROXIMATIONS FOR $P(V)$

At the end of Section 5, it was shown that, for infinitely wide video, $P(V)$ becomes identical with the well-known probability density of the output voltage of a quadratic detector. We will derive now an approximation for the case that the video band width is very large compared with the i-f band width.

It can be shown that in this case one of the eigenvalues say $\lambda_1$, tends to unity while all others approach zero. In order to obtain the dependence of the eigenvalues on the band width ratio we shall write

$$A(f') = \frac{1}{B}a\left(\frac{f'}{B}\right) \tag{8.11}$$

and

$$C(f) = c\left(\frac{f-f_0}{b}\right), \tag{8.12}$$

where

$$\int_{-\infty}^{\infty} a(\nu)d\nu = 1 \tag{8.13}$$

and

$$c(f_0/b) = 1 \tag{8.14}$$

in conformity with our original normalization for $A(f)$ and $K(t)$. The limiting process is carried through for $B/b = \epsilon \rightarrow 0$, while the functions $a(\nu)$ and $c(\nu)$ remain unchanged. In terms of $A$ and $C$ our integral equation becomes

$$\int_{-\infty}^{\infty} A(f_1)C(f_2-f_1)g(f_2)df_2 = \lambda g(f_1) \tag{8.21}$$

and traces $S_k$ are, therefore,

$S_1 = 1,$

$$S_2 = \int\int_{-\infty}^{\infty} d\nu_1 d\nu_2 a(\nu_1)a(\nu_2) \times c(\epsilon[\nu_2-\nu_1]-f_0/b)c(\epsilon[\nu_1-\nu_2]-f_0/b), \tag{8.22}$$

$$S_3 = \int\int_{-\infty}^{\infty}\int d\nu_1 d\nu_2 d\nu_3 a(\nu_1)a(\nu_2)a(\nu_3) \times c(\epsilon[\nu_2-\nu_1]-f_0/b)c(\epsilon[\nu_1-\nu_3]-f_0/b) \times c(\epsilon[\nu_3-\nu_2]-f_0/b),$$

etc. Expanding $c(\epsilon\nu - f_0/b)$ in a power series around $f_0/b$ we shall write

$$c(\epsilon\nu - f_0/b) = 1 + C_1\epsilon\nu + C_2\epsilon^2\nu^2 + \cdots. \tag{8.23}$$

Assuming that

$$\int_{-\infty}^{\infty} a(\nu)\nu^4 d\nu$$

is finite we obtain the following approximations:

$$\begin{aligned} S_2 &\cong 1 + \alpha\epsilon^2 + 0(\epsilon^4), \\ S_3 &\cong 1 + 3\alpha\epsilon^2/2 + 0(\epsilon^4), \\ S_4 &\cong 1 + 2\alpha\epsilon^2 + 0(\epsilon^4), \end{aligned} \tag{8.24}$$

where

$$\alpha = 2(2C_2 - C_1^2)\int_{-\infty}^{\infty} a(\nu)\nu^2 d\nu \tag{8.25}$$

and essential use has been made of the fact that $a(\nu) = a(-\nu)$. Noticing that

$$\lambda_1^2 S_2 > S_4 \tag{8.26}$$

(since $S_n = \sum_1^\infty \lambda_k^n$, and $\lambda_1$ is by defintion the largest eigenvalue) we obtain

$$\lambda_1^2 > S_4/S_2 = 1 + \alpha\epsilon^2 + 0(\epsilon^4). \tag{8.27}$$

Therefore, $\sum_2^\infty \lambda_k^2$ is of order $\epsilon^4$ or higher, and $\sum_2^\infty \lambda_k^4$ is of order $\epsilon^8$ or higher. Now we notice that

$$(S_4)^{\frac{1}{4}} = \lambda_1 + 0(\epsilon^8) \tag{8.28}$$

so that

$$\lambda_1 = 1 + \alpha\epsilon^2/2 + 0(\epsilon^4). \tag{8.29}$$

Making use of the expression

$$V = \sum^{\infty} \lambda_k Z_k \tag{8.31}$$

[cf. Eqs. (4.42), (4.43)], we write

$$V = V_1 + v \tag{8.32}$$

with

$$V_1 = 1 - \lambda_1 + \lambda_1 Z_1 \tag{8.33}$$

and

$$v = \sum_2^\infty \lambda_k(Z_k - 1). \tag{8.34}$$

If $P_1(V_1)$ is the probability density of $V_1$, given by

$$P_1(V_1) = 0 \quad \text{for} \quad V_1 < 1 - \lambda_1 \tag{8.35}$$

and

$$P_1(V_1) = \lambda_1^{-1} \exp\frac{V_1 - (1-\lambda_1)}{\lambda_1} \quad \text{for} \quad V_1 > (1-\lambda_1),$$

and $w(v)$ is the probability density of $v$, we have for $P(V)$ the exact expression

$$P(V)=\int_{-\infty}^{\infty} dvP_1(V-v)w(v)$$

$$=\int_{-\infty}^{V-1+\lambda_1} dvP_1(V-v)w(v). \quad (8.36)$$

Since the width of $w(v)$ is of order $\epsilon^2$ we can use $P_1(V)$ as the first approximation of $P(V)$. To discuss the reliability of this appproximation we expand $P(V)$ in the form

$$P(V)=P_1(V)-P_1'(V)\int_{-\infty}^{V-1+\lambda_1} vdvw(v)$$

$$+\tfrac{1}{2}P_1''(V)\int_{-\infty}^{V-1+\lambda_1} v^2dvw(v)$$

$$+\frac{1}{3!}\int_{-\infty}^{V-1+\lambda_1} v^3dvw(v)P_1'''(V-\xi) \quad (8.37)$$

where, in the last term,

$$0<\xi<|v|.$$

For any fixed value of $V>0$, the integrals in the first and second term can be replaced by $\bar{v}=0$ and $\langle v^2\rangle=\sum_2^\infty\lambda_k^2$ with an error of order $\epsilon^4$ or smaller, because

$$\int_{V-(1-\lambda_1)}^{\infty} vdvw(v)$$

$$\leq\int_0^\infty \frac{v^4}{[V-(1-\lambda_1)]^3}w(v)dv=0(\epsilon^8), \quad (8.38)$$

$$\int_{V-(1-\lambda_1)}^{\infty} v^2dvw(v)$$

$$\leq\int_0^\infty \frac{v^4}{[V-(1-\lambda_1)]^2}w(v)dv=0(\epsilon^8).$$

The last term in (8.37) can be shown to be of order $\epsilon^6$ or higher. Thus we have

$$P(V)=P_1(V)+\tfrac{1}{2}P_1''(V)\langle v^2\rangle_{\mathrm{Av}}+0(\epsilon^6) \quad (8.39)$$

for any fixed $V>0$. Substituting

$$\lambda_1=1+\alpha\epsilon^2/2+0(\epsilon^4)$$

and

$$\langle v^2\rangle_{\mathrm{Av}}=\sum_{k=2}^{\infty}\lambda_k^2=0(\epsilon^4),$$

we see that for fixed $V>0$, $P_1(V)$ is a good approximation except for terms of order $\epsilon^4$ and higher.

If, in addition, the existence of

$$\int_{-\infty}^{\infty} a(\nu)\nu^6d\nu \quad (8.41)$$

is assumed the approximation can be improved by including the term

$$\tfrac{1}{2}P_1''(V)\langle v^2\rangle_{\mathrm{Av}}$$

where

$$\langle v^2\rangle_{\mathrm{Av}}=S_2-(S_6)^{\frac{1}{3}}+0(\epsilon^{12}). \quad (8.42)$$

and $\lambda_1$ [which occurs in $P_1(V)$] is calculated from

$$\lambda_1=(S_4)^{\frac{1}{4}}+0(\epsilon^8). \quad (8.43)$$

Substituting these values we obtain an approximation for $P(V)$ valid up to terms of order $\epsilon^4$ inclusive. In the neighborhood of $V=0$, no approximation which utilizes only the traces of a limited number of iterated kernels, can be expected to hold, since there—as can be seen from the general solution—the eigenvalues individually determine the shape.

The considerations of this section cannot be expected to be applicable to the case treated exactly in Section 7 since there not even

$$\int_{-\infty}^{\infty} a(\nu)\nu^2d\nu$$

exists. In that case one sees directly that the eigenvalues are such that

$$\lambda_1=1-0(\epsilon), \quad \sum_2^\infty\lambda_k^2=0(\epsilon^2).$$

In order to be able to obtain a general approximation for wide videos one must demand that the i-f spectrum falls off sufficiently rapidly at infinity.

In the opposite limit, $b/B\to 0$, similar considerations show that $P(V)$ becomes Gaussian with mean $\langle V\rangle_{\mathrm{Av}}=1$ and spread proportional to $(b/B)^{\frac{1}{2}}$.

## IX. APPLICATION TO A DISCRETE CASE

For some applications of noise theory it is desirable to have the characteristic function

$$\exp\left\langle i\sum_{k=1}^{n}\xi_kI_k\right\rangle_{\mathrm{Av}}=\phi(\xi_1\cdots\xi_n) \quad (9.11)$$

of the joint probability of $n$ successive values $I_1, I_2\cdots, I_n$; $I_k=x^2(t_k)+y^2(t_k)$ of the detector output, from which the averages of products $\langle\prod_k I_k^{m_k}\rangle_{\mathrm{Av}}$ ($m_k$ integer) can be derived. $\phi(\xi_1\cdots\xi_n)$ can be obtained by carrying through the idea of transformation to principal axes for the discrete case, that is, by a slight modification of Section 6. However, we shall derive $\phi(\xi_1\cdots\xi_n)$ from the results of Section 4 since this seems the quicker way.

We simply chose for $K(t)$ the function

$$K(t)=\frac{1}{\xi}\sum_1^n \xi_k\delta(t-t_k) \qquad (9.12)$$

where $\xi=\sum_1^n\xi_k$ for the sake of normalization, and the time variable $t$ is chosen in such a way that all $t_k<0$. For this choice of $K(t)$ we have

$$V=\int_0^\infty K(t)[x^2(t)+y^2(t)]dt=\frac{1}{\xi}\sum_1^n \xi_k I_k \qquad (9.13)$$

and, provided that the $I_k$ are normalized so that $\langle I_k\rangle_{\mathrm{Av}}=1$, we have

$$\phi(\xi_1\cdots\xi_n)\equiv e^{i\sum\xi_k I_k}=\langle e^{i\xi V}\rangle_{\mathrm{Av}}=\frac{1}{\prod_j(1-i\lambda_j\xi)}. \qquad (9.14)$$

The integral equation, whose eigenvalues are $\lambda_j$ degenerates in this case into a system of linear equations for $n$ discrete variables $f(t_k)=f_k$:

$$\frac{1}{\xi}\sum_{k=1}^n \xi_k\rho_{km}f_k=\lambda f_m, \qquad (9.15)$$

where

$$\rho_{km}=\rho(t_k-t_m)$$

with

$$\Lambda=\xi\lambda.$$

We write these equations as

$$\sum_{k=1}^n \xi_k\rho_{km}f_k=\Lambda f_m. \qquad (9.16)$$

To obtain $\phi$, it is not necessary actually to determine the eigenvalues since the product $\prod_j(1-i\Lambda_j)$ can be expressed in terms of the determinant det $|\xi_k\rho_{km}+i\delta_{km}|$ as follows:
We note that

$\prod_1^n(iu-i\Lambda_j)$ is a polynomial in $u$ which has zeros at $u=\Lambda_j$ and starts with $i^n u^n$. The determinant det$|\xi_k\rho_{km}-u\delta_{km}|$ is a polynomial in $u$, which has the same roots and starts with $(-)^n u^n$. We therefore have

$$\prod_1^n(iu-i\lambda_j)=i^{-n}\det|\xi_k\rho_{km}-u\delta_{km}| \qquad (9.17)$$

and, specially, for $u=-i$

$$\prod_1^n(1-i\Lambda_j)=i^{-n}\det|\xi_k\rho_{km}+i\delta_{km}|.$$ [7]

The characteristic function is thus obtained as

$$\langle e^{i\sum\xi_k I_k}\rangle_{\mathrm{Av}}=\frac{i^n}{\det|\xi_k\rho_{km}+i\delta_{km}|}. \qquad (9.18)$$

While it has not been possible to evaluate the joint probability

$$W_n(I_1\cdots I_n)=\frac{1}{(2\pi)^n}\int\cdots\int d\xi_1\cdots d\xi_n \times\phi(\xi_1\cdots\xi_n)e^{-i\sum\xi_k I_k}, \qquad (9.19)$$

explicitly (except for $n=1$ and $n=2$, in which cases they are well known) one can obtain averages of the form

$\langle\prod_k I_k^{m_k}\rangle_{\mathrm{Av}}$ for integer values of $m_k$,

by expanding both sides of (9.18) in power series in the variables $\xi_k$ and by comparing coefficients.

---

[7] For the general kernel a corresponding relation can be derived between the above product and the Fredholm determinant of the kernel.

# Heating and Cooling of Bolometer Elements

J. N. Shive
*Bell Telephone Laboratories, Inc., Murray Hill, New Jersey*

(Received January 20, 1947)

The analogy between thermal and electrical networks is used to obtain solutions to problems relating to the heating and cooling of air-backed and solid-backed bolometer elements exposed to radiation of periodically fluctuating intensity. From the equations derived, thermal response-frequency characteristics are computed for "typical" bolometer elements. Features of these characteristics are discussed, and the physical influences of the various thermal properties of the bolometer material and of the backing material are pointed out.

## INTRODUCTION

In some of the present-day applications of radiation bolometry the heat-sensitive receiver element is placed in series with another resistance, and a d.c. biasing voltage is applied across this series. The radiation incident upon the element is mechanically interrupted, as by a rotating sector disk, so that the element alternately heats and cools. Under these conditions an a.c. voltage is generated across the element, which, when amplified and measured, serves as an indication of the intensity of the incoming radiation.

The amplitude of the a.c. signal thus generated is approximately proportional[1] to the biasing voltage across the receiver element. This, in turn, is limited by the rate at which the element can dissipate the Joule heat produced by the bias. If the element is placed in thermal contact with a solid backing through which this heat can be more rapidly dissipated, the bias voltage can be increased. The amplitude of the temperature fluctuation of the element due to the absorption of a given chopped radiation signal is reduced by the presence of such a backing, but this reduction, for certain ranges of chopping frequency, can be more than compensated for by the use of the higher biasing voltage made possible by the backing. In addition, the use of a backing brings about a faster approach to temperature equilibrium at each interruption of the radiation beam, so that the time constant of the element is correspondingly reduced, a consideration of importance, for example, in the rapid scanning of an infra-red spectrum.

There are a number of questions in connection with the backing of bolometer elements for which both experimental and theoretical answers have been sought. It is of importance to know, for example, what thermal properties and what geometry the backing should have in order to secure maximum dissipation of the bias heating with minimum reduction of the amplitude of the temperature fluctuations of the element. It is equally important to know the effect of such a backing on the frequency dependence of the element.

It is the purpose of this paper to demonstrate a method for obtaining answers to such questions by applying the mathematics of electrical network theory. The electrical analogy has long been useful in the solution of problems in mechanics and acoustics, and some applications have already been made in the field of heat flow.[1–4] Analytical expressions governing the behavior of bolometers

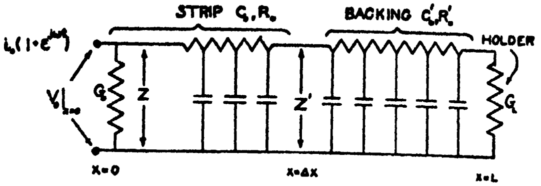

FIG. 2. Electrical analog of the bolometer assembly of Fig. 1.

will be developed from this analogy, and these will be employed in presenting graphical illustrations of the temperature fluctuation of the element in its dependence on the thermal properties of the bolometer and the backing, and on the chopping frequency.

### General Equations for Backed Bolometers

Consider a thin strip of temperature-sensitive bolometer material of 1 sq. cm area and $\Delta x$ thickness. Consider this strip to be fastened to a solid slab of backing material, also of 1 sq. cm area, and extending in thickness from $x=\Delta x$ to $x=L$. At $x=L$ let the backing slab be fastened in turn to some kind of holder or housing. This physical arrangement is sketched in Fig. 1.

Let the exposed front surface of the bolometer strip absorb an incident radiation signal of

$$U_0(1+\epsilon^{j\omega t})^* \tag{1}$$

watts, where $U_0$ is half the radiant power per unit area in the unchopped beam, $\omega$ is $2\pi$ times the chopping frequency, and $t$ is the time. Let heat be dissipated by reradiation and convection from the front face of the strip, according to Newton's law of cooling, at a rate of $\sigma(T_{x=0}-T_a)$ watts, where $\sigma$ is the dissipation constant of the front face in watts per sq. cm per degree, $T_{x=0}$ is the instantaneous temperature of the front face, and $T_a$ is the ambient temperature. Similarly let heat be lost from the rear surface of the backing slab to the holder at a rate $\sigma'(T_{x=L}-T_a)$ watts, where $\sigma'$ is the backing-to-holder dissipation constant (here considered to be thermally nonreactive) and $T_{x=L}$ is the instantaneous temperature of the rear face of the backing. These various heat flows are indicated in Fig. 1. Consider the lateral surfaces of the bolometer and backing to be thermally insulated so that heat can flow only in the $x$ coordinate.

Let $k$ and $k'$ be the thermal conductivities of the bolometer material and backing material, respectively, in watts per sq. cm per degree per cm, $\rho$ and $\rho'$ the respective densities in g per cc, and $C_v$ and $C_v'$ the respective specific heats in Joules per g degree. Then the respective thermal diffusivities $K$ and $K'$ are constants given by

$$K=k/\rho C_v \quad \text{and} \quad K'=k'/\rho' C_v'.$$

The electrical analog of the backed bolometer strip is a short transmission line (Fig. 2) having distributed series resistance $R_0$ and shunt capacity $C_0$ per unit length, looking into a longer transmission line representing the backing and having distributed series resistance $R_0'$ and shunt capacity $C_0'$ per unit length. The front-surface dissipation of the bolometer strip corresponds to a conductance $G_0$ hung across the input end of the short line, while the backing-to-holder dissipation corresponds to a conductance $G_L$ terminating the long line. The following table of equivalents may be found useful in visualizing the correspondence of analogous thermal and electrical entities (Table I).

The problem is now that of finding the input voltage amplitude $V_0|_{x=0}$ as a function of frequency when a current

$$i_0(1+\epsilon^{j\omega t})$$

is fed into the network. The a.c. solution of this network may be obtained by considering the problem as that of a short line of input impedance $Z$ (taken just inside the input dissipation conductance) and terminated at $x=\Delta x$ by the input

TABLE I.

| Entity | Thermal | Electrical |
|---|---|---|
| Input flow, a.c. part | $U_0\epsilon^{j\omega t}$ | $i_0\epsilon^{j\omega t}$ |
| Input amplitude | $T_0\|_{x=0}$ | $V_0\|_{x=0}$ |
| Series resistance per unit length | | |
| bolometer | $\frac{1}{k}$ | $R_0$ |
| backing | $\frac{1}{k'}$ | $R_0'$ |
| Shunt capacity per unit length | | |
| bolometer | $\rho C_v$ | $C_0$ |
| backing | $\rho' C_v'$ | $C_0'$ |
| Front-surface dissipation | $\sigma(T_{x=0}-T_a)$ | $G_0 V\|_{x=0}$ |
| Backing-to-holder dissipation | $\sigma'(T_{x=L}-T_a)$ | $G_L V\|_{x=L}$ |

---

[*] In (1) there is considered, for simplicity's sake, only the fundamental component of the multiply-harmonic radiant power input obtained by the usual mechanical chopping of the incident beam.

impedance $Z'$ of the long line, which in turn is terminated at $x=L$ by the dissipation $G_L$. Thus, the solution is

$$V_0|_{x=0}=i_0/(G_0+1/Z)$$

where $Z$ is given[5] by

$$Z=Z_0\frac{Z_0\sinh\gamma\Delta x+Z'\cosh\gamma\Delta x}{Z_0\cosh\gamma\Delta x+Z'\sinh\gamma\Delta x},$$

and where, in turn, $Z'$ is given by

$$Z'=Z_0'\frac{Z_0'\sinh\gamma'(L-\Delta x)+\dfrac{1}{G_L}\cosh\gamma'(L-\Delta x)}{Z_0'\cosh\gamma'(L-\Delta x)+\dfrac{1}{G_L}\sinh\gamma'(L-\Delta x)}. \tag{2}$$

In these equations $Z_0$ and $\gamma$ are the characteristic impedance and propagation constant, respectively, of the short line representing the bolometer strip, and $Z_0'$ and $\gamma'$ are the corresponding constants for the long line representing the backing. For series-resistance shunt-capacity lines these quantities have the values:

$$\left.\begin{aligned} Z_0&=(R_0/jC_0\omega)^{\frac{1}{2}}\\ \gamma&=(jR_0C_0\omega)^{\frac{1}{2}}\\ Z_0'&=(R_0'/jC_0'\omega)^{\frac{1}{2}}\\ \gamma'&=(jR_0'C_0'\omega)^{\frac{1}{2}} \end{aligned}\right\}. \tag{3}$$

With the quantities (3) replaced into (2), and with the corresponding thermal equivalents substituted into the resulting expressions, the amplitude of the temperature fluctuation at the front surface of the bolometer strip becomes

$$T_0|_{x=0}=U_0/(\sigma+1/Z_{\text{th}}),$$

where

$$Z_{\text{th}}=\frac{1}{k}\left(\frac{K}{j\omega}\right)^{\frac{1}{2}}\frac{\dfrac{1}{k}\left(\dfrac{K}{j\omega}\right)^{\frac{1}{2}}\sinh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x+Z'_{\text{th}}\cosh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x}{\dfrac{1}{k}\left(\dfrac{K}{j\omega}\right)^{\frac{1}{2}}\cosh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x+Z'_{\text{th}}\sinh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x},$$

and where

$$Z'_{\text{th}}=\frac{1}{k'}\left(\frac{K'}{j\omega}\right)^{\frac{1}{2}}\frac{\dfrac{1}{k'}\left(\dfrac{K'}{j\omega}\right)^{\frac{1}{2}}\sinh\left(\dfrac{j\omega}{K'}\right)^{\frac{1}{2}}(L-\Delta x)+\dfrac{1}{\sigma'}\cosh\left(\dfrac{j\omega}{K'}\right)^{\frac{1}{2}}(L-\Delta x)}{\dfrac{1}{k'}\left(\dfrac{K'}{j\omega}\right)^{\frac{1}{2}}\cosh\left(\dfrac{j\omega}{K'}\right)^{\frac{1}{2}}(L-\Delta x)+\dfrac{1}{\sigma'}\sinh\left(\dfrac{j\omega}{K'}\right)^{\frac{1}{2}}(L-\Delta x)}. \tag{4}$$

---

[5] A derivation of this expression for the input impedance of a distributed-constant line terminated by another impedance can be found, for instance, in Slater's *Microwave Transmission*, Chap. I.

The subscript th indicates that the impedances designated are thermal impedances.

### Application to Air-Backed Bolometers

The above equations can equally well be applied to air-backed bolometers. For an air-backed element the only heat loss is by air dissipation at the front and rear surfaces. The thermal impedance of the backing in this case is replaced by the appropriate air-dissipation factor, so that $Z'_{\text{th}}$ in (4) becomes simply $Z'_{\text{th}}=1/\sigma$. With this substitution the first two equations of (4) combine to give

$$T_0|_{x=0}=\frac{U_0}{\sigma+k\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\dfrac{\dfrac{1}{k}\left(\dfrac{K}{j\omega}\right)^{\frac{1}{2}}\cosh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x+\dfrac{1}{\sigma}\sinh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x}{\dfrac{1}{k}\left(\dfrac{K}{j\omega}\right)^{\frac{1}{2}}\sinh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x+\dfrac{1}{\sigma}\cosh\left(\dfrac{j\omega}{K}\right)^{\frac{1}{2}}\Delta x}}. \tag{5}$$

Two approximations to (5) can be made, each being valid over a particular range of parameters, which simplify the task of interpreting physically the results obtained from (5). For small arguments the sinh is nearly equal to the argument and the cosh is nearly equal to unity. Thus, for

$$|(j\omega/K)^{\frac{1}{2}}\Delta x|\lesssim 0.3$$

Eq. (5) becomes

$$T_0|_{x=0}\simeq\frac{U_0(\sigma\Delta x+k)}{\sigma(\sigma\Delta x+2k)+\dfrac{jk^2\omega\Delta x}{K}}. \tag{5a}$$

For large arguments the sinh and cosh are nearly equal. Hence, if

$$|(j\omega/K)^{\frac{1}{2}}\Delta x|\gtrsim 1.8$$

Eq. (5) becomes

$$T_0|_{x=0}\simeq\frac{U_0}{\sigma+k(j\omega/K)^{\frac{1}{2}}}. \tag{5b}$$

Equations (5), (5a), and (5b) can be used to calculate theoretical response-frequency curves for various bolometers. By thermal response is meant the ratio $T_0|_{x=0}/U_0$ of the amplitude of the front-face temperature fluctuation to the amplitude of the incoming chopped radiation signal. Such a response-frequency curve is given by the solid curve of Fig. 3 for a typical bolometer strip made of thermistor material* and having:

$\Delta x=0.0018$ cm
$k=0.01$ watt/cm deg.
$\rho=5$ g/cc
$C_v=0.75$ joule/g deg.
$\sigma=0.005$ watt/sq. cm deg.

This curve is composed of the following three distinct regions, each being characteristic of a particular frequency range.

I. A frequency-independent region for very low frequencies in which, physically, the temperature of the entire flake is always in equilibrium with the incident radiation. From Eq.

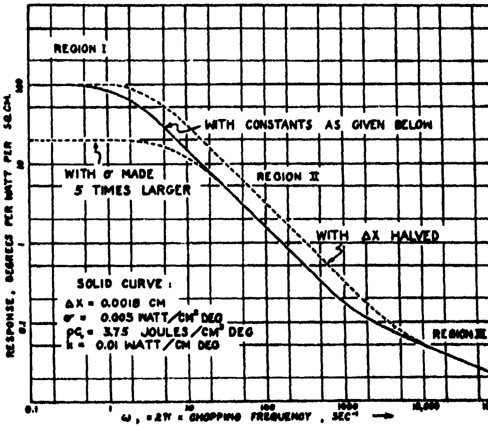

FIG. 3. Response-frequency characteristic for air-backed bolometer.

---

* Thermistor material is a mixture of certain semiconductor oxides. It has a large negative temperature coefficient of resistance.

(5a), appropriate to this region, it is apparent that the temperature fluctuations of the strip are in phase with the fluctuations of the incoming radiation.

II. An intermediate region in which the response is inversely proportional to the frequency. Here the strip temperature is no longer in equilibrium with the incoming radiation, and the phase of the former lags that of the latter by a quarter cycle. As will be shown below, the instantaneous temperature of the whole strip is effectively equal to that of the front surface over the entire frequency region for which this relationship holds. The thermal time constant of the strip is the reciprocal of the frequency at which the transition from region I to region II occurs.

III. A high frequency region in which the response obeys a $1/\sqrt{\omega}$ relationship, as given by (5b). Here the phase of the front-face temperature lags that of the incoming radiation by an eighth cycle.

The physical meaning of the transition from region II to region III can be understood from a consideration of the speed $v$ and wave-length $\lambda$ with which waves of temperature traverse the thickness of the strip in consequence of the periodic heating and cooling of the front face.

The propagation constant $\gamma$ of the electrical line representing the bolometer, as given by Eq. (3) is: $\gamma=(jR_0C_0\omega)^{\frac{1}{2}}$. The imaginary part of this quantity, called the phase constant $\beta$, is: $\beta=(R_0C_0\omega/2)^{\frac{1}{2}}$. And the velocity $v$ of electrical waves along this network is given by $v=\omega/\beta=(2\omega/R_0C_0)^{\frac{1}{2}}$. The thermal analog of this velocity expression is $v_{\text{therm}}=(2K\omega)^{\frac{1}{2}}$, while the wave-length $\lambda$ of the temperature waves is

$$\lambda=\frac{2\pi v}{\omega}=2\pi(2K/\omega)^{\frac{1}{2}}.^{*} \qquad (6)$$

Comparing (6) with the condition in (5b) for which the transition from region II to region III becomes practically complete, it is evident that $\lambda_{\text{III}}\lesssim 4\Delta x$. Thus, the transition corresponds, with increasing frequency, to the physical situation in which the temperature waves have become so short that their wave-length is comparable to the thickness of the strip, and the strip is no longer at the same instantaneous temperature throughout its entire thickness. Hence for chopping frequencies lying in region III various layers within the bolometer strip have temperatures different from $T|_{x=0}$, and the electrical output response of the bolometer bridge is no longer determined by $T_0|_{x=0}$, but rather by the average throughout the thickness of the strip of the local temperature fluctuation amplitude, with due regard for phase. It can be shown* that this electrical response continues to decrease like $1/\omega$ with increasing frequency, even though the front-face temperature fluctuation amplitude falls off like $1/\sqrt{\omega}$. It appears from these considerations that for chopping frequencies in regions I and II this solution could equally well have been obtained from a lumped-constant analogy as from a transmission line analogy.

In Fig. 3 are plotted two dashed curves showing how the response-frequency characteristic is altered if a change is made in the thickness of the strip or in the value of the dissipation constant. The dashed curve characteristic of the 5-times-greater dissipation constant becomes identical with the solid curve for $\omega\gtrsim 30$. It can be seen from this illustration that if, by backing or otherwise, the dissipation from the element can be increased, an advantage will be gained in the operation of the bolometer. For, with this 5-fold greater dissipation a $\sqrt{5}$-fold greater d.c. bias can be placed across the bolometer bridge, and for $\omega\gtrsim 30$ a $\sqrt{5}$-fold increase in the electrical signal to the amplifier will be obtained for a given radiation signal. Furthermore, the time constant has been decreased to $1/\sqrt{5}$ of its former value.

Unfortunately, there is no solid backing material whose dissipation is entirely conductive, and some thermal reactance due to the volume heat capacity of the material is inescapable. The effect of this reactance, as will be shown in the next section, is to modify the advantage gained by the use of a solid backing.

## Application to Solid-Backed Bolometers

As an example of the kind of response-frequency curve to be expected for a solid-backed

---

* These expressions for wave-length and velocity of propagation of temperature waves in a semi-infinite medium were derived (otherwise) and used by Kelvin in his studies of the penetration of diurnal and annual waves of temperature into the earth.

* The author is particularly indebted to W. H. Brattain for helpful discussion of this subject.

bolometer there is shown in the solid curve of Fig. 4 the characteristic of the same strip bolometer as was used in the calculations for Fig. 3, but now fastened intimately to a rocksalt backing having the following dimensions and properties.

$$L=0.1\text{ cm}:\text{area}=1\text{ sq. cm}$$
$$k'=0.07\text{ watt/cm degree}$$
$$\rho'C_v'=2\text{ joules/cm}^3\text{ degree}$$
$$\sigma'=0.1\text{ watt/cm}^2\text{ degree.}$$

In the same figure appear a number of dashed curves showing the effects produced by varying, one or two at a time, some of the parameters of the backing. The caption adjacent to each dashed curve explains which parameter has been changed, and by how much. All of these curves have been computed from (4), using, wherever appropriate, the type of simplifications indicated in (5a) and (5b).

These curves exhibit features which are capable of simple physical explanation. The peculiar shape of the solid-line characteristic *A* is caused by the effect of the thermal reactance associated with the volume heat capacity of the backing. If this reactance could be eliminated, as for curve *B* which, to illustrate an extreme case, has been computed for $\rho'C_v'=0$, the characteristic would resemble that of an air-backed unit with unachievably high surface dissipation. This circumstance is of importance in the practical selection of a backing material. It can be concluded generally that for backings having low $\rho'C_v'$ the response can be expected to remain frequency-independent out to higher chopping frequencies than for backings having comparable $k'$ but higher $\rho'C_v'$.

Curve *C*, which has been computed for the extreme case $k'=0$, appears to coincide exactly with the solid curve of Fig. 3 except in the frequency-independent region, where the limiting response is twice that of the air-backed unit. With $k'=0$, the rear surface of the bolometer strip is thermally insulated, so that it now has only half the total dissipation of the air-backed unit. Of course, such a low-conductivity backing would be of no practical value in dissipating the bias heat of the element.

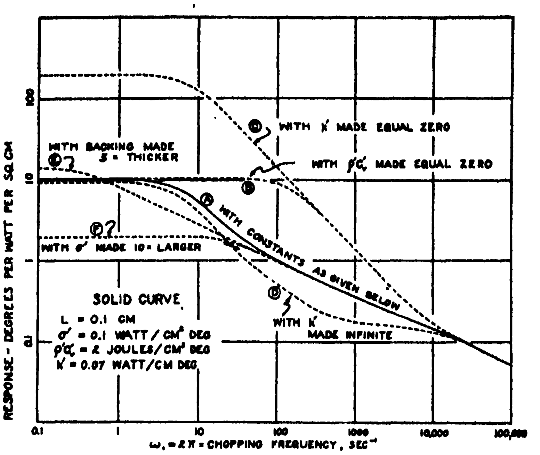

FIG. 4. Response-frequency characteristic for rocksalt-backed bolometer.

In curve *D*, to illustrate still another extreme case, the backing has been given an infinite thermal conductivity. This is equivalent to placing the entire thermal capacity of the backing directly in contact with the rear surface of the bolometer strip. This unbuffered reactance brings about the rapid decrease in response in the range from $\omega=10$ to $\omega=100$ and results in the nearly frequency-independent response in the range from $\omega=500$ to $\omega=10{,}000$. In the latter range the frequency is so high that the heat capacity of the backing presents practically a "short-circuiting" reactance to the rear surface of the bolometer strip. Thus, while the temperature at the front surface of the strip is being driven by the fluctuation of the incoming radiation, the temperature of the rear surface is being held nearly constant by this reactance. And, while the whole strip is at the same phase throughout, it is not at the same temperature throughout. This state of affairs does not change much with increasing frequency until so high a frequency is reached that the wave-length of the thermal waves in the strip becomes shorter than the thickness of the strip. Then, of course, the front-surface temperature of the strip becomes independent of the nature and properties of the backing.

It is to be noted that in the solid curve *A* there appears some tendency toward a levelling-off in the neighborhood of $\omega\sim 100$. The reason is as explained in the last paragraph, except that here the full short-circuiting effect of the backing reactance is buffered by the distributed thermal resistance of the backing, and the levelling-off is not as pronounced.

Curve $E$ shows the modification in the response-frequency curve brought about by making the backing five times thicker than for the solid curve $A$. Increasing the thickness of the backing increases the heat capacity, and the parallel reactance of this extra capacity makes itself felt at a lower chopping frequency than for curve $A$. Curve $E$ tends toward a higher low frequency limiting response than curve $A$ because of the decrease in dissipation, brought about by the increased thermal resistance of the thicker backing.

Finally, curve $F$ shows the effect of making the backing-to-holder dissipation ten times larger than for curve $A$. This increased dissipation lowers the low frequency limiting response and makes it necessary to go to higher chopping frequencies before coming to the fall-off due to the heat capacity of the backing.

It is often stated that an ideal backing material is one having a large value of the diffusivity $K'$. In making such a statement a distinction must be made whether the diffusivity is desired to be large by virtue of a large thermal conductivity $k'$ or by virtue of a small volume heat capacity $\rho' C_v'$. A comparison of curves $B$ and $D$ shows why this distinction is necessary. In a bolometer assembly of such geometry and thermal properties as are considered here the highest permissible d.c. bias across the bolometer strip is determined chiefly by the backing-to-holder dissipation rather than by the thermal conductivity of the backing. As long as the latter is large enough (as it is for rocksalt) so that the backing offers a comparatively small thermal resistance between the element and the holder, there is little virtue in having $k'$ still higher, as, for example, for quartz. However, any decrease in the value of $\rho' C_v'$ improves the response in the frequency region from $\omega \sim 1$ to $\omega \sim 1000$ and also decreases the time constant, both without affecting the permissible d.c. bias.

## DISCUSSION

In the interest of simplifying the development of this presentation a number of short cuts and omissions have been employed which would have to be taken into account in the application of the method here outlined to any physical problem where accuracy of theoretical prediction is desired. There will be pointed out, in the next few paragraphs, the nature of some of these simplifications, their consequences, and, so far as possible, their specific remedies.

All the equations appearing in this paper were derived on the assumption of a single sinusoidal amplitude fluctuation of input radiant power. If the fluctuation is obtained with a sector disk producing a nearly square-wave input of radiant power, a more satisfactory solution would be obtained by solving the appropriate equation for the fundamental chopping frequency and two or three of its harmonics as well, assigning to each harmonic solution a weight corresponding to the Fourier coefficient of the particular harmonic in the square-wave expansion, and summing over the expansion.

While backed bolometers can be made for which the thermal contact between the element and its backing is intimate, it is usually necessary in practice to fasten the two together with a thin layer of cement whose thermal properties may contribute to the behavior of the whole. The backed bolometers discussed in connection with the curves of Fig. 4 have been idealized to the extent of neglecting this layer and its effects. A paper is now in preparation by W. van Roosbroeck in which some of these details are treated. Van Roosbroeck's treatment will also include a consideration of cases in which the incoming radiation, instead of being absorbed, as here assumed, at the front surface of the bolometer strip, is absorbed throughout the thickness of the strip.

In usual practice a backed bolometer is made of a narrow strip of sensitive material cemented to a backing slab much larger in area than the strip. Hence the physical problem is not one dimensional except in a small volume of the backing immediately adjacent to the strip. At larger distances away from the strip in the backing the heat flows along nearly radial lines and the isothermals are nearly semi-cylinders coaxial with the center line of the strip. The analogous electrical problem is one in which the series conductance and parallel capacitance of the transmission line representing the backing increase nearly linearly with distance along the line. Except for special cases exact solutions for varying-parameter lines are not easily obtainable. However, approximate electrical analogs can be set up which are capable of solution. Such approximations, over certain frequency ranges are assisted by the fact that temperature waves in a semi-infinite solid are attenuated in amplitude by a factor $e^{-2\pi}$ per wave-length. Hence, for higher frequencies the temperature waves, which become shorter in wave-length with increasing frequency, do not penetrate far enough into the backing to get into the region where the fanning-out of the heat flow lines occurs, and the constant-parameter solutions already derived can be used as good approximations.

In deriving the equation for the solid-backed element the assumption was made that the holder presented a non-reactive dissipation to the rear surface of the backing slab. This assumption could lead to error only in frequency region *I* where the chopping rate is so low that the temperature waves penetrate clear through the backing. For higher frequencies the exact nature of the holder's impedance would not be of any consequence.

# The Speed of Propagation of Brittle Cracks in Steel

G. Hudson* and M. Greenfield**

*David Taylor Model Basin, USN, Washington, D. C.*

(Received September 30, 1946)

Brittle failure was produced in notched steel tensile specimens. The speed of propagation of the brittle crack was measured and found to be approximately 40,400 in./sec.

THERE have been recent reports of the brittle failure of steel plate used in a variety of engineering structures. This rupture occurred when the steel was subjected to certain severe conditions. In the main these brittle failures may be characterized by the following:

(1) A crack is propagated with extreme rapidity through the steel plate,

(2) The surface of rupture created by this crack is orthogonal to the plane of the plate,

(3) This rupture surface shows a characteristic "herringbone" pattern,

(4) There exist small permanent strains, often of less than 2 percent, in the neighborhood of the fractured surface. It was thought that a study of the speed of propagation of brittle cracks in steel might contribute to an understanding of the mechanisms of these phenomena.

A preliminary note on the beginning of this study has been given in an earlier paper.[1] This work was subsequently extended with a more refined technique, to include more variation in the path length over which the average velocity of the crack was measured, and a variation in the distance of this path from the point of initiation of the crack. In the present paper, in addition to reporting the later results which agree with the previous ones within the limit of experimental error, more details are given of the technique used.

It has been found possible to produce brittle failure in a steel tensile specimen at room temperatures in a controlled experiment of the following type. The specimens consisted of rectangular plates of a plain carbon structural steel (also known as medium steel) with a carbon content not exceeding 0.31. This steel had a minimum average ultimate strength of 60,000 lb./in.$^2$, and a minimum average yield strength of 34,000 lb./in.$^2$. This steel had not been heat treated. The specimens were approximately 2 feet long, $5\frac{3}{4}$ inches wide, and 1 inch thick. To fix

the point of initiation of the failure, a notch consisting of a milling saw cut of the order of $\frac{1}{32}$ inch in width and $\frac{1}{4}$ inch deep was machined into one edge of the specimen midway between its ends. See Fig. 1.

The specimen was placed in the grips of a tensile machine† and pulled to failure. A brittle crack initiated at the milling cut, as indicated by Fig. 1, was propagated across the specimen, at right angles to the edge.

An attempt was made to photograph the crack as it spread through the plate. The camera used was a Fastax Western Electric, operating at about 3000 frames per second. Even this speed was insufficient to catch the phenomenon, as the crack invariably spread across the specimen between two successive frames. It was possible, however, to infer by this method a lower limit of the order of 5000 in./sec. for the velocity.

The following method using electronic recording was finally adopted for determining the speed of propagation of the crack in these specimens. The specimens were first prepared by heating them to a temperature sufficient to melt but not boil a layer of medium de Khotinsky cement. This cement was spread smoothly on the surface of the metal in the region through which the crack was to be propagated. While the de Khotinsky was still fluid, several lengths of one-mil Nichrome wire were embedded in the cement, as shown schematically in Fig. 1. These wires were arranged to be approximately parallel, about one inch apart, and perpendicular to the expected path of the crack. The de Khotinsky thus served not only to cement the wire firmly to the tensile specimen,

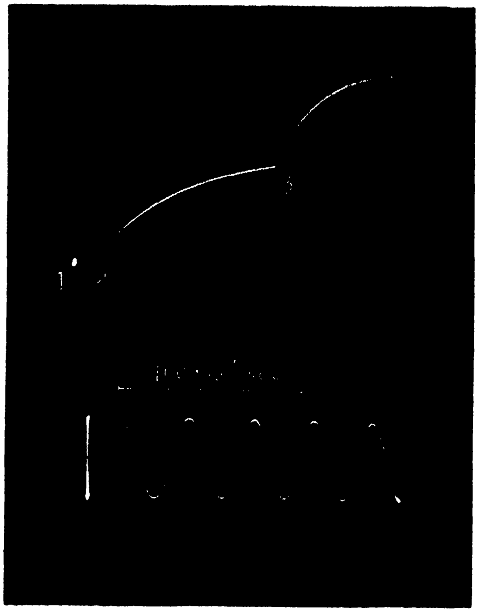

FIG. 2. A typical record obtained from the breaking of a tensile specimen like that shown in Fig. 1. The numbers 1, 2, and 3 designate the positions of the electron beam at the instants of breaking of wires 1, 2, and 3, respectively.

TABLE I. Speed of propagation of brittle crack.

| Testing machine | Specimen number | Wire numbers | Distance inches | Average velocity inches/second |
|---|---|---|---|---|

| NBS | G-5 | 3–4 | 1.00 | 41,200 |
|  | C-5 | 4–5 | 0.99 | 33,000 |
|  | C-5 | 5–6 | 0.98 | 41,000 |

Average of above velocities = 40,400 ± 2500 in./sec.

---

† These specimens were actually tested in two different types of machines; one is a Baldwin Southwark hydraulic type with a 600,000 lb. capacity located at the David Taylor Model Basin, USN, Washington, D. C., and the other, an Olsen screw type with a 600,000 lb. capacity, located at the National Bureau of Standards, Washington, D. C.

but also insulated the wire from the specimen. The ends of the wires which protruded from the cement were insulated from the specimen by strips of paper stuck to the specimen partly by the de Khotinsky cement and partly by Scotch Tape. After cooling the specimen, the ends of the wires were then soldered to binding posts on Bakelite strips. These were held by rubber bands to the specimen about two inches on either side of the path of the crack.

When a crack is propagated from the base of the saw cut, it breaks the fine wires in succession. The breaking of the first wire is used to start a single horizontal sweep of the electron beam on the screen of a cathode-ray oscillograph. Each of the succeeding wires, on breaking, introduces a voltage step on the vertical deflection plates by means of a simple voltage divider arrangement. The resulting staircase-like record may be photographed, e.g., see Fig. 2. The rounding off of the successive steps is caused by the impedance of the circuit used. A calibration wave for timing is provided by a standard oscillator. See Fig. 2.

The average velocity of the crack between any two successive wires is calculated by dividing the measured distance between them by the corresponding time interval measured from the oscillograph record.

Table I gives the final results. Column 1 states where the specimen was tested, i.e., either at the Taylor Model Basin or at the National Bureau of Standards. Column 2 is the specimen number. Columns 3 and 4 give, respectively, the numbers of the 1-mil Nichrome wires between which the speed was measured, and the distance between those wires. For example, Specimen F-3 had six (6) 1-mil Nichrome wires cemented to it. The breaking of the first wire started the single sweep across the c.r.o. screen. Then there were signal wires 2 through 6 spaced as indicated in column 4. Column 5 gives the average velocity for the corresponding distance listed in column 4.

The average of all the velocities listed in column 5 is 40,400 in./sec. with a mean absolute deviation of 2500 in./sec.

It is intended to continue this work to learn whether there is a significant variation of the velocity of the brittle crack with the thickness of the steel plate, its temperature, and its composition.

# Use of the Broadcast Band in Geologic Mapping*

LARKIN KERWIN**
*Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received December 4, 1946)

A review of the literature indicates that a method of geologic mapping by means of observing the effect of geologic anomalies on electromagnetic field intensity should be practical. Field equipment is designed and assembled for that purpose and proves accurate and simple to use. Preliminary investigations with it successfully locate several anomalies.

## INTRODUCTION

THE practicability of using high frequency electromagnetic waves in sub-surface geologic investigation is generally viewed as dubious. Joyce's theoretical conclusions from Maxwell's work[1] promise great attenuation under the assumed conditions. Eve,[2] Terman,[3] and Ollendorf support these considerations. However King predicted less attenuation, while Fritsch[4] declares that theoretical assumptions are never justified in practice and suggests that practical procedures are quite possible.

Relatively few experimental investigations

---

* This paper is based on a portion of a thesis entitled "The Development of Field Equipment Suitable for Measuring the Significant Properties of the Earth and Their Effect on Electromagnetic Wave Propagation," submitted for credits towards the degree of Master of Science at M.I.T. Financial support for the work was provided through a grant from The Geological Society of America, which is hereby gratefully acknowledged.

have been undertaken and these are inconclusive. Potter and Friis[5] determined that ordinary topographic variations did not have great effects on high frequency field intensities. On the other hand, Cloos,[6] Howell,[7] and Fritsch[8] found that field intensities did vary with the sub-surface geology. Joyce, Eve,[9] Allen, and Silverman and Sheffet[10] worked qualitatively in mines or tunnels and found in general that broadcast frequencies often penetrate the ground for considerable distances, but that higher frequencies were quickly absorbed. Joyce also did some quantitative work at 500 cycles, but it is highly doubtful if this frequency justified the use of electromagnetic wave theory in considering the results. The effect was undoubtedly a simple inductive one in view of the tremendous wave-length. Fritsch[11, 12] lists many interesting results of successful underground propagation.

These results and others indicated that the effect of geology on the field intensity of electromagnetic waves might provide a useful method of geologic mapping. The Geologic Society of America provided a grant for the purpose of developing equipment, and preliminary results obtained with it last summer indicate that the band from 200 kc to 1000 kc will prove useful in future work.

It was decided that the investigation of the field patterns of various frequencies over the same area would provide useful information. Geologic anomalies would cause irregularities in the pattern which would vary with frequency according to the penetrating power of the various wave-lengths. Equipment was purchased and adapted or constructed to produce, monitor, and measure suitable electromagnetic fields.

## EQUIPMENT

The field intensity recorder was assembled inside a wooden-bodied station wagon supplied by the Geotechnical Corporation. Its basic component was a modified Model DAE radio direction finder. The antenna consisted of a 14-inch shielded loop, mounted in a stationary cylinder provided with azimuth scale and commutator rings connected to a shielded lead. This loop was mounted on a spring tripod which was bolted to the floor of the station wagon. This mount was firm, but protected the loop from the shocks produced by the car's motion.

The associated receiver was mounted on a small oak table, directly in front of the operator's seat. This unit was of the superheterodyne type, covering the frequency range 240 kc to 2000 kc in three bands. It was provided with volume control, antenna tuning, and beat frequency oscillator, which made the receiving of unmodulated signals considerably easier. The case was provided with shock mounts screwed to the reinforced table top. In this unit the field produced a proportionate I.F. voltage, and that of the 2nd I.F. stage was selected as the most satisfactory for recording purposes. It was tapped to a jack on the panel, the signal from which was then proportional to the field strength, but could be controlled by the volume control circuit.

This voltage was measured by a vacuum-tube voltmeter of the "Vomax" type, installed immediately above the receiver on shock mounts attached to the latter's case. Sponge rubber pads were glued to the roof of the wagon and the voltmeter as added protection. For continuous recording, an Esterline-Angus recording milliammeter was used, having speeds up to six inches per minute. It was connected into the voltmeter circuit *via* a jack mounted on the meter face. By using this system throughout, any component could be removed for alteration or replacement without necessitating a rewiring job each time. For transportation and moderate speeds of recording the meter was mounted in sponge rubber padded clamps on a shelf under the table. Here it was easily available for inking, marking the chart, etc. The needle was weighed somewhat more than usual, and it was found that it would not jump from the paper if the car was driven at low speeds. For continuous operation at high speeds, a low frequency spring suspension should be used.

All of these units were operated with 110-volt, 60-cycle power. In the mobile unit this was provided by a Janette rotary converter operated by storage batteries. This produced a steady voltage at about 200 watts and operated silently. When well charged, the batteries provided 24 volts to operate the equipment for about 8 hours, more than a normal day's field work. A battery charger was mounted underneath the operator's seat and connected so that after the day's operations a long power cable could be connected to any convenient 110-volt outlet and the batteries charged overnight. This system proved completely satisfactory. A constant-voltage transformer proved useful for last-minute work at the day's end, in case the batteries began weakening. A general view of the equipment in the station wagon is given in Fig. 1.

It was intended that frequency ranges from 200 kc and up should be investigated. For preliminary work the broadcast band seemed suitable, and first field runs were made by recording the fields of various commercial transmitters as described later. For easily controllable work and for greater frequency range, a compact 75-watt transmitter was obtained. Known as the BC-375-E in the U. S. Army Signal Corps for whom it was designed, this transmitter provided continuously variable frequencies from 200 kc to 500 kc and from 1500 kc to 12,500 kc by means of six plug-in tuning units. This transmitter was designed to operate from 24-volt d.c. supply; plate voltages, etc., being supplied by a dynamotor. This supply provided approximately 750 watts. For portable operation battery operation was indicated, but was impractical because of the heavy drain of about 30 amperes. Accordingly, after some search a small gasoline driven generator was obtained which provided the required power, and delivered it through a number of "floating" storage batteries. This provided a smooth d.c. supply of about 28 volts for which the transmitter was easily modified.

During the process of taking field intensity measurements over various ground conditions, it was possible that the electromagnetic field would undergo certain variations independent of the geology. Fluctuations at the transmitter, atmospheric changes, the time of day at which readings were taken, etc. all contributed to fluctuation. It was therefore necessary to provide a stationary monitoring field intensity meter which would keep a record of these changes. The fact that relative field strengths and not absolute measurements were required simplified matters somewhat. A Hallicrafters Model SX-28 all-band receiver was obtained and provided with a simple fixed antenna. A vacuum-tube voltmeter was connected into the a.v.c. circuit of the receiver. Thus by the adjustment of the r-f amplifier amplitude and the use of a suitable voltmeter scale, a convenient deflection was obtained. This followed accurately the variations in field intensity. In order to obtain a continuous record of these changes, an Esterline Angus recording milliammeter was placed in the voltmeter circuit. This meter was adjusted to record at the rate of 1 foot per hour, which provided a satisfactory record of field strength changes without noting any minor fluctuations.

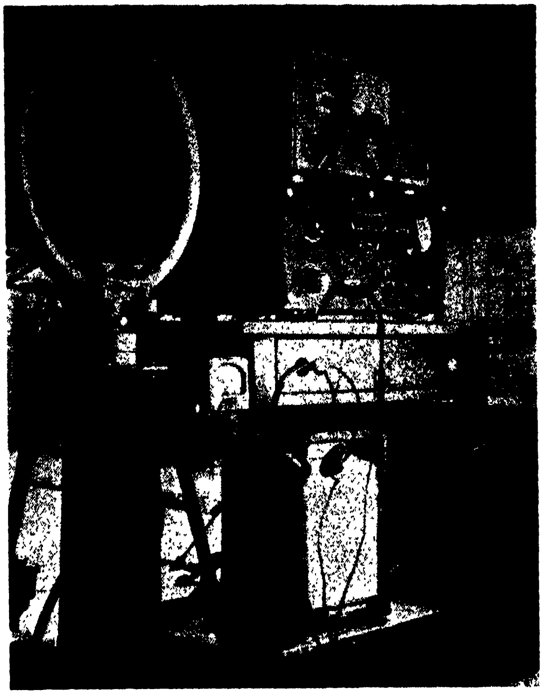

FIG. 1. Field intensity recording equipment mounted in station wagon.

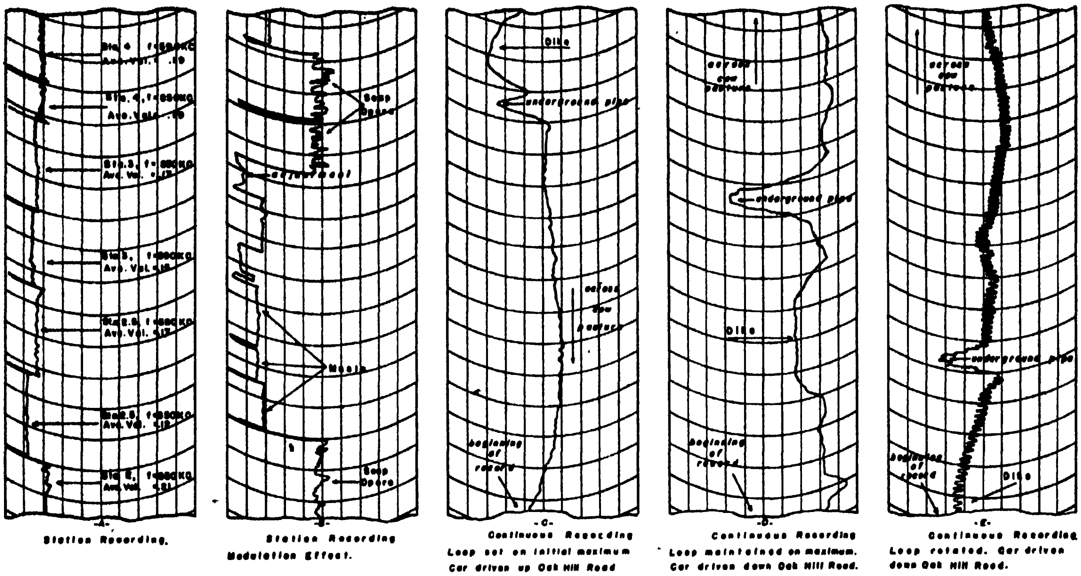
All of this equipment operated from 110-volt, 60-cycle current which was usually available near the scene of operations, or could be provided by a small motor generator.

In the course of the field work which was



-A- Station Recording.

-E- Continuous Recording Loop rotated. Car driven down Oak Hill Road.

FIG. 2. Field intensity recordings (taken from recording meter chart).

extended over several weeks, the station wagon was driven over all kinds of roads, and a complete gamut of speeds. The equipment and mountings were thus subjected to a most thorough testing, and after a few adjustments following the first couple of days' experience, the apparatus proved entirely field-worthy. The only precaution taken was to remove the recording

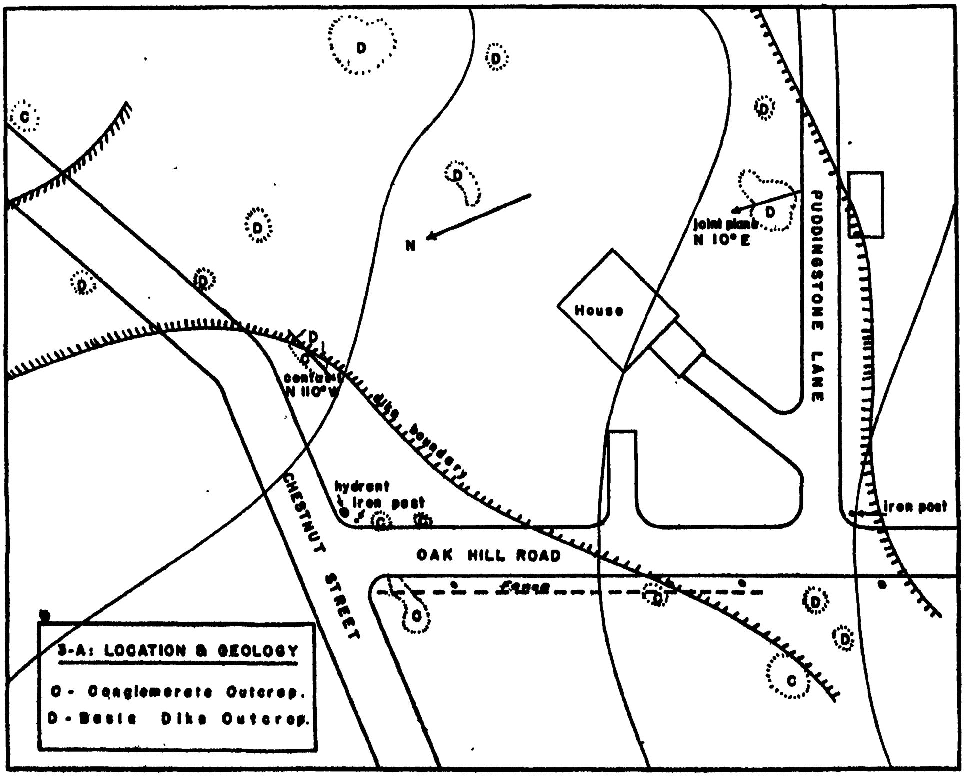

FIG. 3a. Area location and geology.

milliammeter needle if it was intended to proceed over rough ground at high speed. At low speeds it recorded satisfactorily. On this score, it is believed that future equipment patterned after this will provide a simple and rugged tool for the investigator.

### FIELD PROCEDURE

For preliminary work, a dike situated in Newton, Massachusetts was selected as a suitable testing ground. This dike had been roughly located during a survey by Mr. Blumberg of Harvard, who kindly lent some of his field maps to this project. An extension of basic melophyre was found protruding through the roxbury conglomerate which was characteristic of the area. The contrast in the physical properties of these rocks is considerable, making them quite suitable for the purpose in hand.

The district was suburban, with considerable vegetation and the houses widely separated. Some time was spent in examining the geology in order to locate the dike factually if possible. In Fig. 3a the dike location based on surface geology is indicated.

Field intensity measurements were then made under a variety of conditions. First, detailed runs were made by taking field intensity records of about five minutes duration at points about twenty-five feet apart along the road. In each case the location of the loop and its orientation were established by taping and bearings taken with a Brunton-type pocket transit. The latter readings were taken from two directions and at some distance from the station wagon, eliminating the latter's effect on the compass. The bearings so taken were all consistent with those established from surveyed maps.

The duration of the five-minute reading was important in order to achieve an averaging effect. An example of the readings obtained over several stations as taken from the field chart is given in Fig. 2a. One of the disadvantages of using the broadcast band with the present equipment here became apparent. The modulating voltage had some effect on the instantaneous readings, although not the average. Therefore readings extending over some period of time were necessary to obtain accurate values. The type of program being broadcast also has an effect, as the modulation of musical programs is much

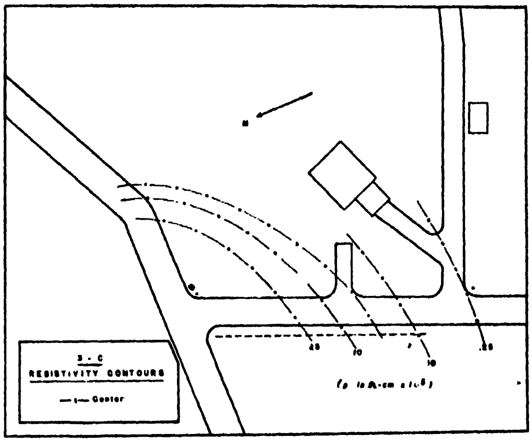

FIG. 3c. Resistivity contours.

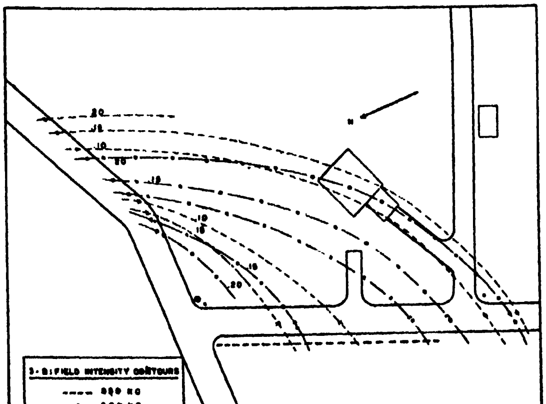

FIG. 3b. Field intensity contours.

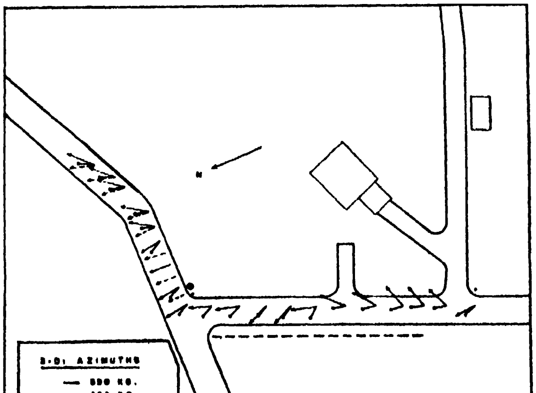

FIG. 3d. Field intensity azimuths.

smoother than those of the "soap-opera" type, and gave records which were much easier to interpret. An example is shown in Fig. 2b. These difficulties are avoided when using the unmodulated wave of the local transmitter.

The procedure was repeated several times, for several frequencies. Records were also made in the sunshine, rain, under dull clouds, and at night.

In addition to this, several types of continuous recording were investigated. By keeping the loop in a constant position of initial maximum strength and driving the station wagon slowly over the area, a figure such as that shown in Fig. 2c was recorded. This shows the prominent features which are marked. Other runs were made by keeping the loop manually oriented as much as possible in the direction of maximum intensity. The result is shown in Fig. 2d, where it is seen to bear close resemblance to the former record. Note that runs were made in varying directions and must be properly interpreted as to orientation. Continuously rotating the loop so as to produce an average effect gave a record such as shown in Fig. 2e, which follows the same general pattern as before.

A series of resistivity measurements was also made in the area in order to determine whether any relation existed between resistivity and field intensity. These measurements were made by inserting four metal stakes into the ground about twenty-five feet apart along the line of measurement. 150 volts, 60 cycle, as supplied by the small motor generator in the station wagon were applied between the two outer stakes. By measurements taken of the resistance between them the current put into the ground could be calculated. The voltage drop between the two inner stakes was then measured with a vacuum-tube voltmeter, and from these readings the resistivity was calculated.[13] By advancing the rear stake and changing terminals, successive readings were quickly taken. In this manner the resistivity was measured along the same direction as that in which the field intensity was recorded.

From the accumulated data, field intensity contours were drawn on the field map, and are shown in Fig. 3b. We see that the contours follow closely the direction of the dike as determined by the surface geology. Resistivity contours were also determined and are shown in Fig. 3c, where they assume the same general pattern as the other figures. The resistivity of the dike is substantially lower than the conglomerate, and as would be expected, the field intensity above the dike was also lower.

Azimuths of maximum field intensity are given in Fig. 3d, but they do not appear to convey any conclusive information. Over the dike, on Oak Hill Road, they seem to orient more towards the North than at other places.

Certain characteristics of the graphs drawn from the accumulated data are of some interest. It was observed that data taken at night showed considerably less variation than that taken by day. Measurements of low frequencies showed greater disturbance over the dike than did those of higher frequencies. Data taken during rainy weather showed the fields to be in general stronger and less affected by geology. Low intensities over the dike pointed to its higher conductivity, as was verified by resistivity measurements. The low frequency irregularities were more widespread than the others, indicating that the ground anomaly was more than a surface effect. To some extent here, and more so in urban areas later investigated, the effects of manholes, steel rails, etc. were quite obvious and easily detected.

Besides the detailed investigations in this area, other districts were investigated, using both stationary and rotating loop techniques. In the more urban area of Hammond Street, Brookline, a similar dibase dike protruding through the conglomerate was located by this method, and its presence verified by an examination of the surface geology. The boundaries of the dike were fairly sharply recorded as the field weakened over it. In Medford there is a noted extrusion of Medford dibase through Lynn volcanic complex. In this instance the resistivity of the dike is higher than the surrounding rocks, and the field intensity increased over it.

It was also observed that topography appeared to have relatively little effect. In driving over stretches of country in Arlington where the geology was uniform, the field remained essen-

---

[13] C. A. Heiland, *Geophysical Exploration* (Prentice-Hall, Inc., New York, 1940), p. 709.

tially constant except for manhole effects, etc., whether the receiver was passing over rolling hills, proceeding through cuttings, or on level ground. A notable exception was observed on the top of Pine Hill, a prominence beside the Medford Dike and very close to the transmitting antenna of the broadcast station being recorded. At the top of the hill the signal was extremely strong, but it weakened considerably as the bulk of the mountain was interposed sharply between the receiver and transmitter.

For most of these field measurements the field itself remained very constant, as shown by the monitoring station. Variations were observed between daytime and nighttime records, and with weather; but over considerable periods (3-4 hours) if the weather and daylight conditions were constant the field remained quite steady.

In general it is considered that the results obtained thus far show sufficient promise to warrant a continuation of the research. The equipment has proven sufficiently rugged, sensitive and simple to operate over long periods of field measurements. The cost of operation involves only the depreciation of equipment, and station wagon expenses. The method of field intensity recording has been used to locate a geologic anomaly as determined by other independent means, and has generally located other geologic features. Accordingly, further work on the subject is being done.

## MODIFICATIONS

In light of past experience, several modifications are recommended for the equipment, and will be incorporated into it shortly. The portable transmitter will provide a much more satisfactory field from the point of view of modulation as well as that of situation and pattern. For continuous recording, the milliammeter is being equipped with speedometer drive. This will permit operation by one person rather than the operator and driver previously necessary. The loop antenna is being supplemented by a vertical antenna, the two being interchangeable by means of a switch. This will eliminate the necessity of rotating the loop when azimuths are not being taken. A switching system in the charging circuit will make that operation somewhat more convenient to perform. The monitoring unit is being made self-sufficient by powering it with another rotary converter operating from 12 volts d.c. The SX-28 Hallicrafters receiver is being replaced by a smaller, more portable one.

Considerable attention is being devoted to frequencies below the broadcast band, as field experience here supports the general theory that low frequencies are more suitable. Experiments will also be performed on bands above the broadcast, up to about 12,000 kc.

## ACKNOWLEDGMENT

The writer expresses his sincere personal appreciation to Dr. R. F. Beers of the Geological Society of America and the Geotechnical Corporation; and to Dr. W. B. Nottingham of the Institute Department of Physics for their unstinted and practical assistance as well as moral encouragement.

# A Note on a Paper by Faust and Beck

WILLIAM M. STONE
*Iowa State College, Ames, Iowa*

(Received October 31, 1946)

An infinite sum transformation is defined and applied to a system of linear difference equations discussed by Faust and Beck in their paper on single tuned amplifiers. Some transforms of the more common functions are given and points of superiority of the transform method over the classical methods of solution of difference equations are emphasized.

---

IN their paper, "Oscillation Conditions in Single Tuned Amplifiers,"[1] Faust and Beck solved a simultaneous set of two first-order difference equations by classical methods. The purpose of this paper is to introduce the Generalized Laplace Transformation of Samuelson[2] and to illustrate its application to the same problem in circuit analysis. The advantages are that (1) a difference system is reduced to an algebraic system, (2) there are no extraneous constants introduced, and (3) no assumptions need be made as to the nature of the solution.

The generalized Laplace transformation is defined as

$$L\{F(k)\}_E = f(s) = \sum_0 F(n)s^{-n-1}, \tag{1}$$

where $F(k)$ must be of exponential order, $F(k) < M\alpha^k$, $k > K$, and defined for all positive integral values of $k$. The series is then uniformly convergent for all values of $s > \alpha$. The subscript refers to the shifting operator, $E^m F(k) = F(k+m)$, and serves to distinguish the generalized Laplace transformation from the ordinary case. Some transforms may be found by elementary summation but a more powerful method is readily available. By definition of the $E$ operator

$$\begin{aligned} L\{E\cdot F(k)\}_E &= \sum_0^\infty F(n+1)s^{-n-1}, \\ &= s[F(0)s^{-1} + F(1)s^{-2} + \cdots] - F(0), \\ &= sf(s) - F(0), \end{aligned} \tag{2}$$

which may be generalized at once by mathematical induction to the form

$$L\{E^m \cdot F(k)\}_E = s^m f(s) - \sum_{j=0}^{m-1} s^{m-1-j} F(j). \tag{3}$$

Following is a list of some of the more useful transform pairs:

| $F(k)$ | $f(s)$ |
|---|---|
| $1$ | $1/(s-1)$ |
| $a^k \cos wk$ | $\dfrac{s - a\cos w}{s^2 - 2as\cos w + a^2}$ |
| $a^k \sin wk$ | $\dfrac{a\sin w}{s^2 - 2as\cos w + a^2}$ |
| $a^k \cosh wk$ | $\dfrac{s - as\cosh w}{s^2 - 2as\cosh w + a^2}$ |
| $a^k \sinh wk$ | $\dfrac{a\sinh w}{s^2 - 2as\cosh w + a^2}$ |
| $a^k k^{(n)}$ | $a^n n!/(s-a)^{n+1}.$ |

Here $k^{(n)}$ means the Newton factorial polynomial, $k(k-1)(k-2)\cdots(k-n+1)$.

Using capital letters for the object function, small letters for the transforms, Faust and Beck's equations for voltage and current may be written as

$$E(k+1) - E(k) - Z_1 I(k) = 0, \tag{4}$$

$$E(k+1) + g_m Z_2 E(k) - Z_2 I(k+1) + Z_2 I(k) = 0. \tag{5}$$

By means of (2) these may be transformed at once to an algebraic system:

$$(s-1)e(s) - Z_1 i(s) = E(0), \tag{6}$$

$$(s + g_m Z_2)e(s) - Z_2(s-1)i(s) = E(0) - I(0)Z_2. \tag{7}$$

---

[1] Faust and Beck, J. App. Phys. 17, 749 (1946).

[2] Samuelson, Bull. Am. Math. Soc., Abstract 52-3-86 (1946).

The solution of this system is found to be

$$e(s)=\frac{E(0)\left[s-\left(1+\frac{Z_1}{2Z_2}\right)\right]+I(0)Z_1-E(0)\frac{Z_1}{2Z_2}}{s^2-2s\left(1+\frac{Z_1}{2Z_2}\right)+1-g_mZ_1},\tag{8}$$

$$i(s)=\frac{I(0)\left[s-\left(1-\frac{E(0)}{I(0)Z_2}\right)\right]+E(0)g_m}{s^2-2s\left(1+\frac{Z_1}{2Z_2}\right)+1-g_mZ_1}.\tag{9}$$

Substitute

$$a=(1-g_mZ_1)^{\frac{1}{2}},\quad \cosh w=\frac{1+\frac{Z_1}{2Z_2}}{a},\quad \sinh w=\frac{\left[\frac{Z_1}{Z_2}+\left(\frac{Z_1}{2Z_2}\right)^2+g_mZ_1\right]^{\frac{1}{2}}}{a},$$

$$=A/a,\qquad\qquad =B/a,$$

so that

$$e(s)=\frac{E(0)(s-A)+I(0)Z_1-E(0)\frac{Z_1}{2Z_2}}{s^2-2As+a^2},\tag{10}$$

$$i(s)=\frac{I(0)\left[s-\left(1-\frac{E(0)}{I(0)Z_2}\right)\right]+E(0)g_m}{s^2-2As+a^2}.\tag{11}$$

Making the denominators conform with the list of transforms the object functions may be written as

$$E(k)=a^{k/2}\left[E(0)\cosh wk+\frac{I(0)Z_1-E(0)\frac{Z_1}{2Z_2}}{B}\sinh wk\right],\tag{12}$$

$$I(k)=a^{k/2}\left[I(0)\cosh wk+\frac{I(0)\frac{Z_1}{2Z_2}+\frac{E(0)}{Z_2}(1+g_mZ_2)}{B}\sinh wk\right].\tag{13}$$

The boundary conditions are

$$I(n)=0,\tag{14}$$

$$E(0)=E_{in}+Z_gI(0),\tag{15}$$

where $I(n)$ is the current in the last mesh, $E(0)$ is the voltage in the input stage, $E_{in}$ is the voltage of the input generator whose internal impedance is $Z_g$. Substitution of both conditions in (13) and algebraic reduction leads to

$$E(0)=E_{in}\frac{B\cosh wn+\dfrac{Z_1}{2Z_2}\sinh wn}{B\cosh wn+\left[\dfrac{Z_1}{2Z_2}+Z_0\left(\dfrac{1}{Z_2}+g_m\right)\right]\sinh wn}, \tag{16}$$

$$I(0)=-E_{in}\frac{\left(\dfrac{1}{Z_2}+g_m\right)\sinh wn}{B\cosh wn+\left[\dfrac{Z_1}{2Z_2}+Z_0\left(\dfrac{1}{Z_2}+g_m\right)\right]\sinh wn}. \tag{17}$$

In practice the gain off all $n$ stages is of most importance. If $Z_0$ is set equal to $Z_2$ as is customary the gain of the $n$ stages may be reduced to

$$\frac{E(n)}{E_{in}}=\frac{B(1-g_mZ_1)^{n/2}}{B\cosh wn+(A+g_mZ_2)\sinh wn}. \tag{18}$$

The well-known expansion formulas

$$\cosh wn=\sum_k\binom{n}{2k}(\cosh w)^{n-2k}(\sinh w)^{2k}, \tag{19}$$

$$\sinh wn=\sum_k\binom{n}{2k+1}(\cosh w)^{n-2k-1}(\sinh w)^{2k+1}, \tag{20}$$

where $\binom{n}{2k}$ represents the binomial coefficients as $k$ takes on the values 0, 1, 2, ..., lead to the form of (18)

$$\frac{E(n)}{E_{in}}=\frac{(1-g_mZ_1)^n}{\sum_k\binom{n+1}{2k+1}A^{n-2k}B^{2k}+g_mZ_2\sum_k\binom{n}{2k+1}A^{n-2k-1}B^{2k}}, \tag{21}$$

which is equivalent to the general formula for the gain given by Faust and Beck.

# Internal Friction of Zinc Single Crystals*

IRVIN H. SWIFT†** AND JOHN E. RICHARDSON***
*Department of Physics, The State University of Iowa, Iowa City, Iowa*

(Received December 24, 1946)

**Measurements were made of the internal friction of single crystal rods when vibrating longitudinally at 45 kilocycles per second. The decrement, or ratio of energy dissipated per cycle to twice the total vibrational energy, was used as a measure of the internal friction. At strain amplitudes below about $10^{-5}$ or $10^{-6}$ the decrement was independent of strain amplitude. The value of the constant decrement at low amplitudes, and the changes which occurred as the amplitude was increased, were both greatly dependent on the history of the specimen. The constant decrement for different crystals ranged from $7\times 10^{-6}$ to values higher than could be measured (about $200\times 10^{-6}$). For some of the initially high-decrement crystals, values decreased with time (room temperature anneal). In general, for annealed crystals the decrement, measured as a function of increasing strain amplitude, remained almost constant up to and beyond the static elastic limit and then rose rapidly. It returned to the initial value when the strain amplitude was again reduced. On a second run, however, the rise in decrement occurred at much lower amplitude than on the initial one. It is concluded that the decrement is the result of two separate processes. The changing decrement at higher strain amplitudes is qualitatively explained with the use of dislocation theory.**

## INTRODUCTION

THE internal friction of single crystals of exceedingly pure zinc has been measured by Read,[1] and of less pure zinc by Read and Tyndall.[2] The decrement, which is the ratio of the energy dissipated per cycle to twice the total vibrational energy, was taken as a measure of the internal friction. Read found the decrement to be dependent on the past history of the specimen, strain or stress amplitude at which it was measured, time, etc. For the purer zinc decrements of the order of $10^{-5}$ were found at the lowest strain amplitudes but these, for most of the crystals, increased many fold with increasing amplitude. The present work consists of further observations of the behavior of the decrement of longitudinally oscillating zinc crystals under various circumstances and with partially controlled history.

## EXPERIMENTAL METHOD

The zinc[3] used in this investigation was slightly less pure than that used by Read.[1] The crystals were grown by the Bridgman method in which a small casting is lowered through a furnace. The majority of the crystals were grown with the casting imbedded in dental investment compound and the rest were grown in the glass tube in which the original casting was made. The dental investment compound was easily softened by water after the crystals were grown and could then be removed with little danger of straining the crystals. The crystals had a cross-sectional area of 9 sq. mm and had fairly smooth surfaces.

The decrements were measured by essentially the same method as that used by Read[4] in which a composite oscillator is constructed by cementing to a quartz crystal a zinc crystal of the same cross-sectional area and cut with a fine jeweler's saw to a length such that the composite oscillator resonates at a frequency within less than 4 percent of the resonant frequency of the quartz crystal. The resonant frequency of the quartz crystal used in the present work was 45 kilocycles when vibrating longitudinally in the fundamental mode. The composite oscillator was suspended by silk fibers placed at displacement nodes of vibration between, but not touching, parallel plane electrodes. The assembly was then placed in a jar and the jar evacuated to a pressure of less than

[3] The zinc used was "Bunker Hill," a commercial zinc with not more than 0.01 percent impurity. Read and Tyndall (reference 2) report data from three crystals grown from this same zinc and two with additional impurity.

[4] The writers are indebted to Dr. Read for information about his bridge circuit, etc., in addition to that in reference 1.

0.1 mm of mercury. The quartz crystal was etched with hydroflouric acid before using and had a decrement of $2.7\times 10^{-6}$.

The electrical apparatus consisted of an alternating-current bridge containing the composite oscillator as one arm and driven by a stable 35–100 kc oscillator. The detector used with the bridge consisted of an r-f amplifier, pentagrid converter, and associated oscillator which changed the high frequency signal from the bridge to an audible signal, and several stages of audio amplification. Its sensitivity with headphones was greater than that needed in any of the measurements. Either a vacuum thermocouple or a vacuum tube voltmeter were used to measure the voltage $\epsilon$ applied to the composite oscillator. The maximum strain amplitude, $U_0$, in the zinc specimen was then computed from the following formula:[5]

$$U_0=\frac{2\epsilon}{RV_0}(10K)^{\frac{1}{2}}\times 10^3, \tag{1}$$

where $R$ is the electrical resistance of the composite oscillator at resonance, $V_0$ is the velocity of sound in the zinc specimen, and $K$ is the constant relating the inductance $L$ of the composite oscillator and the masses $M_1$ and $M_2$ of the cylinders in the equation:

$$L=K(M_1+M_2). \tag{2}$$

The subscripts 1 and 2 in Eqs. (1) and (2) refer to the quartz and specimen, respectively.

The decrements of the zinc crystals were obtained from a knowledge of the inductance in the equivalent circuit, the resistance measured by the bridge, the resonant frequency of the composite oscillator, and the masses of the quartz and specimen. The constant $K$ was evaluated with Eq. (11) in a paper by Cooke[6] and Eq. (2), from the observed variation of the reactance of the quartz crystal alone with frequency in the immediate neighborhood of the resonance frequency. It was determined to an accuracy of 1.5 percent. The accurate measurement of changes in frequency required in the plotting of the resonance curve was obtained as follows. The crystal controlled multivibrators of a piezoelectric frequency standard were adjusted in frequency until a harmonic of one of them was within about 50 cycles of the resonance frequency of the quartz crystal. The difference frequency obtained from this reference frequency and the frequency of the oscillator driving the bridge was amplified and used to drive a Cenco counter. The number of counts per second was then equal to the deviation of the unknown frequency from the crystal controlled reference frequency.

## EXPERIMENTAL RESULTS

Before describing the quantitative results, some qualitative observations may be of interest. It was noted that some of the crystals could be made to give a high pitched "ringing" sound when set into flexural oscillations by suspending them from the mid-point and tapping lightly. Later work showed that crystals for which this ringing was audible for 2 or 3 seconds had decrements of the order of $10^{-4}$ or less, whereas higher decrement crystals instead of ringing yielded a metallic or even wooden sound. A rough idea of the behavior of the decrement of a crystal could be obtained by subjecting it to this simple test. For example, eight crystals were tested just after they had been sawed to the desired length and then again after an anneal at 250°C for three hours. No noticeable difference was obtained at this time, but after storage at room temperature for several days a noticeable drop in the decrement, as judged by the increased time of ringing, was observed for some of the crystals while the rest showed little change. The crystals of the former class seemed to be persistent in their behavior. For example, crystal No. 1 (orientation 15°) would always return to a low decrement after two or three days' rest at room temperature without handling, regardless of its previous history. At one time when it was known to have a low decrement, it was accidently dropped onto the floor and bent considerably. It was then straightened by hand and left idle for several days after which it appeared to ring as well as ever. The data in Fig. 1 (curve $A$) and Fig. 8 (curve $A$) were taken on this crystal after it had rested nine days before it was mounted in the

---

[5] This formula is an obvious modification of formula (1), reference 2; for stress amplitude. It may be obtained by equating the expression for total energy in electrical terms to that in mechanical terms, and solving for $U_0$.

[6] W. T. Cooke, Phys. Rev. 50, 1158 (1936). Cooke's $K$ is eight times the $K$ used in Eq. (2).

apparatus and 7½ hours afterward. Other crystals behaved similarily although none of these were subjected to such drastic treatment. Crystals which did not develop a ring in a few days after growth did not do so after months of lying idle. Several crystals of this type were also annealed at 250°C and still did not develop a ring. These qualitative tests moreover showed very clearly how little handling was needed to increase the decrement. If a crystal which had a good ring was placed on a table and one end was elevated about a fourth of an inch and then dropped, the crystal thereafter would give only a metallic "clink" when tapped. In fact, while the crystals were being subjected to the ringing test, the gentle taps needed to set up the oscillations a few times would noticeably reduce the time of ringing. One or two days of rest at room temperature after the above treatment was however sufficient to restore the ringing properties of the crystals.

Nothing was found in the method of growth, amount of handling, etc., which gave any clue as to why some crystals had a low decrement while others had decrements which were too high to measure with the apparatus and which would not decrease with either a high or room temperature anneal. There was no apparent correlation of high and low decrement crystals with the degree of smoothness of their surfaces.

The writers observed, as did Read,[1] that the decrement measured at low amplitudes immediately after mounting in the apparatus was always much higher than after the crystal had been allowed to rest in the apparatus for some time undisturbed except for infrequent low amplitude measurements.[7] Two examples of this behavior are given in Fig. 1. Curves *A* and *B* are for two different crystals. The decrease in decrement with time after mounting was caused by, at least primarily, the self-annealing of the crystals at room temperature. Part of the decrease, particularly the initial rapid decrease, may have been caused by the drying of the cement between the specimen and the quartz. Calculations based on estimates of the thickness of the cement layer, etc., indicate, however, that the decrement of the cement would have to be as large as 100 to 1000 to cause the high decrements obtained. This seems improbable in view of the fact that the cement had dried for twenty or thirty minutes before the crystals were mounted. Also, Fig. 2 in Read's paper[1] shows a similar decrease of the decrement with time after mounting and his crystals were fastened to the quartz with beeswax and rosin which would show no drying effect.

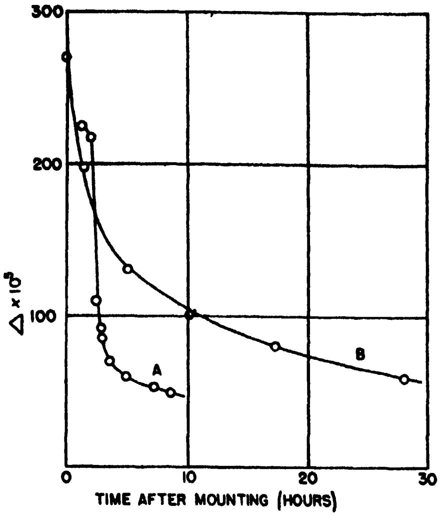

FIG. 1. Decrease of decrement with time after mounting, showing room temperature annealing. Curve *A* was taken on crystal No. 1.

Observations were made of the decrement as a function of maximum strain amplitude and time for thirteen crystals. It is not possible to present all of these data in full detail, but certain rather typical data are summarized and presented graphically. In Fig. 2 are shown curves of the decrement against strain amplitude for three crystals which had been allowed to rest in the apparatus for the following lengths of time: No. 2, two days; No. 3, three days; No. 4, thirty hours. In all cases the decrement had decreased to a nearly constant value before the data were taken. Crystal No. 4 (curve *C*) is particularly interesting as its decrement was practically constant to a value of maximum strain amplitude over five times that at the static elastic limit[2] (about $80 \times 10^{-7}$) for this crystal. Subsequent to the data in Fig. 2, crystal No. 4 was stored at room temperature for over six months. It was then remounted in the apparatus and the data

---

[7] The crystals of reference 2 made of the same zinc as the writers' did not show this decrease of decrement with time. These crystals however were of larger cross section than the writers' and the natural conclusion seems to be that they could be mounted without producing any detrimental strains.

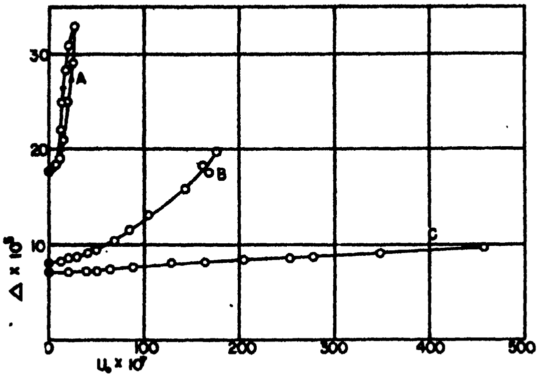

FIG. 2. Typical decrement *versus* maximum strain amplitude curves. Curve *A* was for crystal No. 2 $(\theta = 71^\circ)$; curve *B* was for crystal No. 3 $(\theta = 71^\circ)$; and curve *C* was for crystal No. 4 $(\theta = 70^\circ)$.

shown in Fig. 3 were taken. The decrement had been allowed to reach a fairly constant value after mounting before the data were taken. The time given with each curve is the elapsed time after the taking of the first curve. The decrement was measured for increasing and then decreasing strain amplitude, as shown by the arrows. The decrement at the lowest strain amplitude decreased from $95\times10^{-5}$ to $70\times10^{-5}$ in the course of 143 hours, but did not come down to the previously measured value of $7.0\times10^{-5}$ (Fig. 2). It may be seen from the lower branch of each of the curves shown in Fig. 3 that the strain amplitude required to increase the decrement by some amount, say 50 percent, increases considerably with elapsed time. In curve *J* the maximum strain amplitude was at the static elastic limit $(80\times10^{-7})$ before the decrement started to increase very rapidly. Where two curves were taken with little intervening time, such as *B* and *C*, *G* and *H*, and *I* and *J*, the ascending branch of the second curve of a pair was nearly identical to the descending branch of the previous curve. After these data were taken, the crystal was removed from the apparatus and allowed to rest for 20 days. It was then remounted in the apparatus and left idle for seven days after which the data shown in curve *B*, Fig. 4, were obtained. The decrement in this curve shows only a gradual rise to a strain amplitude nearly three times that at the elastic limit. The decrement at low strain amplitude is still however about nine times as large as the first previously measured value (curve *C*, Fig. 2).

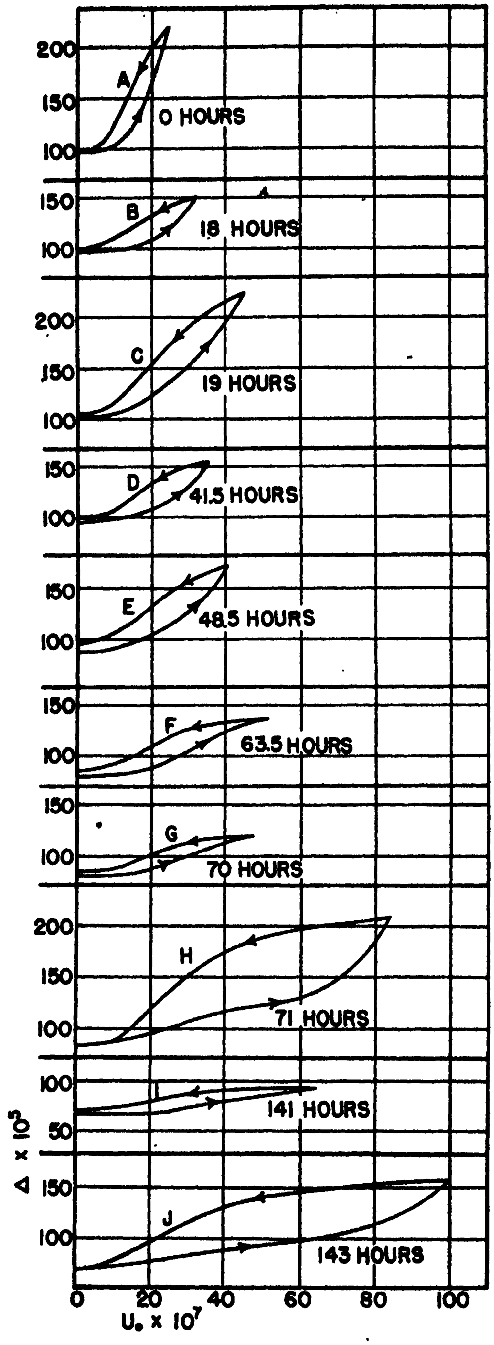

FIG. 3. Decrement *versus* maximum strain amplitude $U_0$ for crystal No. 4 $(\theta = 70^\circ)$. The time given by each curve is the elapsed time after the first curve was taken. These curves show the effect of self-annealing at room temperature.

The curves shown in Fig. 5 demonstrate very well the phenomenon mentioned in connection with Fig. 3. These curves were taken on crystal

No. 6 ($\theta = 56°$) which was known to be strained prior to mounting. Data were first taken to a strain amplitude of $50 \times 10^{-7}$ (curve 1) and the strain amplitude was then reduced to its lowest value. Curve 2 was then run to a strain amplitude of $80 \times 10^{-7}$, with curves 3 and 4 following in a similar fashion. From these curves it appears that previous runs affect subsequent runs only at strain amplitudes below the highest maximum strain amplitude obtained on the previous run. Thus, had the crystal been taken continuously from the minimum to the maximum strain amplitude ($94 \times 10^{-7}$), it would probably have followed the lowest curve, which is a smooth continuation of curve 1. Also, while descending curves are not shown, they coincide quite well with the next ascending curve, as previously pointed out in connection with Fig. 3.

The curves shown in Fig. 6 taken on crystal No. 5 (orientation 80°) illustrate some effects of room temperature annealing. The decrement of this crystal remained constant until a critical value of strain amplitude was obtained and then started to rise. As successive runs were taken, this critical value of strain amplitude increased. The data for curve *A* were taken soon after the crystal was mounted. Data for curve *B* were taken 53 hours after *A* was taken; and curve *C*, 98 hours after *B*. Other sets of data were taken on the crystal during these two periods and therefore they should not be considered strictly as rest periods. Finally the crystal refused to anneal any further at room temperature and data could be very nearly repeated on successive runs taken several days apart. These later curves were substantially identical to curve *C*, Fig. 6. At this point the crystal was annealed for several days at 260°C, mounted in the apparatus, and left idle for a week. The decrement then remained nearly constant for a range of stress amplitude 2½ times the value at the static elastic limit, as shown by curve *D*, Fig. 4. It will be noticed that after the high temperature anneal and remounting, the decrement at low strain amplitudes was higher than before the anneal (Fig. 6).

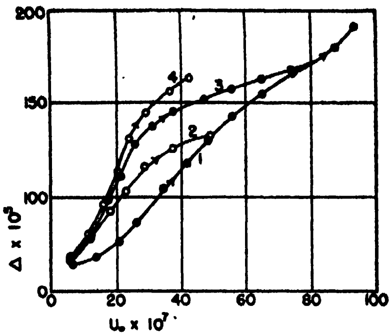

FIG. 5. Decrement *versus* maximum strain amplitude $U_0$ for crystal No. 6 ($\theta = 56°$), which was known to be strained before mounting in the apparatus. The curves are shown for increasing strain amplitude only and were taken in the order designated. They show that the decrement was influenced by previous runs only at strain amplitudes lower than the highest strain amplitude obtained on previous runs.

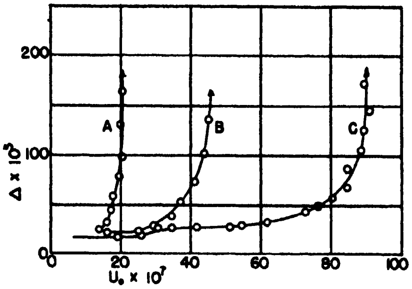

FIG. 6. Decrement *versus* maximum strain amplitude $U_0$ for crystal No. 5 ($\theta = 80°$). Curve *A* was taken soon after mounting, curve *B* 53 hours after *A*, and curve *C* 98 hours after *B*. Succeeding curves were very little different from curve *C*. As the crystal annealed at room temperature, the point of rise of the decrement occurred at higher strain amplitudes.

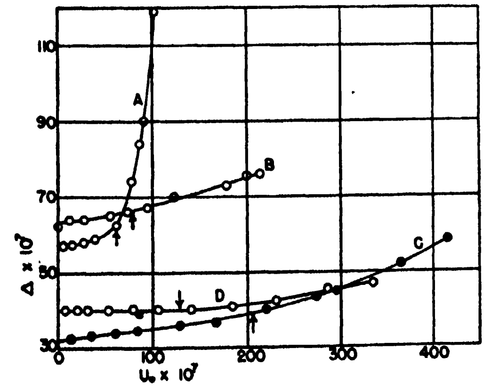

FIG. 4. Decrement *versus* maximum strain amplitude $U_0$ for crystals No. 9, 4, 10, and 5 corresponding to curves *A*, *B*, *C*, and *D*, respectively. All of these crystals had rested for a long period of time in the apparatus after mounting and before measurements were taken. The arrows on each curve designate the strain corresponding to the minimum static stress which will produce glide in the basal plane.

The two curves given in Fig. 7 indicate the diverse results that can be obtained when the conditions are very nearly the same. Curve *A* is

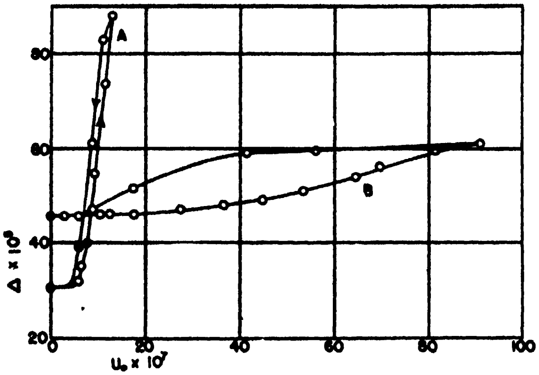

FIG. 7. Decrement *versus* maximum strain amplitude $U_0$. Curve $A$ was for crystal No. 7a and curve $B$ was for crystal No. 7b. Each of these two crystals were sections cut from one long 60° crystal.

for crystal No. 7a and curve $B$ is for No. 7b. These two crystals were sections cut from the same original 60° crystal and annealed for two hours at 250°C. Crystal No. 7a was mounted four days after the anneal and curve $A$ was taken after it had rested in the apparatus for one day. Crystal No. 7b was mounted eleven days after the anneal and curve $B$ was taken after it had rested in the apparatus for two days. Curve $A$ rises sharply at a low value of strain amplitude, while curve $B$ shows a constant decrement as the strain amplitude is increased to a value of six or seven times that at which curve $A$ starts to rise. The only known difference in the histories of the two crystals was in the time they were allowed to rest before and after mounting in the apparatus. Crystal No. 7b apparently had sufficient time to anneal at room temperature while No. 7a was still in a strained state. One other curve was taken on crystal No. 7b one day previous to curve $B$ (one day after mounting), and it was nearly identical to curve $B$ indicating that this crystal was in an annealed state (see discussion of Fig. 6).

Curve $A$ of Fig. 8 was taken on the crystal (crystal No. 1, orientation 15°) which was dropped, bent, and subsequently straightened, as mentioned earlier. After the above treatment it was left idle for five days and mounted in the apparatus. At this time its resonant frequency was found to be too low and it was necessary to cut it to a shorter length. Three days after the sawing operation it was remounted in the apparatus and left idle for about eight hours except for occasional measurements of the decrement at very low strain amplitudes (curve $A$, Fig. 1). The data for curve $A$, Fig. 8 were then taken. Curve $B$ represents data on crystal No. 8 (orientation 73°). It had rested for several days before mounting, and 34 hours after, before the data were taken. These two crystals had about the same resolved shear stress in the basal plane for a given tensile stress. The two curves are similar in form, indicating that crystal No. 1 had recovered fairly well from the severe strain given it.

The curves $A$, $B$, $C$, and $D$ in Fig. 4 are for crystals which had been allowed to rest for long periods of time in the apparatus after they were mounted. The histories of crystals No. 4 and No. 5 have been given earlier in this paper. Crystal No. 9 (orientation 50°) and crystal No. 10 (orientation 20°) were left idle in the apparatus for about the same periods of time as crystals No. 4 and No. 5. The decrement of three of the crystals rose slowly with strain amplitude for values of strain amplitude considerably greater than the value of the static elastic limit, while the decrement of the other crystal began to rise sharply at about the static elastic limit (curve $A$). This crystal (orientation 50°) probably was still in a strained state as crystals with orientations near 45° are much more easily strained than those with orientation angles near 0° or 90°.

When the voltage across the composite oscillator was suddenly changed from one constant value to another, the decrement took an appreciable time to change from the previous value

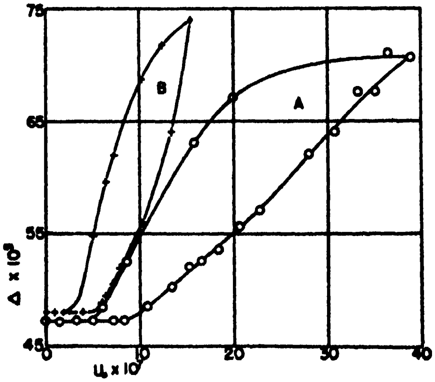

FIG. 8. Decrement *versus* maximum strain amplitude $U_0$. Curve $A$ was for crystal No. 1 and curve $B$ was for crystal No. 8.

to the final value at the new stress amplitude. The curves in Fig. 9 illustrate this effect. For curves 1 and 2 the voltage change was an increase while for the others the voltage was decreased. Usually when the voltage across the crystal was changed, a time of less than 20 seconds was required for the decrement to attain, say, 90 percent of its total change. In two of the curves of Fig. 9, however, the decrement required about a minute to attain 90 percent of its change. No attempt was made to fit these data with a mathematical function because the data were too inaccurate, particularly in the region where the decrement was changing rapidly with time. In addition there were other complicating factors. The strain amplitude is proportional to the current through the crystal and hence as the decrement (proportional to resistance, which determines the current) changed with time after the voltage across the crystal was changed to the new value, the strain amplitude was not constant during the time indicated in Fig. 9. Also, because of the low decrements involved, the time required for the strain amplitude to reach a steady state upon a change of the applied voltage from one value to another was large enough to make the effective zero of time uncertain.

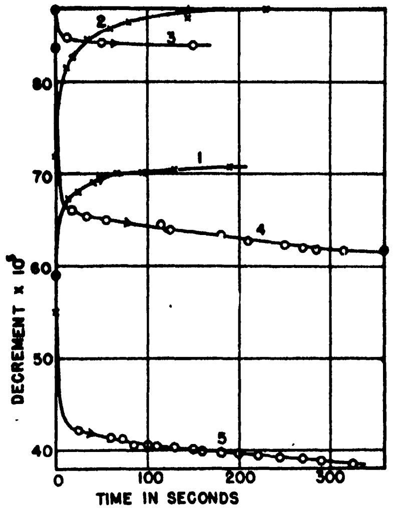

FIG. 9. Curves showing for crystal No. 7a the change in decrement with time following a sudden change of driving voltage across the composite piezoelectric oscillator. The curves were taken in the order designated by the numbers on each curve.

### DISCUSSION OF DATA

A number of points should be mentioned in regard to the measurements described above. These are:

(1) The decrement measured at low amplitude decreased with time after mounting in the apparatus, approaching a constant value (Fig. 1). The final value reached was not, however, unique, in that a crystal after a second mounting would show a decline in decrement to a constant value but not necessarily to the same value found in the first experiment.

(2) The decrement was independent of strain amplitude for all maximum strain amplitudes below a critical value of the order of $10^{-5}$ to $10^{-6}$ (the bridge detector was sufficiently sensitive to balance the bridge at strain amplitudes much lower than $10^{-7}$, probably $10^{-9}$). The value of the low amplitude decrement was, for a given mounting in the apparatus, affected only by time (as shown in Fig. 1).

(3) The value of the low amplitude decrement was higher for all crystals measured than for Read's[1] spectroscopically pure zinc crystals. The lowest decrements found were about the same as for those of crystals made of the same zinc, as reported by Read and Tyndall.[2] It does not follow, however, that the decrement is a function only of the amount of impurities present. Other factors are much more important as is shown by the data on crystal No. 4. In Fig. 2 it had a decrement of $7\times10^{-5}$ whereas after it had lain idle for six months and was remounted in the apparatus, the decrement at low amplitudes was $70\times10^{-5}$ (Fig. 3).

(4) The value of strain amplitude at which the decrement started to increase became greater with elapsed time following mounting in the apparatus, i.e., increased as the value of the low amplitude decrement decreased. This effect is illustrated in Figs. 3 and 6.

(5) If a crystal had been oscillated at a sufficient amplitude momentarily to increase the decrement, then on measurements made soon after, the decrement was larger at all strain amplitudes between the value at which the decrement started to rise and the highest value obtained on the previous run. The amount that a run influenced the decrement obtained on a succeeding run decreased with elapsed time between the runs. The effect of time between runs is

illustrated particularly well by Fig. 5 but is also evident from the series of curves in Fig. 3.

(6) The decrement lagged in time behind the oscillation amplitude when the amplitude was changed suddenly. It is apparent from these curves that a finite time was required for the decrement to reach a stable value after the oscillation amplitude was changed.

The shape of the curves of decrement *versus* strain amplitude suggests that the observed decrement was composed of a constant decrement plus an amount which varied with strain amplitude. The portion of the decrement (to be designated by decrement $A$) which was constant with strain amplitude was measured alone at small strain amplitudes. Decrement $B$ is that portion which was zero or negligible at zero strain amplitude and increased with increase of strain amplitude. It is possible on this basis to give a qualitative explanation of the behavior of the decrement in the experiments described above. The dislocation theory is used together with several assumptions to be listed later.

The dislocation theory[8] is based upon a certain type of local imperfection in the crystal lattice called a line dislocation. The local imperfection is concentrated about a line in a slip plane and is composed of such an arrangement of atoms that movement of the line imperfection through the crystal along a slip plane gives the same effect as if the material above the slip plane had been shifted a distance of one atomic spacing with respect to that below. The dislocations can be either positive or negative, one being complementary to the other in the sense that it is the mirror image of the other. A dislocation experiences a force in a shear stress field which reverses in sign with change in sign of the dislocation. Hence since a dislocation sets up a shear stress field of its own, dislocations of unlike sign are attracted to each other and those of like sign are repelled. Also a dislocation is attracted to the crystal surface by the force which would be given by an image dislocation of opposite sign outside of the surface. Dislocations can be formed in pairs in the interior of a crystal or singly at the surface as the result of shear stress.

In addition to the properties of dislocations summarized briefly above, the following assumptions will be used in the interpretation to be given for the results:

(a) The dislocations present as a result of previous low frequency, or "static" strains tend to form a stable lattice-like array within the crystal specimen.[8]

(b) The low amplitude decrement ($A$) is a function only of the total number of dislocations present at a given time in the specimen.

(c) The number of dislocations, if any, that are formed in the specimen as a result of the oscillating stress is a negligible fraction of the total number present. Presumably the short time during which stress was applied did not allow much opportunity for dislocations to form either pairwise in the interior, or at the surface.

(d) The value of decrement $B$ is a function of the number of dislocations present which are "free" to dissipate energy. Whenever a dislocation is held within a dislocation lattice it is assumed to mean that the dislocation is prevented, or at least restricted, from participation in the energy dissipation process.

A crystal which had been recently mounted in the measuring apparatus would be expected to be in a strained state as a result of handling during mounting. Hence there would be a large number of dislocations of both signs distributed throughout the crystal. With the aid of thermal fluctuations, the forces on and between dislocations would cause them to migrate. Some dislocations, particularly those near the surface, would diffuse out of the crystal, others would disappear by cancellation of positive and negative dislocations (if the pair was originally in the same slip plane), and the remaining ones would migrate to positions such that the crystal had a minimum of potential energy, i.e. they would arrange themselves in some sort of orderly pattern. After a long time the number of dislocations in the crystal would be essentially constant, all being held in the lattice. Under assumption (b), that decrement $A$ is a function only of the total number of dislocations present, the curves of Fig. 1 would follow. Furthermore, the final value reached by the decrement several days after

---

[8] A summary of the dislocation theory is given in the article by Frederick Seitz and T. A. Read, J. App. Phys. 12, 100 (1941). The forces between certain types of dislocations and other related matters are discussed in J. S. Koehler, Phys. Rev. 60, 397 (1941).

mounting would not be expected to be the same for a different mounting in the apparatus. Each mounting would entail a different kind and amount of the unavoidable strain, resulting in a different number and distribution of dislocations immediately thereafter. Hence the stable lattice reached would not be unique. This explains such data as that in Fig. 2 (crystal No. 4) where the low amplitude decrement was $7\times10^{-5}$ and later after the crystal was remounted the decrement was $70\times10^{-5}$, as shown in Fig. 3. The process by which energy is dissipated in an amount proportional to the total number of dislocations and independent of amplitude is difficult to determine without more detailed information. One possibility is that irreversible heat flow occurs as the result of oscillating stress in an elastically inhomogeneous medium. In this event, the dislocations would presumably provide the elastic inhomogeneity. Quantative calculations should show whether or not this possibility is reasonable.

Decrement $B$, a function of strain amplitude, could be interpreted according to the following picture. The dissipation represented by decrement $B$ would be assumed to be the result of movement of the dislocations. This movement would result in a plastic change in length of the specimen, with consequent loss of oscillation energy. The data could then be interpreted by assuming that the dislocations did not move appreciably when they were attached to the dislocation lattice and that they could be broken away from the lattice by the application of a sufficiently large stress. The amount of stress required would vary according to how tightly each dislocation was bound in the lattice. Hence as the oscillation amplitude was increased steadily from zero, more and more dislocations would be freed from the restraining influence of their neighbors and be made available to dissipate energy, with a consequent rise of the decrement. The decrement, during the subsequent decrease of amplitude would then be larger at a given amplitude than on the ascending curve because more dislocations would be free than before. Examples of this hysteresis-like effect are given in Figs. 2, 3, 5, 7, and 8. This picture, furthermore, would explain the effect shown in Figs. 3 and 5 in which an ascending branch of a curve was nearly identical to the descending branch of a curve taken soon before it. It would be due to the fact that the same number of dislocations were free to dissipate energy on both curves. The dislocations that had been freed from the dislocation lattice by the oscillating stress would, upon removal of the stress, gradually take either their old positions, or new positions in the lattice. This process would, however, take a finite time as thermal energies would be expected to be an important factor. The data given in Fig. 3 show how elapsed time after a run erases the effect of a previous run. Also, the increase of the point of rise of the decrement shown in Fig. 6 would be caused by the fact that as the crystal had more time to anneal, the dislocations which were loosely bound in the lattice would disappear from the crystal, leaving only those which were tightly bound and required a large stress to make them available to dissipate energy.

The number of dislocations that are freed from the lattice would be expected to depend somewhat on the time that the crystal was oscillated at a given amplitude, i.e., some time would be required to establish an equilibrium state. The curves of Fig. 9 show that several seconds were required for a stable value of the decrement to be reached when the oscillation amplitude was changed from one constant value to another.

In conclusion, the writers wish to express their appreciation to Professor E. P. T. Tyndall for his guidance and help during the progress of this work.

## Measurement of Surface Tension

ROBERT WEIL
*South-West Essex Technical College and School of Art, Walthamstow, England*
January 27, 1947

SUGDEN'S[1] method was employed for measuring the surface tension of distilled water at a temperature of 25°C in order to determine how the value would be affected by imperfections in the circularity of the capillaries. The procedure was as follows: six capillaries were drawn out from pieces of glass tubing so that the diameter at the tip was between .04 and .06 cm. While still soft the tips were squeezed to different degrees; thus the cross sections assumed elliptical shapes. It was argued that the ratio $R$ of the minimum to the maximum diameter was a measure of the deviation from the true circularity. This ratio, as determined by means of a cathetometer, varied from .537 to .914. The diameter of the large tube was .2814 cm.

The maximum bubble pressures were determined for each specimen. A high rate of bubbling was used at first with smaller rates following it. The mean of three readings for each rate was taken: the divergences were negligible. No automatic counting device being available, it was not possible to exceed a rate of about 140 to 150 bubbles per minute. Graphs were drawn plotting pressure against rate and extrapolated to infinitely long periods of bubble formation. This extrapolation seemed justified since, after some practice, it became possible to reduce the rates to as small values as two bubbles per minute. A mean value of the measured radii was used in order to calculate the surface tension.

Two interesting results have been found: for $.9<R<1$ values for the surface tension agree very well with data as obtained by other workers with capillaries whose cross section approximates to a circle to a greater degree than those used in this investigation.

It would appear that Martin's[2] conclusions obtained from work on similar deviations in Jäger's original method do not apply here.

Secondly, when plotting the pressure $p$ against the rate of bubbling, it was found in all cases that the values of $p$ increased with the rate of bubbling up to about 60 bubbles per minute or more, and then definitely decreased for higher rates. It was found, as might be expected, that, on raising the rate to a greater value than could be measured visually, the pressure rose considerably. The cause for this kink in the curves is not quite obvious. It is a matter of some conjecture whether it can be accounted for by the fact that at small rates actual maxima and minima are recorded in the positions of the liquid in the gauge, while at great frequencies it is the mean positions which are observed. In some unpublished work L. B. Wood points out the necessity of extrapolating to infinitely long periods of bubble formation to obtain reliable and consistent results. It would seem that there are occasions when it is not sufficient to maintain the rate of bubbling at less than two per second, as is suggested by Adam.[3]

It was not possible to extend the measurements to capillaries with different diameters and different wall thicknesses: it is certainly desirable that this should be done.

## Letter to the Editor

FRANCIS J. MURRAY
*The Institute for Advanced Study, School of Mathematics, Princeton, New Jersey*
January 8, 1947

MAY I respectfully call your attention to the fact that the suggestion of Mr. Eaglesfield on linear equation solvers, on page 1125 of the current issue of the *Journal of Applied Physics* (December, 1946) duplicates a paper of mine presented to the American Mathematical Society, September 1945, and abstracted in the November issue of the *Bulletin of the American Mathematical Society*, Vol. 51 (1945), page 883.

The content of the paper appears in full in my book *The Theory of Mathematical Machines*, a current publication of the Columbia University Press.

In this paper, I prove the convergence in the case in which $\Sigma\, d_i^2$ is used. In the case of a machine which uses $\max d_i$ as an indication, one can give examples where the machine will reach a minimum not zero.

I have constructed a number of models upon the $\Sigma\, d_i^2$ principle and a large one is now being constructed by the Watson Scientific Computing Laboratories at Columbia University.

### Personnel

The National Bureau of Standards recently announced the retirement of two longtime employees. Harvey L. Curtis, physicist at the Bureau since 1907, had deferred his retirement in 1945 to continue direction of interior ballistics research. Frederick J. Bates, sugar physicist who had also been chief of the Optics Division since 1941, has given more than 43 years of continuous service to the Bureau.

On December 30 Carroll L. Wilson resigned as vice president and director of National Research Corporation in order to assume his duties as general manager of the Atomic Energy Commission.

Ross Gunn has resigned as superintendent of the Physics Division, Naval Research Laboratory, to act as director of physical research for the U. S. Weather Bureau.

In January three appointments to the new Department of Engineering Sciences and Applied Physics at Harvard

University were announced. Leon N. Brillouin was appointed Gordon McKay Professor of Applied Mathematics, and James B. Fisk and Ronold W. P. King were named Gordon McKay Professors of Applied Physics.

Chester Peterson has been appointed physicist in the Resistance Measurements Section of the National Bureau of Standards.

The following men have new appointments to the Department of Physics at the University of Minnesota: Charles A. Critchfield, Frank Oppenheimer, Edward J. Lofgren, Joseph Weinberg, and Otto H. Schmitt.

### Division of High-Polymer Physics

The following are officers for 1947 of the Division of High-Polymer Physics of the American Physical Society: Chairman, Lawrence A. Wood; Vice Chairman, Hubert M. James; Secretary, W. James Lyons; Treasurer, Robert S. Spencer. Professor James and Dr. Spencer were also elected to the executive committee.

### General Electric Fellowships at Union College

For the third year General Electric Company is offering 50 six-week, all-expense fellowships to high school science teachers in seventeen northeastern states, for summer study at Union College in Schenectady, New York.

### Leonard Loeb Honored

*School and Society* reports that Leonard B. Loeb, professor of physics, University of California (Berkeley), has been chosen to deliver the 38th annual Kelvin lecture at the Institution of Electrical Engineers, London, England, on April 24. Professor Loeb will speak on "Electrical Discharge through Gases."

### Junior Chamber Puts Physicist in Top List

The U. S. Junior Chamber of Commerce published in January its selection of the nation's ten outstanding young men of the year. Included among them was Philip Morrison of Cornell University, atomic physicist, "for his outstanding work in the development of the atomic bomb and his struggle to educate the people to the danger and promise of atomic energy."

### Electronics Fellowships at MIT

A number of graduate and advanced research fellowships are being offered by the Massachusetts Institute of Technology, Cambridge, Massachusetts, for study and research in the field of electronics. They will be known as Industrial Fellowships in Electronics and are sponsored jointly by a group of industrial organizations concerned with the advancement of electronics and its applications. Applicants should communicate with the Director, Research Laboratory of Electronics. Under normal circumstances application must be made at least four months prior to the intended date of entrance.

### Work to Start Soon on Schenectady Atomic Laboratory

Construction of the Knolls Atomic Power Laboratory to be built near Schenectady, New York, by the Atomic Energy Commission will start this spring. The laboratory is being erected under the supervision of the General Electric Company, which will operate it for the government when completed. It is predicted the new building will be occupied by the middle of 1948.

### *Acta Crystallographica*

A special international organization, formed largely for this purpose, is planning the publication of a journal to perform the services formerly rendered by the *Zeitschrift für Kristallographie. Acta Crystallographica*, as it will be called, will be published either in England or America, and while French, German, and Russian will be permitted languages, the bulk of the journal will be in English. It is expected that there will be six issues per year totaling approximately 1000 pages. The price to individual subscribers is tentatively set at $10 a year.

The American representatives in the international organization are extremely anxious to obtain a good idea of the probable circulation of the journal in North America. Any reader of this notice who would, or who might, subscribe to *Acta Crystallographica* is urged to send a note or postcard to that effect addressed to Dr. Henry A. Barton, American Institute of Physics, 57 East 55 Street, New York 22, New York.

### Reorganization of American Institute of Physics

Reorganization of the American Institute of Physics and plans for a new semi-popular journal devoted to physics and its relation to society have been announced by the Institute. Effective immediately, the 7000 members of five societies (The American Physical Society, The Optical Society of America, The Acoustical Society of America, The American Association of Physics Teachers, and The Society of Rheology) will become members of the Institute. Heretofore the Institute has been an organization of these five Member Societies without any individual memberships. Provision is also made for associate membership in the Institute, open to others interested in physics. No change is made in the organization, functions, and activities of the five societies.

The new journal, for which initial financing is now being sought, will contain news about physicists, their meetings, their work, and other activities, and about similar features in related fields; information about the action of governmental and other non-physics agencies affecting physics; articles and letters presenting the views of physicists on problems of general importance; references to current literature in physics; book reviews, etc. Technical journals in the field of physics already being published by the Institute and its Member Societies will remain unchanged.

### Division of Electron and Ion Optics

The Division of Electron and Ion Optics will hold a meeting in connection with the Washington meeting of the American Physical Society on May 1–3, 1947. There will be a program of invited papers in the general field of "The Physics of Surface Phenomena." Contributed papers will be welcomed. For further information address J. R. Pierce (secretary-treasurer), Bell Telephone Laboratories, Inc., 463 West Street, New York 14, New York.

### The Bulletin of Mathematical Biophysics

The following is the table of contents for the March 1947 issue of *The Bulletin of Mathematical Biophysics:*

**Suggestions for a Mathematical Biophysics of Some Psychoses**—N. RASHEVSKY

**A Problem in Mathematical Biophysics of Interaction of Two or More Individuals Which May Be of Interest in Mathematical Sociology**—N. RASHEVSKY

**Mathematical Theory of Motivation Interactions of Two Individuals:** I.—ANATOL RAPOPORT

**The Mechanism of the Middle Ear: I. The Two Piston Problem**—MARTINUS H. M. ESSER

The University of Chicago Press, Chicago, Illinois
Volume 9 Number 1.

### Symposium at Ohio State

A Symposium on Molecular Structure and Spectroscopy will be held at the Mendenhall Laboratory of Physics at The Ohio State University from Monday, June 9, through Saturday, June 14. There will be discussions of the interpretation of molecular spectroscopic data as well as methods of obtaining such data. In addition, there will be sessions devoted to microwave and Raman spectroscopy. A dormitory will be available for those who wish to reside on the campus during the meeting. For further information, or for a copy of the program when it becomes available, write to Professor Harald H. Nielsen, Mendenhall Laboratory of Physics, The Ohio State University, Columbus 10, Ohio.

### International Nickel Cooperative Educational Program

A broadening of International Nickel Company's cooperation with universities and colleges in the United States and Canada in the field of engineering education through the distribution of technical literature has been announced by T. H. Wickenden, manager of the development and research division of The International Nickel Company, Inc.

The program will make available useful material for classroom instruction in training students in scientific fields. It has been offered to, and accepted by, a number of institutions in the United States and Canada which give accredited courses in mining, metallurgy, chemical engineering, and one or more other engineering courses. As rapidly as possible the program will be offered to all engineering schools.

The development and research division of the company will furnish to each institution an exhibit containing approximately 50 specimens of nickel-containing materials; a portable metals identification kit containing approximately 35 specimens of important metals and alloys for qualitative identification of metals and alloys; literature and other information concerning nickel and its alloys; and other data. Motion pictures of the company's mining, smelting, and refining operations will be made available.

# New Books

## Circuit Analysis by Laboratory Methods

BY CARL E. SKRODER AND M. STANLEY HELM. Pp. 288+xvi, 6×9 in. Prentice-Hall, Inc., New York, 1946. Price $5.35.

Some twenty years ago Professor Harry E. Clifford planned a system of laboratory reports which was used under his cognizance at M.I.T. and Harvard, and the form of which is still used there and in many other schools. The purpose of this system was to encourage the student to plan and think about the experiment rather than treat it as a mere manual exercise. The modus operandi was to require a preliminary report which involved the following sections: a. A statement of the problem, b. The theory involved, c. The procedure, d. The circuit diagrams, e. The results expected together with a sample calculation, and f. A proposed analysis of the results.

After having this preliminary report, together with a list of needed instruments, accepted by the instructor, the student was then free to perform the experiment and was expected to perform it with little additional guidance. The experiment was finished only when a final report, including the completion of Sections e and f, was accepted. This method was and still is in sharp contrast with the cook book method prevalent in some schools. This latter method is sometimes reduced to a point where the student is asked only to read instruments and to put the readings in appropriate squares on a data sheet provided by the instructor. There is no question as to which method does the better job of teaching.

In the book *Circuit Analysis by Laboratory Methods*, the authors attempt to follow the preliminary report system and at the same time reduce some of the drudgery involved in merely copying sections of theory from references. This they do admirably. However, by the title one is rather led to expect that the book will contain an entirely new and different set of experiments. This is not so, since many of the experiments are good old standbys, but the emphasis has very definitely been shifted from machines to circuits. Only three out of the thirty-five experiments are on rotating machine characteristics. Eight of the remainder are on series and parallel circuits including resonance, which acknowledges their importance both in engineering and as a teaching mechanism. Three are on polyphase circuits, and three on reactive power. The remainder are distributed among instruments, Kirchhoff's laws, power, resistance, etc.

Although the text explaining the philosophy of the experiments is good, it is expected that the course would be taken concurrently with a theory course in circuits. Since there should be some correlation between this and the laboratory, one would hope to find a classroom text which covers the same material in the same order. This might not be easy, although it might be accomplished by a certain amount of reorganization.

The chapter describing the report to be expected of the student is good, but it could have been rendered more vivid by including an example of what the authors consider to be a good report on one of the experiments included in the later chapters.

It seems that the authors have lost some crispness in trying to make the book so general that it can be used in all laboratories with all kinds of equipment. Somehow the sentence, "The inductance of the coil and the capacitance of the condenser should be such that resonance will be obtained at a frequency about in the middle of the frequency range designated by the instructor," does not seem nearly as authoritative as, "Choose the inductance and capacitance so that resonance will be obtained at 2000 cps."

ERIC A. WALKER
*The Pennsylvania State College*

### The Diffraction of X-Rays and Electrons by Free Molecules

BY M. H. PIRENNE. Pp. 160+xii, Figs. 82, $5\frac{1}{4}\times 8\frac{1}{4}$ in. Cambridge Series of Physical Chemistry. Cambridge University Press, Cambridge, England, 1946.

The thirteen chapters cover the following topics: Coherent scattering, incoherent scattering, fluorescence radiation, experimental measurements of the scattering of x-rays by atoms, diffraction of fast electrons by atoms, diffraction of x-rays by free molecules, intermolecular interferences in gases and liquids, thermal movements in molecules, the chemical bond, use of x-ray and electron diffraction for determination of structure, Fourier analysis of interference measurements of free molecules, measurement of x-ray scattering functions of gases, and a list of molecules studied by x-ray diffraction. An excellent bibliography contains 187 references.

The book is essentially a report of the work of the Debye school in the field of x-ray scattering by free molecules. The material is well presented and the book makes easy and interesting reading. Theoretical considerations and derivations are summarized, the results and conclusions are clearly stated, and the step-by-step details omitted. The first twelve chapters could well serve as a complete coverage for twelve semi-popular lectures. Most of the work presented in the book is more than ten years old, and much of it is familiar to workers in the field. However, even the experienced x-ray diffraction worker will find that the careful authoritative presentation clears up for him a few misunderstood points. The book should serve a useful purpose as a general report and reference for this phase of the x-ray diffraction field.

B. E. WARREN
*Massachusetts Institute of Technology*

## New Booklets

Tracerlab, Inc., 55 Oliver Street, Boston 10, Massachusetts, has published the first issue of *Tracerlog*, the purpose of which is "to publish technical information on laboratory, medical, and industrial uses of radioactivity, not to mention an occasional 'commercial' plug for Tracerlab's own products and services." It will be published monthly and mailed free of charge on request to physicists, chemists, physicians, and engineers interested in radioactivity and its applications.

Tube Department of Radio Corporation of America has announced the publication of two 16-page booklets. Form PG-101 is entitled "Power and Gas Tubes for Radio and for Industry" and Form 1275-C is named "Receiving Tubes for Television, FM, and Standard Broadcast." Either booklet may be obtained for 10 cents a copy from RCA tube distributors, or by sending 10 cents direct to Commercial Engineering, Tube Department, Radio Corporation of America, Harrison, New Jersey.

Miniature Precision Bearings, Inc., Keene, New Hampshire, offers a four-page bulletin on miniature ball bearings for precision instruments and mechanisms. It describes in detail five series: radial, super-light radial, pivot, angular contact, and thrust.

Acme Scientific Company, 1448 West Randolph Street, Chicago 7, Illinois, has issued a four-page folder describing in detail Acme's new mold polishing service. The company feels that the type of surface which it can provide on irregular contours may be useful to the readers of this journal.

Eberbach and Son Company, Ann Arbor, Michigan, publishes a 16-page house organ called *Announcer of Scientific Equipment*, of interest to research, control, and development laboratories.

Rex Rheostat Company, P. O. Box 232, Baldwin, Long Island, New York, announces its new *Catalogue No. 3*, 8 pages. The company manufactures slide-contact rheostats and resistors.

Leeds and Northrup Company, 4934 Stenton Avenue, Philadelphia 44, Pennsylvania, has published a new catalog, *ND46(1)*, which provides information about a pyrometer which supplements the Micromax line of instruments for those applications which require split-second response to temperature changes, or unusually rapid concentration on a single chart of data from many points. 16 pages.

Walker-Jimieson, Inc., 311 South Western Avenue, Chicago 12, Illinois, makers of radio and electronic supplies, have issued their 1947 *Reference Book and Buyer's Guide*. 106 pages.

Radio City Products Company, Inc., 127 West 26 Street, New York 1, New York, is announcing its new *Catalogue No. 129*, which describes a comprehensive line of radio, electrical, and electronic test instruments. 24 pages.

American Documentation Institute, 1719 N Street, N. W., Washington 6, D. C., has published its first *Catalogue* *of Auxiliary Publications in Microfilms and Photoprints.* To be distributed free so long as this first edition is available. 52 pages.

Dow Corning Corporation, Midland, Michigan, has announced the third edition of its *DC Silicone Catalogue.* 12 pages.

RCA Victor Division, Camden, New Jersey, has published two new booklets for the wider dissemination of technical information about electron tubes. Each contains 16 pages, and the titles are *Receiving Tubes for Television, FM, and Standard Broadcast*, and *Power and Gas Tubes for Radio and for Industry.*

Castle Films Division of United World Films, Inc., 30 Rockefeller Plaza, New York 20, New York, is announcing a new catalog listing many new films released during the past year for school and industrial training purposes.

The Ruberoid Company, 500 Fifth Avenue, New York 18, New York, has issued a 40-page illustrated booklet by Dr. Oliver Bowles entitled *Asbestos—The Silk of the Mineral Kingdom.* Dr. Bowles is chief of the Nonmetal Economics Division of the U. S. Bureau of Mines and is a prominent authority on the subject of asbestos.

Philips Research Laboratory has published a 20-page index listing all articles which have appeared in *Philips Technical Review* during the period January 1936 (first issue) to June 1942 (last issue prior to suspension of publication during the German occupation of Holland). It is available on request from Elsevier Book Company, Inc., 215 Fourth Avenue, New York 3, New York. The index, distributed free as a service to readers, alphabetically catalogs by subject all articles which appeared during that period.

## Calendar of Meetings

# Special Issue on High Polymers

**The following six papers were presented at the meeting of the Division of High Polymer Physics of the American Physical Society at Columbia University, January 30–February 1, 1947.**

## Measurements of the Refractive Index of Films*

Fred W. Billmeyer, Jr.
*E. I. du Pont de Nemours and Company, Plastics Department, Arlington, New Jersey*

The refractive index of a film of transparent or translucent material may be determined by immersing the film in a suitable liquid mixture and observing the intensity of light reflected from the surface of the specimen. The composition of the immersion liquid is varied, and a record is made of its refractive index (measured on a refractometer) and of the reflected light intensity. The refractive index of the film is the same as that of the immersion liquid giving the lowest reflected intensity. This has been confirmed by experiments with a glass plate, whose refractive index was known. According to Fresnel's laws of reflection, the experimental data should fit a parabola with its minimum at the refractive index of the film. On fitting the data by the method of least squares, the minimum is obtained with a standard deviation of the order of 0.002 refractive index units. The method has been applied to several plastic materials.

### INTRODUCTION

A METHOD has been developed for measuring the refractive index of a solid material. Originally used with thin films of translucent plastics, it may be applied as well to thicker specimens, of more highly absorbing or colored material. Mentioned by R. W. Wood[1] and used to some extent in the investigation of anomalous dispersion phenomena, the procedure consists in immersing the specimen in a suitable mixture of liquids and observing the intensity of light reflected from its surface. The composition of the immersion liquid is varied, and a record is made of its refractive indices (measured by a refractometer) and of the corresponding intensities of the reflected light. The refractive index of the sample is the same as that of the immersion liquid which gives the lowest intensity of reflected light.

### THEORY

When a material of refractive index $n_0$, immersed in a liquid of refractive index $n$ not too far different from $n_0$, is illuminated with unpolarized light striking its surface at an angle $i$ (see Fig. 1), the fraction of the light reflected is given by Fresnel's Law as[2]

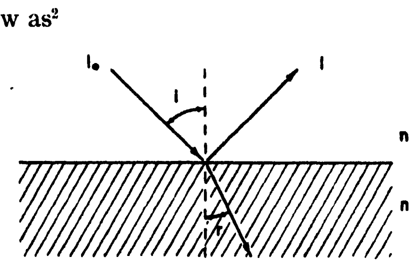

Fig. 1.

---

[*] Presented at the meeting of the Division of High Polymer Physics, American Physical Society, January 30–February 1, 1947.

[1] R. W. Wood, *Physical Optics* (The Macmillan Company, New York, 1934), third edition, pp. 411–12, 509.

[2] The coefficient ½ in these equations becomes nearly 1 when reflections from the back face of a transparent sample are included. For these experiments its actual value is immaterial.

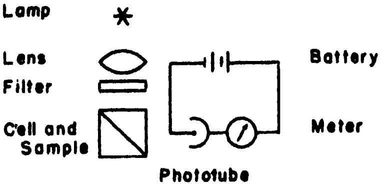

FIG. 2.

$$\frac{I}{I_0}=\frac{1}{2}\left[\frac{\sin^2(i-r)}{\sin^2(i+r)}+\frac{\tan^2(i-r)}{\tan^2(i+r)}\right], \qquad (1)$$

where $I_0$ and $I$ are the initial and reflected light intensities, respectively, and $i$ and $r$ are the angles of incidence and refraction. The angle $r$ is given by Snell's Law:

$$n \sin i = n_0 \sin r. \qquad (2)$$

If $i$ is chosen as 45°, a convenient angle experimentally, and $n$ is nearly equal to $n_0$, $r$ becomes nearly 45°, and Eq. (1) reduces to

$$I/I_0=\tfrac{1}{2}(\tan^2(i-r)-\tan^4(i-r)). \qquad (3)$$

Use of Eq. (2) then gives, for $i-r$ small,

$$I/I_0=\tfrac{1}{2}\left(\frac{n-n_0}{n_0}\right)^2+\cdots \qquad (4)$$

which is a parabola with its minimum at $n=n_0$.

## EXPERIMENTAL

### Apparatus

A diagram of the essentials of the apparatus is shown in Fig. 2.

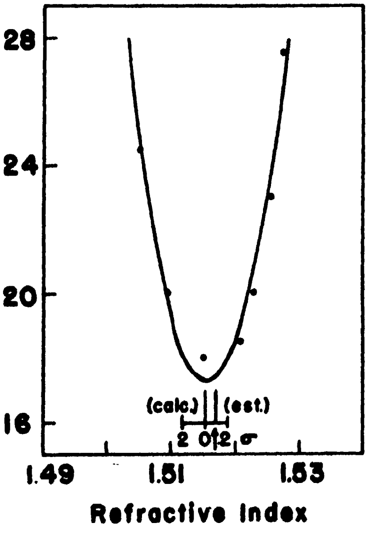

FIG. 3. Glass plate.

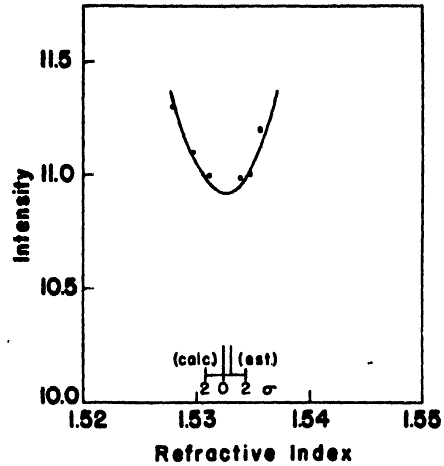

FIG. 4. Type FM-3 Nylon.

In the actual experiments two sets of apparatus were used. One consisted of a Bausch and Lomb projection microscope illuminator as light source and a Photovolt photometer, model 500, as detector. The tungsten lamp was run from a voltage-stabilizer, and a Wratten 62 filter was used to approximate mercury green light.

Later experiments were made with the light-scattering apparatus built by the author (to be described elsewhere). A stabilized incandescent lamp was used in conjunction with Wratten filters 11 and 22 to approximate sodium yellow light. Occasionally the filters were omitted.

In each case the sample was a thin film held between two pieces of polythene approximately 0.080 inch thick, arranged so as to fit tightly along the diagonal of a 4-centimeter square glass cell. The polythene was cut away so as to allow the light to hit the film and to allow free circulation of the immersion liquid. Polythene is especially suitable because of its general insolubility.

The immersion liquids must be miscible with one another and must not dissolve, swell, or otherwise affect the sample. Some liquid pairs which have been used are benzyl alcohol and carbon tetrachloride for the range in refractive index around 1.5, and carbon tetrachloride and benzene, or carbon tetrachloride and ethanol, for lower indices.

Measurements were carried out by starting with a liquid mixture about 0.01 refractive index unit away from the index of the film (chosen by experience or in a preliminary experiment) and adding small increments of a liquid with index beyond that of the sample. For each liquid mixture used, the refractive index and the intensity of reflected light were measured.

The measurements of refractive index were carried out either on a Bausch and Lomb "Precision" refractometer using mercury green light, or on a Bausch and Lomb Abbé refractometer, which gives a reading for sodium light. All experiments were carried out at room temperature (approximately 25°C) and the refractometers were checked against standard glass plates occasionally.

### Glass Plate Experiment

To test the accuracy of the procedure, the refractive index of a microscope slide was measured both by the method described here and directly by the Abbé refractometer, with the following result:

by refractometer,

$$n = 1.5171$$

by light reflection,

$n = 1.5156 \pm 0.0036$ (95 percent reliability).

The two values agree within one standard deviation. The data are presented in Fig. 3, with the refractometer value indicated by an arrow.

TABLE I. Refractive indices of films.

| Material | Index | Color of light | Notes |
|---|---|---|---|
| polythene | 1.515 | mercury green | PM-1, lot 720 |
|  | 1.519 | mercury green | PM-1, lot 859 |
| tetrafluoroethylene | 1.378 | white | "Teflon," density 2.18 |
|  | 1.376 | sodium yellow | "Teflon," density 2.12 |
| hexamethylene sebacamide | 1.532 | sodium yellow | Type FM-3 Nylon |

### COMPUTATIONS

The refractive index of the test specimen may be obtained from the experimental data either by inspection or from the equation of the parabola fitted to the observed points by the method of least squares.

In the latter case, the reflected intensity is represented by the equation

$$I = a + bn + cn^2 \qquad (5)$$

and the position of the minimum is

$$n_0 = -\frac{b}{2c} \qquad (6)$$

In the experiments carried out on films of plastics, the standard deviation in the value of $n_0$ was computed directly from the experimental data for the case of the glass plate. For each of the other cases the standard deviation was estimated from this value and the relative magni-

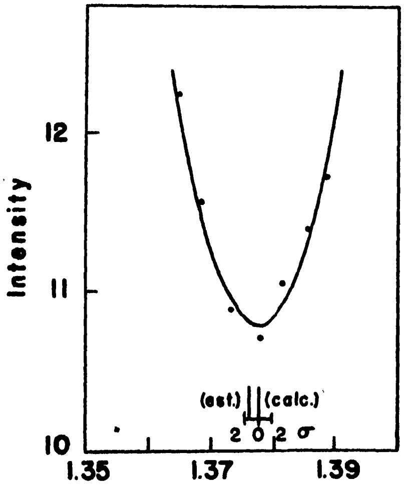

FIG. 5. "Teflon," density 2.18.

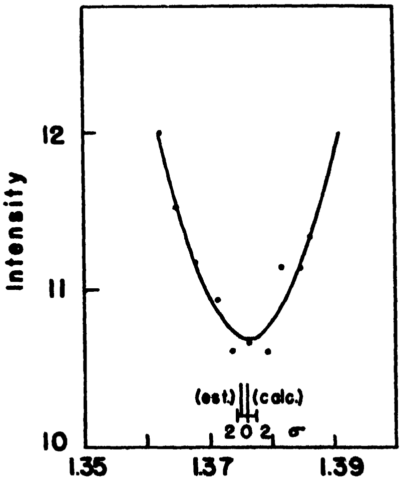

FIG. 6. "Teflon," density 2.12.

tudes of the "chi-square" index of precision[3] for glass and for the case in question.

Whenever the refractive index as determined by a visual inspection of the data was compared with that computed by least squares, the difference between the two was less than twice the standard deviation of the computed value.

Some experimental results are presented in the following table, and a few of the computed curves are shown in Figs. 4, 5, and 6. Included on the graphs are the estimated and computed indices of refraction of the respective films, and a scale of standard deviation, $\sigma$. The intensity is represented in arbitrary units, with the zero of intensity considerably below the axis.

The intensity at the minimum will depend upon the transparency of the film. For a very transparent material such as glass, it will be limited chiefly by the scattered and stray light in the apparatus. The value of $n_0$ is not influenced by the magnitude of this residual intensity.

## CONCLUSION

A method similar to the mineralogical immersion technique for measuring the refractive index of a solid has been presented. The test specimen may be a thick or thin piece with a reasonably plane face, or a film. The material may be clear or translucent, and may also be colored. The optical quality of its surface need only be fair. For these reasons this technique has proved successful in several cases where other methods, such as the determination of Brewster's angle, have failed.

Some experimental results are given in the accompanying table and figures.

# A Sound Velocity Method for Determination of Molecular Weight of Liquid Polymers†

Alfred Weissler, James W. Fitzgerald,* and Irving Resnick**
*Naval Research Laboratory, Washington, D. C.*

A new method is presented for determining number average molecular weights of liquid polymers, by means of easily performed measurements. The molecular weight is an explicit function

$$M=\frac{Bd}{v^{\frac{1}{3}}-A\left(\frac{n^2-1}{n^2+2}\right)}$$

of the sound velocity $v$, density $d$, refractive index $n$, and the two empirical constants $A$ and $B$. Accuracy of about 2 parts per hundred was attained for the lower polyethylene glycols. The method seems suitable for molecular weights up to several thousand. Sound velocities were measured by an acoustic interferometer, at one megacycle frequency.

The molecular weight of a polymer is so fundamental a property, and the methods available for its determination are so few in number, that any new technique warrants a certain interest. This paper presents such a new method, suitable for liquids, which is based on the relatively simple measurements of sound velocity, density, and refractive index.

## I. BASIS OF THE METHOD

Sound velocity in liquids became useful for the investigation of molecular structure after the discovery by M. R. Rao[1] of the empirical constant

$$R=Mv^{\frac{1}{3}}/d \qquad (1)$$

where $M$ is the molecular weight, $v$ and $d$ are the sound velocity and density measured at the same temperature, and $R$ may be called the molar sound velocity. For each pure liquid (except water) the molar sound velocity is a constant independent of temperature; therefore, density and the cube root of velocity vary in such a way that their ratio is fixed.

TABLE I. Physical properties of polyethylene glycols at 30°C.

| Glycol | Mol. wt. | Density | Sound velocity | $n_D$ | Viscosity | Boiling point |
|---|---|---|---|---|---|---|
| Ethylene | 62.1 | 1.1068 g/cc | 1642.9 m/s | 1.4295 | 13.95 c.p. | 69°/1.2 mm |
| Diethylene | 106.1 | 1.1094 | 1567.7 | 1.4438 | 22.55 | 105°/2.0 |
| Triethylene | 150.1 | 1.1158 | 1593.3 | 1.4531 | 29.96 | 123°/1.2 |
| Tetraethylene | 194.2 | 1.1159 | 1580.1 | 1.4567 | 35.16 | 138°/0.5 |
| Pentaethylene | 238.2 | 1.1165 | 1580.0 | 1.4593 | 42.37 | 176°/0.5 |
| Poly 200 | 200±10 | 1.1168 | 1592.2 | 1.4572 | 39.71 | |
| Poly 300 | 300±15 | 1.1176 | 1578.0 | 1.4618 | 59.02 | |
| Poly 400 | 400±20 | 1.1182 | 1576.0 | 1.4636 | 74.70 | |
| Poly 600 | 600±30 | 1.1183 | 1570.2 | 1.4653 | 104.62 | |

Although the velocity of sound varies irregularly within a given homologous series, such as the alcohols or ketones, the molar sound velocity was found to be an additive property of the atoms (or bonds) in the molecule. From the published tables of $R$ increments for atoms of carbon, hydrogen, oxygen, etc., the molar sound velocity may be calculated with good accuracy, just as in the familiar case of molar refraction.

Further, Lagemann and Dunbar[2] showed that, within a homologous series, linear relationships exist between any two of the following molar constants: (a) molar sound velocity, (b) molar refraction

$$N=\frac{M}{d}\left(\frac{n^2-1}{n^2+2}\right) \tag{2}$$

where $n$ is index of refraction, (c) molar viscosity as defined by Souders[3]

$$I=(2.9+\log\log\eta)\frac{M}{d} \tag{3}$$

where $\eta$ is viscosity in millipoises, (d) molar magnetic rotation, (e) parachor, (f) critical volume, and (g) van der Waals' $b$.

An example of such a relationship is the one involving refraction and sound velocity

$$R=AN+B \tag{4}$$

where $A$ and $B$ are, respectively, the slope and intercept. Upon substitution of Eqs. (1) and (2), this immediately yields an expression for the molecular weight

$$M=\frac{Bd}{v^{1/3}-A\left(\frac{n^2-1}{n^2+2}\right)} \tag{5}$$

in terms of the two empirical constants and the observed sound velocity, density, and refractive index. Similar expressions may be obtained from other pairs of molar constants; for example:

$$M=\frac{B'd}{v^{1/3}-A'(2.9+\log\log\eta)} \tag{6}$$

and

$$M=\frac{B''d}{\left(\frac{n^2-1}{n^2+2}\right)-A''(2.9+\log\log\eta)} \tag{7}$$

where $A'$, $A''$, $B'$, and $B''$ are the analogous slopes and intercepts of the other linear relations.

These results should be applicable not only to a homologous series, in which the difference between two successive members is $-CH_2-$, but also to a polymer homologous series, where the difference is any monomer structural unit.

## II. EXPERIMENTAL

It was therefore decided to test the validity of Eq. (5), and incidentally of (6) and (7), by using it to determine the molecular weights of several pure members and commercial mixtures of the polyethylene glycol series. These polymers, of type formula $HO-(-CH_2-CH_2-O-)_n-H$, have been studied intensively in the past.[4,5] The

chemical individuals (the monomer, dimer, trimer, tetramer, and pentamer) were purified by fractional distillation through a 40 cm Widmer column, at about 1 mm pressure. The mixtures were those of average molecular weight 200, 300, 400, and 600, as manufactured by Carbide and Carbon Chemicals Corporation.

Several physical properties of these nine liquids were measured at 30°±0.1°: refractive index for sodium light by the Abbé refractometer, density by a 25 ml pycnometer, sound velocity by the acoustic interferometer described below, and viscosity by the Ostwald-Fenske viscometer. These properties are listed in Table I.

The acoustic interferometer[6] was of conventional type,[7-9] energized by a one megacycle crystal-controlled oscillator. Figure 1 shows the circuit used. Figure 2 is a sectional view of the brass interferometer cell, containing the quartz crystal source and the movable reflecting plate, immersed in the thermoregulated oil bath. About 300 ml of liquid are required for a measurement. As the reflector is moved vertically through the liquid by the micrometer head, cyclical variations in the standing wave pattern recur at distances of integral half-wave-lengths. These cause corresponding cycles in the current through the interferometer crystal, which are observed on a suitable microammeter. The micrometer-head travel required for an interval of two current maxima, then, is equal to the wave-length; and the velocity of sound is, of course, the product of this wave-length and the frequency. In practice, one measures the travel for twenty maxima, which makes possible a precision of a few hundredths of a percent.

## III. DISCUSSION

From the physical properties of the nine liquids, there were computed the molar refractions, viscosities, and sound velocities. These observed molar constants agree reasonably well (Table II) with the values calculated[10] from the molecular structures, using the published tables[2,3,10] of the bond increments for each type of constant. In the case of molar sound velocity, the agreement is better than 1 percent, which is less than the dispersion in values among the original com-

[10] Molar refraction was calculated by the method of K. Fajans, *Physical Methods of Organic Chemistry*, edited by A. Weissberger (Interscience Publishers, New York, 1946), Vol. I, pp. 672, 679.

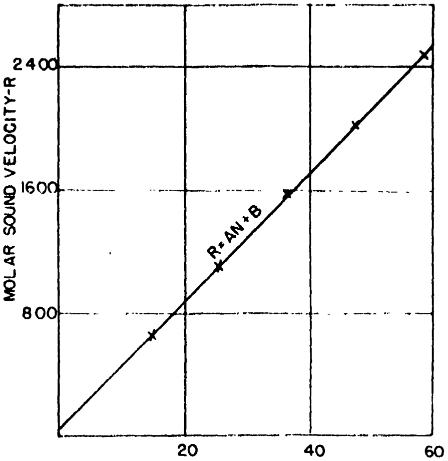

FIG. 3. Linear relation between molar sound velocity and molar refraction.

pounds used for constructing the table of increments. Compared to values previously reported[11] for 20°, the molar refractions show the customary increase of 0.01–0.02 percent per degree, attributed by Fajans[10] to loosening of the electron shell. The agreement is poorest for the molar viscosities.

Next, the existence of a linear relation between molar sound velocity and molar refraction was verified for the five pure compounds. The points lie on the straight line of Fig. 3, of which the slope $A$ is 41.59 and the intercept $B$ is 57.7. The slope may also be calculated from the tables of bond increments: for each $-CH_2-CH_2-O-$ structural unit, the $R$ increment is 454 and the $N$ increment is 10.88. The quotient of these two, which should be the slope, is 41.73, so that the agreement is a few parts per thousand.

TABLE III. Determination of molecular weight by sound velocity.

$$M=\frac{57.7d}{v^{\frac{1}{3}}-41.59\left(\frac{n^2-1}{n^2+2}\right)}$$

| Glycol | Theoretical Mole. wt. | Mole. wt. by sound velocity | Deviation | Mole. wt. number avg. | Mole. wt. wt. avg. |
|---|---|---|---|---|---|
| Ethylene | 62.1 | 59.9 | −3.5% | 60.8 | 62 |
| Diethylene | 106.1 | 111.5 | 5.1 | 101.6 | 109 |
| Triethylene | 150.1 | 147.3 | −1.9 | 148.5 | 155 |
| Tetraethylene | 194.2 | 195.7 | −0.8 | 195.4 | 190 |
| Pentaethylene | 238.2 | 237.7 | 0.2 | 234.5 | 238 |
| Poly 200 | 200±10 | 186.2 | −2.0+ | 183 | 219 |
| Poly 300 | 300±15 | 302.7 | 0.0+ | 315 | 359 |
| Poly 400 | 400±20 | 381.8 | 0.0+ | 384 | 480 |
| Poly 600 | 600±30 | 546.9 | −4.0+ | 561 | 720 |

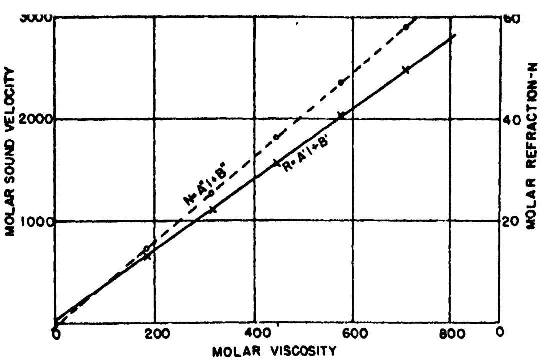

FIG. 4. Verification of other linear relations.

As expected, linear relations were found (Fig. 4) for the two other pairs of molar constants, sound velocity and viscosity, and refraction and viscosity. For the former pair, slope $A'=3.466$ and intercept $B'=31.9$; for the latter, $A''=0.08337$ and $B''=-0.640$. The agreement between observed and calculated slopes is not as good in these cases.

Next came the crux of the entire work. For each of the nine liquids, the molecular weight was calculated as indicated by Eq. (5), from the density, sound velocity, index of refraction, $A$, and $B$. The results show an average accuracy of about 2 percent (Table III) on the basis of the theoretical molecular weights, which compares well with that of other methods.

For purposes of comparison, the number average molecular weight was determined by freezing-point depression in water as solvent.[12] Measurements were made at concentrations of approximately 2 percent and 4 percent, and the values extrapolated to infinite dilution. The precision is estimated at about 3 parts per hundred. It is apparent from Table III that, within experimental error, the sound velocity molecular weight is the same as the number average

---

[11] A. F. Gallaugher and H. Hibbert, J. Am. Chem. Soc. **58**, 813 (1936).

[12] Using water as solvent avoided the anomalous results encountered in ethylene dibromide solution by Gallaugher and Hibbert, reference 11, presumably because the glycols tend to be solvated, rather than associated, in aqueous solution. The apparent molecular weights obtained in the present work decreased slightly with increasing concentration, which indicates that association of glycol molecules is negligible compared to solvation.

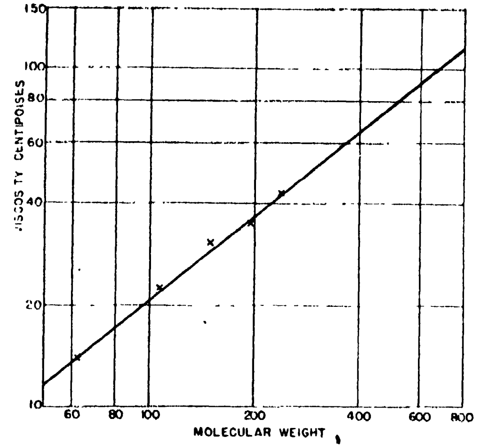

FIG. 5. Bulk viscosities of polyethylene glycols at 30°.

molecular weight. In addition, a weight average molecular weight was determined from the log-log plot of bulk viscosity against molecular weight[13] (Fig. 5). As would be expected, for the heterogeneous mixtures the weight average results shown in Table III are considerably higher than the number average or sound velocity molecular weights.

Attempts were also made to calculate the molecular weights from Eqs. (6) and (7), the analogous relations involving the other two pairs of properties. However, the errors are large, as demonstrated in Table IV. This may be due partly to the fact that the precision of measurement of viscosity is only about one-tenth as good as that of sound velocity or refractive index. Unfortunately, the errors increase for higher molecular weights because the calculations involve a decreasing difference between the two terms in the denominator of the expression for $M$.

## IV. SUMMARY

A new method for determining molecular weights of polymeric liquids has been shown to yield results of about 2 percent accuracy in the case of the lower members of the polyethylene glycol series. This method, which gives the number average molecular weight, consists of calculating $M$ from two empirical constants and the observed sound velocity, density, and refractive index. We intend to investigate extension of its applicability to solid polymers or solutions of solids.

## V. ACKNOWLEDGMENTS

Grateful acknowledgments are made to the many physicists and chemists at the Naval Research Laboratory who were generous with their facilities, materials, and advice during the prosecution of this work; and also to the Dow Chemical Company and to the Carbide and Carbon Chemicals Corporation, for generously supplying samples of these polyethylene glycols.

[13] These lower polyethylene glycols appear not to conform to the relation $\log\eta = A + BM^{\frac{1}{2}}$ suggested for bulk viscosities by P. J. Flory, J. Am. Chem. Soc. **62**, 1057 (1940).

# An Instrument for Measuring Particle Diameters and Constructing Histograms from Electron Micrographs*

E. E. HANSON AND J. H. DANIEL
*Chemical and Physical Research Laboratories, The Firestone Tire and Rubber Company, Akron, Ohio*

An instrument for shortening the time and labor required in constructing particle size histograms from electron micrographs is described. Representative histograms obtained with the instrument for GR-S latices are shown. Linear, surface, and volume-equivalent diameters of non-spherical particles are defined, and variations in the instrument for plotting such diameters are proposed.

## INTRODUCTION

IN certain studies of the polymerization of synthetic rubbers, it is desirable to obtain particle-diameter distribution curves or histograms for the rubber latices. Such diameter histograms may be obtained from electron microscope photographs of the latex particles.

The technique used in this laboratory for preparing latex specimens for the electron microscope[1] consists essentially of forming a film from a dilute water solution of polyvinyl alcohol containing a small amount of the latex.

The construction of particle diameter histograms is tedious and time consuming. In the usual procedure, the "longest" and "shortest" diameters of the projected image (or of a photographic enlargement) of a particle are measured with a rule, their arithmetic mean is computed, and finally the number of particles with mean diameters lying in chosen diameter intervals is plotted against the diameters. Multiplication by a scale factor, containing the reciprocal of the magnification, converts the diameter axis of the histogram to read directly in Angstrom units. To obtain a representative distribution, at least 200 particles should be measured.

The instrument to be described here was developed to reduce the time and labor required in constructing such histograms. It will be called a "histogram computer."

In the development of the histogram computer, consideration was given to the question of whether the arithmetic or the geometric mean, or some other function of the "longest" and "shortest" diameters of a particle, should be plotted. With an unbroken film in the electron microscope, the latex particles usually appear approximately spherical in shape. However, when holes are present in the film, as frequently is the case, the particle contours are elliptical. The problem, then, is to compute the diameter of the equivalent spherical particle having either the same volume, or the same surface area, as the actual ellipsoidal particle. The two cases require, of course, calculation of different functions of the major and minor axes. In addition, the

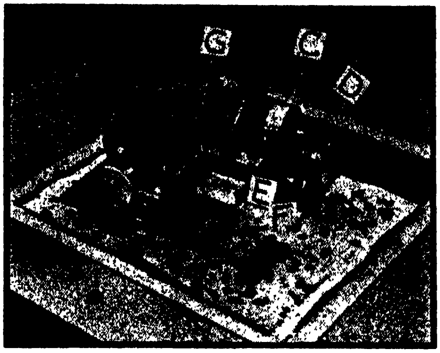

FIG. 1. The scanning mechanism.

particles may be either prolate or oblate, or some shape in between. Without going through some time-consuming process, such as taking stereo-photographs, there is no way of determining what volumetric shape a particle has.

A comparison between the diameters of the volume-equivalent and the surface-equivalent spheres, and the arithmetic and geometric mean diameters for both prolate and oblate spheroids is given in Table I. In some cases the geometric mean is the closer approximation, and in others the arithmetic mean is the closer. It was therefore decided to design the simplest of possible mechanisms, which gives the arithmetic mean. In general, the measurements should be restricted to particles having a major to minor axis ratio of less than two.

## APPARATUS

The histogram computer consists essentially of a scanning mechanism for setting manually two pairs of mutually perpendicular lines on the outline of the particle, and a coupled recording mechanism for dropping a steel ball into a compartment corresponding to a range of diameters containing the arithmetic average of the two measured diameters of the particles.

Figures 1 and 2 are photographs of the scanning and the recording mechanisms, respectively. The scanning mechanism consists of a steel baseplate with a right angle section cut out for viewing the electron micrograph field, two mutually perpendicular screws (one labelled $E$) for translating non-rotating nuts to which clear Lucite blocks are attached, two equal gear trains coupling the rotations of the screws to their respective Selsyn motors, and a sub-base plate of clear Lucite on the under side of which are two scribed, inked-in lines drawn parallel with, and perpendicular to the two screws. Each of the movable Lucite blocks has a scribed, inked-in line drawn on its top and bottom surface, in a vertical plane parallel to a line in the sub-base plate. This enables the operator to set the lines without parallax on the edge of the particle. Each of the two Selsyn motors is coupled to a corresponding motor on the recorder so as to transmit its rotation.

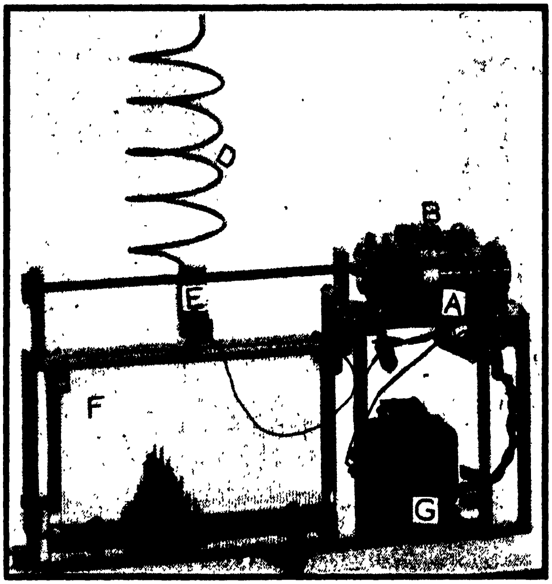

FIG. 2. The recording mechanism.

In the recorder unit, the Selsyn motors, $A$ and $B$, transmit their rotations additively through a differential gear, $C$, to a screw 10 inches long. The screw serves to position the ball-dispensing mechanism $E$. Directly below the ball-delivery

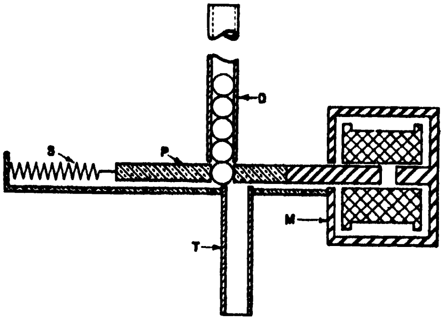

FIG. 3. The ball release mechanism.

tube, and parallel to the screw, is a thin rectangular Lucite box, *F*, divided into 80 compartments for receiving the steel balls as they are dropped.

The ball-dispensing unit consists of a $\frac{1}{8}''$ I.D. copper-tubing magazine, *D*, for holding a supply of $\frac{3}{32}''$ diameter steel balls, and an electromagnetically controlled "valve" by which the operator can cause the balls to be dropped one at a time. A cross-sectional diagram of the valve is shown in Fig. 3. The axis of the delivery-tube is sufficiently offset from the magazine, *D*, to prevent the balls from falling through. The flat plunger, *P*, normally held by the spring, *S*, in the position shown, is pierced by a hole slightly larger in diameter than the steel balls. When the circuit to the magnet, *M*, is closed, the plunger carries one ball over and discharges it into the delivery tube. The delivery tube projects between two parallel guides to a position $\frac{3}{16}''$ above the opening in the recorder compartments. The parallel guides also serve the purpose of preventing any rotation of the dispensing unit nut.

The recorder compartment box, *F*, was made by bolting together the two ends of two pieces of $6''\times11''\times\frac{1}{4}''$ Lucite blocks against .096″ thick spacers. Strips of .010″ thick shim stock were inserted into grooves which had been accurately milled into the inner surfaces of the plates on $\frac{1}{8}''$ centers. The bottom of the box is a metal blade which can be removed at the end of a run to release the accumulated balls into a flat box below.

End-play was taken out on the three screws by special thrust bearings. Back-lash was eliminated through the use of split-nuts engaging the screws.

The Selsyn motors were designed to be operated normally at 115 volts and 400 cycles. However, since no 400 cycle source was available, they were operated from the transformer, *G*, at 60 cycles and 24 volts.

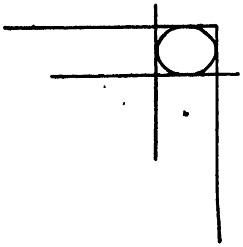

FIG. 4. Appearance of the scanning lines set on a particle.

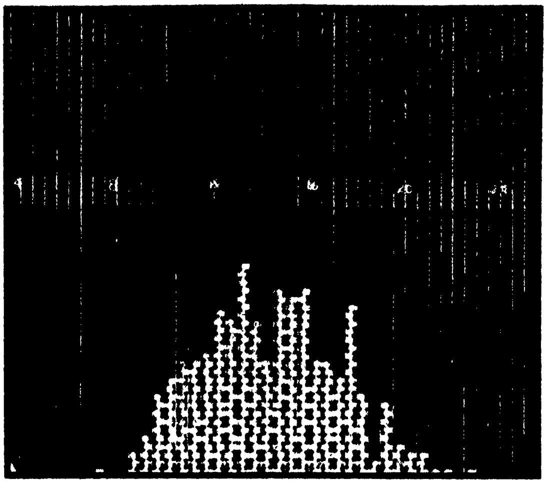

FIG. 5. Contact print of the recorder compartmented box showing distribution from which histogram of run 3, Fig. 6, was obtained.

The gear train normally used gave an amplification factor of 18 from the scanning to the recorder units. Therefore, a total magnification of 35,300 diameters was required in the electron micrograph to give a value of 50 Angstroms to each $\frac{1}{8}''$-long compartment interval. Other values could be given to the compartment interval by a suitable choice of gears and total magnification of the electron micrograph.

In practice, a particle count can be made either from a photographic enlargement, or directly from an image of the electron micrograph plate projected at the desired magnification on a ground-glass screen. The procedure is first to set the scanner unit on the zero position (scribed lines directly over each other), and the ball dispensing unit approximately at the zero position of the recorder box, and finally to shift the compartmented box slightly by hand until the balls fall equally often on both sides of the chosen zero wall. The scanning unit is then set successively on the particles to be measured, so that each particle is bracketed by the scribed lines as shown in Fig. 4. As each particle in turn is thus bracketed, the ball release switch is closed to record that particle. A counter, coupled to the switch, automatically totals the number of particles as the measurements proceed.

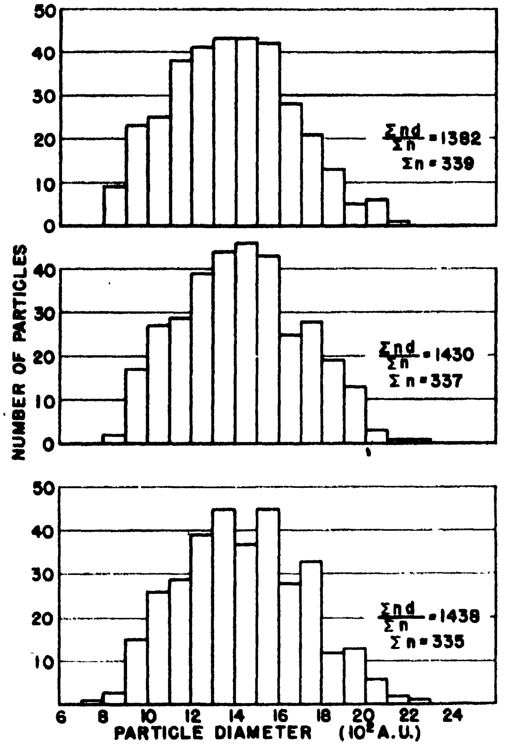

FIG. 6. Histograms of experimental latex. Each run made from same electron micrograph field.

### TYPICAL RESULTS

Figure 5 is a direct contact print of the record given by the histogram computer of 335 particles of an experimental GR-S latex. The print was made by placing F-2 contact paper against the back of the recorder compartments, and illuminating the front of the box for 15 seconds with a 60 watt Mazda bulb placed 7 feet away. In this case the electron microscope magnification was 5600, and the photographic enlargement was 6.3× to give a total magnification of 35,300×.

In Fig. 6 are three histograms of an experimental GR-S latex. All were constructed from the same electron micrograph field, and are, therefore, indicative of the reproducibility of the instrument. In these measurements an interval of 100 Angstrom units was chosen. Since the limit of resolution of the electron microscope was about 50 Angstroms for the specimens used, it was concluded that the sharp variations between 50 Angstrom intervals, shown in Fig. 5, were not significant.

Figure 7 is similarly a record of three successive histograms constructed from the same field of an electron micrograph of another GR-S type latex.

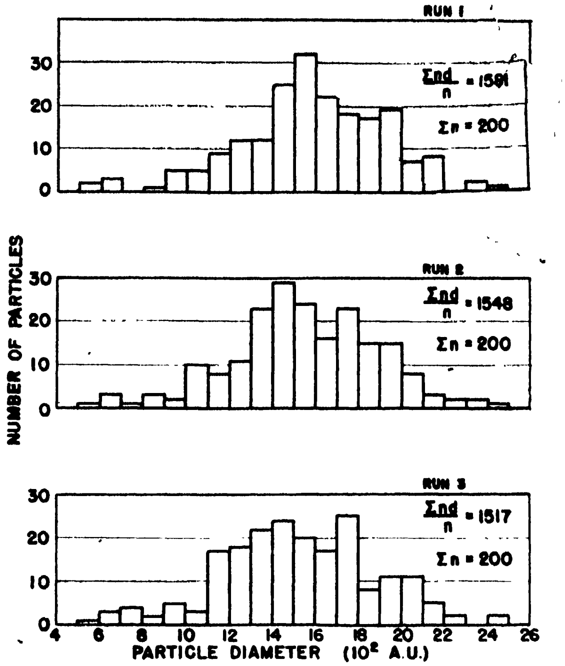

FIG. 7. Histograms of another experimental latex. Each run made from same electron micrograph field.

In general, the reproducibility of the curves is considered satisfactory.

It has been our experience that it is much less tedious to operate the computer than to measure particles with a rule, that the accuracy is increased, and that the time required to construct a histogram is reduced by about one-half.

### OTHER POSSIBLE MECHANISMS

Construction of an electronic servo-system, to replace the Selsyns and differential in the histogram computer, was not justified in this laboratory because of extra complications, but would give added features which might be desirable in some applications. Among such features may be listed the following:

1. Distribution of the geometric as well as arithmetic means of major and minor axes.
2. Distribution of surface area (approximate) or of volume (exact), assuming particle shape to be an ellipsoid of revolution.
3. Flexibility of size of histogram increments.

One such scheme is shown in Fig. 8. Circular potentiometers, $P_1$ and $P_2$, have resistances linear with their respective angles of rotation, $\theta_1$ and $\theta_2$, to the desired degree of accuracy. In use, $\theta_1$ and $\theta_2$ are set proportional to the major and minor axes, $D_1$ and $D_2$, respectively. Similar potentiometers, $P_3$ and $P_4$, are mechanically inter-connected so that their angles of rotation remain always equal to the single angle $\theta$. This angle $\theta$ is determined by the position of the servo-motor, which also runs the ball dispenser of the recorder (minus differential gear). In Fig. 8, the two voltages, $V_2$ and $V_3$, applied to the sum amplifier will always differ 180° in phase, so when their magnitudes are equal, the sum amplifier output to the servo-motor will be zero. The direction of rotation of the servo-motor when $V_2$ and $V_3$ are not equal will depend on which voltage is the greater. The blocks labeled *CF* are cathode followers with amplification, $A_{CF}$, extremely constant and slightly less than unity. Setting $R_1 = R_2 = 0$ for the moment, the following relations will exist:

$$V_2 = V_1 A_{CF_1}\theta_2 = V_1 A_{CF_1} k_2 D_2$$

$$= k_1 D_1 C_1 V_0 A_{CF_1} k_2 D_2, \quad (1)$$

$$V_3 = V_4 A_{CF_2}\theta = -A_{CF_2}\theta^2 C_4 V_0, \quad (2)$$

where $\theta_1 = k_1 D_1$; $\theta_2 = k_2 D_2$; voltage across $P_1 = C_1 V_0$; voltage across $P_4 = -C_4 V_0$.

When the servo-motor has equalized $V_3$ and $-V_2$, and the recorder ball dispenser comes to rest, the following relation will exist:

$$A_{CF_2}\theta^2 C_4 V_0 = k_1 D_1 C_1 V_0 A_{CF_1} k_2 D_2,$$

$$\theta = \left(k_1 k_2 \frac{C_1}{C_4}\frac{A_{CF_1}}{A_{CF_2}}\right)^{\frac{1}{2}} (D_1 D_2)^{\frac{1}{2}}. \quad (3)$$

Hence the position of the recorder ball dispenser is proportional to the geometric mean of the particle major and minor axes.

Since $V_0$ does not appear in Eq. (3), line voltage regulation is unnecessary. Rheostat $R_1$ allows the increment of diameter for the histogram to be varied. The combination of $R_1$ and $R_2$ allows a shift of recorder zero for cases where no small particles are present.

To obtain a histogram of approximate surface areas, a switching arrangement feeds $V_4$ instead of $V_3$ to the sum amplifier, thus giving $\theta$ proportional to the product $D_1 D_2$.

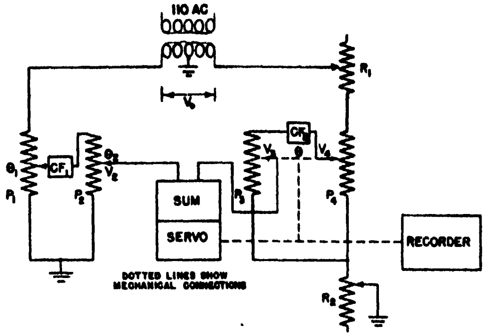

FIG. 8. Schematic diagram of proposed servo-mechanism for histogram computer.

To obtain a histogram of the arithmetic mean of particle diameters, a switching arrangement removes $CF_1$ and $CF_2$ from the circuit, connects the ungrounded ends of $P_1$ and $P_2$, and feeds $V_1$ and $V_2$ separately, and $V_4$ instead of $V_3$, to the sum amplifier (for this arrangement $k_1$ must equal $k_2$, as would normally be the case).

To obtain a histogram of volumes, $V_4$ instead of $V_3$ is fed to the sum amplifier, $P_3$ is connected mechanically and electrically to $P_2$ in the same manner it was formerly connected to $P_4$, and the series outputs of $P_1$, $P_2$, and $P_3$, are fed to the sum amplifier. In the case of a prolate spheroid, $\theta_1$ must be set proportional to the major axis; for an oblate spheroid, $\theta_1$ must be set proportional to the minor axis. Obviously, only a small range of particle sizes can be covered in volume histograms as compared to diameter histograms.

## ACKNOWLEDGMENTS

It is a pleasure to acknowledge the assistance given by Mr. George Cervana in laying out the design of the instrument and in operating it. Mr. F. S. Grover and Mr. Howard Hentzell did the constructional work and contributed valuable ideas to the design. We are indebted to Mr. G. E. White of the Sperry Gyroscope Company, Inc., for the gift of the small differential gear used in the recorder. Thanks are due the Firestone Tire & Rubber Company for permission to publish this paper, and to Dr. J. H. Dillon and Dr. F. W. Stavely for their interest in the problem.

# Torsion of a Rubber Cylinder*

R. S. Rivlin
*British Rubber Producers' Research Association, Welwyn Garden City, Herts., England, and National Bureau of Standards, Washington, D. C., U. S. A.*

It has been predicted theoretically that, in general, a right-circular cylinder of incompressible, highly elastic material, which is isotropic in its undeformed state, cannot be held in a state of pure torsional deformation by means of a torsional couple alone. In addition, normal surface tractions must be exerted over the plane ends of the cylinder. These normal surface tractions depend on the amount of torsion and on position on the plane ends of the cylinder. Experiments are reported here in which this phenomenon is observed in a right-circular cylinder of pure gum compound. The dependence of the surface traction on amount of torsion and its distribution over the surface of the cylinder is studied by measuring the bulging of the rubber into small holes in a metal plate on one end of the cylinder.

## I. INTRODUCTION

In a series of papers which is pending publication elsewhere,[1] the mechanical properties of highly elastic materials, such as rubber, which can be assumed incompressible and isotropic in their undeformed state, are discussed in terms of a stored-energy function $W$. This stored-energy function is specified in terms of the invariants of strain. It is shown that, once $W$ is specified in this manner, the forces, which must be applied in order to support any given state of deformation, can be calculated. This calculation has been carried out for the pure torsional deformation of a right circular cylinder, for an assumed stored-energy function of simplest possible type and subsequently for any general form of stored-energy function.

The theory predicts that in order to produce a pure torsion in the cylinder, a torsional couple must be exerted on the plane ends of the cylinder, as in the classical theory of elasticity for small deformations. In addition, normal tractions must be exerted over these surfaces. The distribution of these normal tractions over the ends of the cylinder and their dependence on the amount of torsion have been calculated for any specified form of the stored-energy function.

In this paper experiments are reported in which this distribution and dependence on amount of torsion is measured for a cylinder of pure gum compound, on the assumption that the surface traction is measurable by the bulging of the rubber into small holes in a metal plate on one end of the cylinder. The results obtained are compared with those derived theoretically for two simple forms of the assumed stored-energy function. Agreement, within the accuracy of the experiments, is obtained if the stored-energy function has a form equivalent to that put forward for rubber by Mooney.[2] This form involves two physical constants for the material.

## II. SPECIFICATION OF THE STORED-ENERGY FUNCTION

The stored-energy function for an ideal perfectly elastic material may be completely defined in the following manner. If a cube of the material, of unit edge, is subjected to a pure, homogeneous deformation in which it is deformed into a cuboid of dimensions $\lambda_1$ by $\lambda_2$ by $\lambda_3$, then the strain invariants $I_1$, $I_2$, and $I_3$ are defined as

$$I_1=\lambda_1^2+\lambda_2^2+\lambda_3^2,$$
$$I_2=\lambda_2^2\lambda_3^2+\lambda_3^2\lambda_1^2+\lambda_1^2\lambda_2^2$$

and

$$I_3=\lambda_1^2\lambda_2^2\lambda_3^2. \tag{1}$$

If the material is isotropic in its undeformed state, the energy stored in the deformed cube is defined as the stored-energy function for the material. It must be a function of $I_1$, $I_2$, and $I_3$, provided it depends only on the state of deformation of the cube and not on the manner in which the deformation is reached. Once the form of this

---

* Presented at the meeting of the Division of High Polymer Physics, American Physical Society, January 30–February 1, 1947.

[1] R. S. Rivlin, Phil. Trans. Roy. Soc. A (pending publication).

[2] M. Mooney, J. App. Phys. 11, 582 (1940).

function is specified, the mechanical properties of any body of this material are, in principle, completely determinate and are purely a matter for calculation, provided such phenomena as internal friction and creep are negligible.

For an incompressible material, the volume of the cube considered is unaltered in the deformation, so that

$$I_3=\lambda_1^2\lambda_2^2\lambda_3^2=1. \tag{2}$$

Then $W$, the stored-energy function, is given by

$$W=W(I_1, I_2). \tag{3}$$

In general, the form of the function $W(I_1, I_2)$ will be such that when the body is undeformed $W=0$.

### III. THE TORSION OF A RIGHT-CIRCULAR CYLINDER

Let us consider a right-circular cylinder of radius $a$ and length $l$ of incompressible material, for which the stored-energy function $W$ is given by (3). It has been shown that, in such a body, a pure torsion, in which each circular cross section of the cylinder is turned in its own plane through an angle $\phi(=\psi z)$ proportional to its distance $z$ from one end, can be maintained by the application of surface tractions alone. The necessary system of surface tractions is indeterminate to the extent of an arbitrary hydrostatic pressure, but if the surface tractions applied to the curved surface of the cylinder are zero, then the surface tractions which must be applied to the plane ends have been calculated as

(*i*) tangential surface tractions $\Theta$ acting azimuthally in the deformed state of the cylinder (these effectively act as a torsional couple on the cylinder), and
(*ii*) normal surface tractions $Z$.

$\Theta$ and $Z$ are measured per unit area of the surfaces on which they act and their distribution over the plane ends of the cylinder and dependence on $\psi$ are given by

$$\Theta=2\psi r\left(\frac{\partial W}{\partial I_1}+\frac{\partial W}{\partial I_2}\right)$$

and

$$Z=-2\psi^2a^2\frac{\partial W}{\partial I_2}+2\psi^2\int_a^r r\left\{\left(\frac{\partial W}{\partial I_1}-2\frac{\partial W}{\partial I_2}\right)-2\left[\frac{\partial^2 W}{\partial I_1^2}+(3+\psi^2r^2)\frac{\partial^2 W}{\partial I_1\partial I_2}+(2+\psi^2r^2)\frac{\partial^2 W}{\partial I_2^2}\right]\right\}\cdot dr. \tag{4}$$

$r$ is the distance of the point considered from the axis of the cylinder. $\partial W/\partial I_1$, $\partial W/\partial I_2$, $\partial^2 W/\partial I_1^2$, etc., are, in general, functions of $I_1$ and $I_2$ which can be calculated if the form of $W(I_1, I_2)$ is known. For the deformation considered,

$$I_1=I_2=3+\psi^2r^2. \tag{5}$$

We shall consider here two particular choices of the form of the stored-energy function $W$ for which Eq. (4) are considerably simplified.

In the series of papers[1] mentioned above, particular attention was paid to the stored-energy function given by

$$W=C_1(I_1-3), \tag{6}$$

when $C_1$ is a physical constant characterizing the material. Materials for which Eq. (6) are valid were described as incompressible, neo-Hookean materials.

The particular interest residing in this choice of the stored-energy function rests on the facts that

(*i*) it is the simplest choice that can be made, from the point of view of the formulation of a theory of large elastic deformations;
(*ii*) it is the form derived by Treloar,[3] for an ideal rubber, on the basis of the kinetic theory of large elastic deformations.

Equation (6) is a particular form, obtained by making $C_2=0$, of the relation

$$W=C_1(I_1-3)+C_2(I_2-3), \tag{7}$$

which was first suggested by Mooney[2] as suitable for describing the elastic properties of rubber. It is noted that Eq. (7) involves two physical constants for the material, $C_1$ and $C_2$.

If the relation (7) is introduced into (4), we

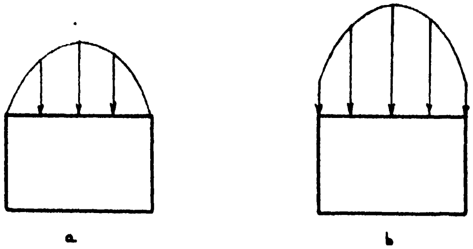

Fig. 1. Distribution of normal surface traction over plane ends of cylinder in pure torsion.
(a) When $W = C_1(I_1 - 3)$
and
(b) when $W = C_1(I_1 - 3) + C_2(I_2 - 3)$.

obtain

$$\theta = 2\psi r(C_1 + C_2)$$

and

$$Z = -2\psi^2 a^2 C_2 - \psi^2 (a^2 - r^2)(C_1 - 2C_2). \quad (8)$$

The equations for $\Theta$ and $Z$, when $W$ takes the form (6) can, of course, be obtained by putting $C_2 = 0$ in (8).

We see that if the physical properties of the material are represented by either Eqs. (6) or (7), the force $Z$ which must be exerted at each point is proportional to the square of the amount of torsion. If Eq. (6) applies, $Z$ must everywhere have the nature of a thrust (since $C_1$ is essentially positive), which is distributed over the diameter of a plane end as shown in Fig. 1(a). If Eq. (7) applies, then $Z$ does not vanish at the periphery (where $r = a$) and provided $C_2$ is positive and sufficiently small compared with $C_1$, its distribution will have the form shown in Fig. 1(b).

### IV. EXPERIMENTAL PROCEDURE

The experiments which will be described in this paper have as their object the study of the distribution of the normal force $Z$ defined in the previous section and its dependence on the amount of torsion.

In a preliminary qualitative experiment a rubber cylinder of pure gum compound, with brass plates bonded onto its plane ends, was subjected to a torsional couple by means of a lever attached to one of the ends while the other end was held in a vise. It was found that unless a longitudinal thrust was intentionally exerted parallel to the axis of the cylinder, the cylinder elongated, its axial cross section before and after torsion being shown roughly in Fig. 2. This simple experiment bears out the mathematical conclusion that a pure torsional couple does not give rise to a pure torsion. Clearly, if a pure torsion is to be obtained, normal compressive forces, whose resultant must have the nature of a thrust, must be exerted over the plane ends of the cylinder. This is in general agreement with the theoretical predictions outlined in the previous section.

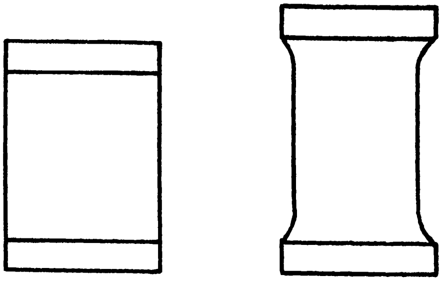

Fig. 2. Axial cross section of cylinder before and after twisting by a couple.

Consequently, an apparatus was designed in which the pure gum cylinder, to whose plane ends brass disks are bonded, is restrained from elongating. So, when one disk is rotated with respect to the other by the application of a torsional couple, the longitudinal thrusts required for the production of a pure torsion in the rubber cylinder are automatically called into play. The upper brass disk $A$ contains five circular holes, each ½-inch in diameter, varying in distance from the center and spaced as shown in Fig. 3, in order to have as little mutual interaction as possible. The lower disk $B$ has rigidly attached to it a steel disk $C$.

The assembly of rubber cylinder and disks $A$, $B$, and $C$ is held in a robust steel frame $D$, as shown in Fig. 4. The upper disk is rigidly attached to the frame and the lower disk is capable of being rotated in its own plane about its axis, by means of a crowbar which is introduced into one of a series of holes in the steel disk $C$. Provision is made for holding the cylinder in a state of torsion by means of steel pegs, which can be introduced into one of the holes $E$ in the frame. A scale is also provided for measuring the angle through which the lower disk is rotated.

When this disk is rotated, the rubber bulges slightly in the holes in disk $A$ and the amount of this bulging is assumed to be proportional to the thrust which would have to be exerted to prevent the bulging.

The bulging represents a small deformation superposed on a relatively large torsional deformation. At each of the holes this torsional deformation approximates to a state of simple shear of an amount depending on the amount of the torsion and the position of the hole considered. The assumption that the amount of bulging is proportional to the normal force tending to produce it is equivalent to an assumption that the former does not depend greatly on the state of simple shear on which the bulging deformation is superposed. There are certain theoretical reasons for assuming that this is approximately valid in the experiments described here.

In order to produce a simple extension in a cylinder superposed on the simple torsion, an additional normal surface traction must be exerted over each of the plane ends. If the stored-energy function for the material of the cylinder has the form (6), it has been shown[1] that this additional normal surface traction is independent of the amount of torsion and of position on the surface of the cylinder. The stress distribution in the neighborhood of the hole is complex, but for small deformations, it is reasonable to assume that the amount of bulge in each hole is dependent only on the force tending to produce the bulging and not on the amount of torsion or position of the hole, except insofar as this force is determined by them. This conclusion should be approximately valid if the stored-energy function has the form (7), provided $C_2$ is small compared with $C_1$. However, there is no reason to believe that it should be true for every possible form of the stored-energy function.

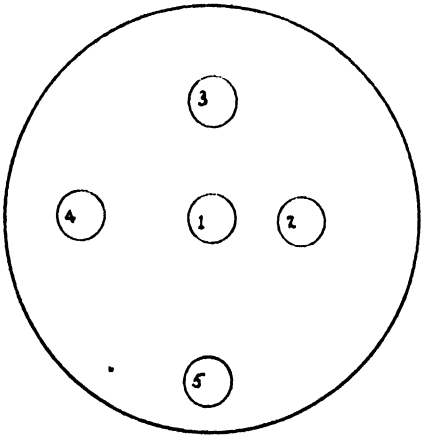

FIG. 3. Upper brass disk vulcanized to rubber cylinder.

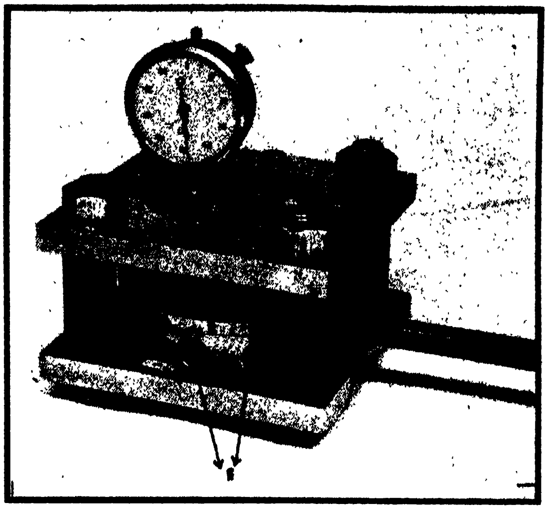

FIG. 4. The torsion apparatus.

The amount $d$ of the bulging in each of the holes is measured at the center of the hole, for various angles of rotation $\theta$ of the disk $B$, by means of a dial gauge. The top of the disk $B$ is ground flat and used as a reference plane in carrying out this measurement.

## V. EXPERIMENTAL RESULTS

If Eq. (8) is valid for $Z$, then the relation between $d$ and $\theta$ should be

$$d = K\theta^2[2a^2C_2 + (a^2 - r^2)(C_1 - 2C_2)], \qquad (9)$$

where $K$ is some constant of proportionality. $r$ is now taken as the distance of the center of the hole from the center of the disk. This assumption is justified if the radius of each hole is small compared with that of the cylinder, but it is impracticable to make it too small as the values of $d$ are thereby reduced. The repeatability with which $d$ could be measured in the experiment was estimated as ±0.002 in. using the same dial gauge. The accuracy with which $\theta$ could be measured in the arrangement employed was $\pm\frac{1}{2}°$.

The gum compound used had the following

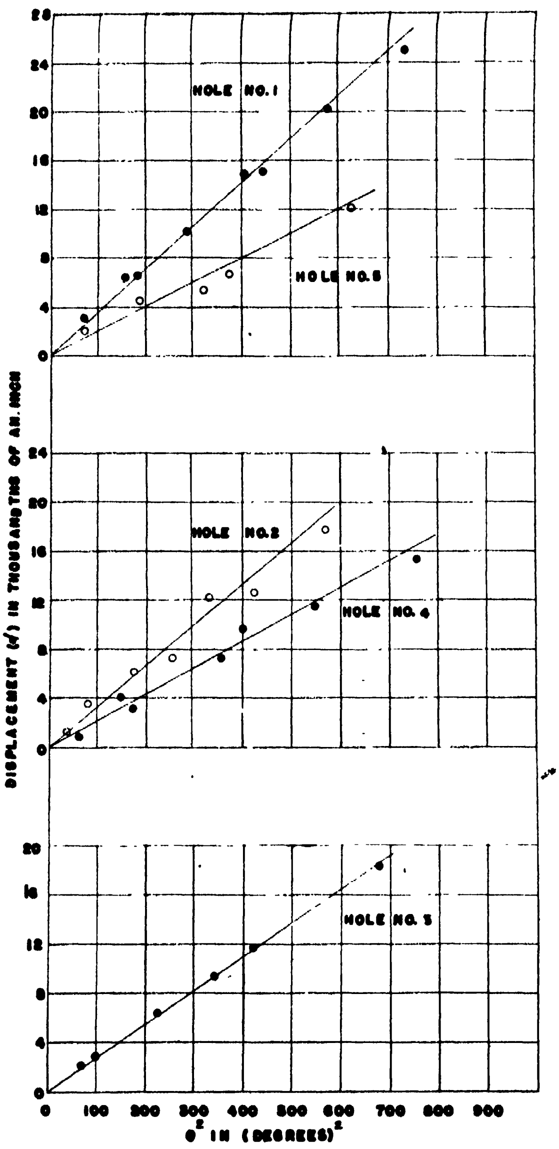

FIG. 5. Relation between displacement and the square of the angle of torsion.

composition in parts by weight:

| | |
|---|---|
| Rubber | 100 |
| Sulphur | 3.0 |
| Captax | 0.8 |
| Stearic acid | 1.0 |
| Agerite | 1.0 |
| Zinc oxide | 5.0 |
| Tuads | 0.08 |

The mix was vulcanized for 30 min. at 134°C. In order to produce a strong bond between the brass plates, a "tie gum" layer, less than $\frac{1}{32}$" thick, was introduced between the main rubber cylinder and each of the brass plates, and a cement marketed as "Reanite, No. 3615" was employed. The composition of the "tie gum" layer was, in parts by weight,

| | |
|---|---|
| Rubber | 100 |
| Stearic acid | 1.0 |
| Sulphur | 3.5 |
| Captax | 1.0 |
| Zinc oxide | 5.0 |
| Thermatomic black | 40 |

The rubber cylinder employed had a radius of 2.12 in. and length of 1 in. The holes in disk $B$ each had a diameter of $\frac{1}{2}$ in. and the distances of their centers from the center of the disk are given in the following table:

| Hole number | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| $r$ in inches | 0 | .85 | 1.18 | 1.47 | 1.69 |

Equation (9) suggests that the results of the experiments be plotted as a relation between $d$ and $\theta^2$ on linear graph paper. This should yield a straight line passing through the origin for each hole.

This is done in Figs. 5 for each of the five holes, and it is seen that the linear relation between $d$ and $\theta^2$ of Eq. (9) is borne out within the accuracy of the experiment.

The slope $m$ of the straight line obtained for each hole is the value of $K[2a^2C_2+(a^2-r^2)\times(C_1-2C_2)]$ for that hole, and if this is plotted against $(a^2-r^2)$ a straight line should be obtained, which passes through the origin if $C_2=0$ and otherwise gives an intercept of $2a^2C_2K$ on the $m$-axis. If $m$ is plotted against $(a^2-r^2)$ as in Fig. 6, it is seen that within the accuracy of the experiment the relation (9) between $d/\theta^2$ and $(a^2-r^2)$ is again borne out.

If $m_0$ is the intercept of the straight line in Fig. 6 on the $m$-axis and $b$ is its slope, we have $m_0=2a^2C_2K$ and $b=K(C_1-2C_2)$. Whence

$$\frac{C_1}{C_2}=\frac{2b}{m_0}a^2+2. \tag{11}$$

From measurements on Fig. 6, we obtain

$$m_0=10\times10^{-6}\text{ in. deg.}^{-2},$$

and

$$b=5.65\times10^{-6}\text{ in.}^{-1}\text{ deg.}^{-2}$$

so that

$$\frac{C_1}{C_2}=7.1.$$

Mooney[2] uses the constants $C_1$ and $C_2$ to define three additional constants as follows:

$$G=2(C_1+C_2)$$
$$H=2(C_1-C_2)$$

and

$$\alpha=H/G.$$

He then shows that the constant $G$ is the modulus of rigidity of the material. The constant $\alpha$ is named the coefficient of asymmetry. From the definitions it follows that

$$\alpha=\frac{C_1/C_2-1}{C_1/C_2+1}.$$

Consequently, the experimental results presented here lead to a value of 0.75 for the coefficient of asymmetry of the pure-gum compound studied. This is somewhat larger than the values found for two compounds studied by Mooney. Further work would be required to establish the variation of $\alpha$ with the nature of the compound.

## VI. CONCLUSIONS

The experiments bear out the general conclusion of the theory that in order to produce pure torsion in a rubber cylinder, normal surface tractions must be exerted on the plane ends and that these surface tractions vary with the amount of torsion and the position on the plane end of the cylinder. If the assumption is made that the amount of bulging in each hole is proportional to the force producing it and does not depend on the state of local strain on which the bulging is superposed, then the results of the experiments are in accordance with the assumption of an expression of the form (7) for the stored-energy function of the rubber. It has already been pointed out by Mooney that a stored-energy function of this form describes the linear shearing stress *vs.* amount of shear relation for rubber in simple shear, with a fair measure of accuracy, up to reasonably large deformations. Also, Treloar[4] has recently obtained results in agreement with this for pure, homogeneous strain of a sheet of rubber.

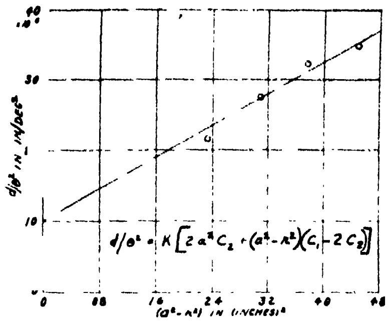

FIG. 6. Relation between slopes of lines in Fig. 5 and positions of holes.

The form (6) for the stored-energy function is that derived from the kinetic theory of rubber-like elasticity. Load *vs.* deformation relations derived from this have been compared with experimental results for simple types of deformation and have yielded fairly good agreement, depending on the type of deformation employed.

It appears then that the form (6) for the stored-energy function provides a first approximation to the stored-energy function for vulcanized rubber and that a second approximation is provided by the form (7). The differences between these forms are more or less accentuated depending on the type of deformation studied.

## VII. ACKNOWLEDGMENTS

This work forms part of a program of fundamental research on rubber undertaken by the Board of the British Rubber Producers' Research Association. The work was carried out at the National Bureau of Standards, Washington, D. C., where the author is at present a guest worker. The author is indebted to W. L. Holt of the National Bureau of Standards for advice and assistance in connection with the mechanical design of the apparatus.

# Elastic Losses in Some High Polymers as a Function of Frequency and Temperature*

H. S. SACK, J. MOTZ,** H. L. RAUB, AND R. N. WORK
*Cornell University, Ithaca, New York*

The frequency and temperature dependence of the elastic losses of polyvinyl chlorides (0° to 80°C, 60 to 1400 c.p.s.) and of natural rubber and butadiene-styrene copolymers (GRS) of different relative concentration (−50° to 35°C, 20 to 3500 c.p.s.) was studied by 3 methods, in which the motion of a reed in free or forced vibration is observed. Natural rubber at temperatures above 20°C, and polyvinyl chloride exhibit frequency independent losses, the mechanism of which is not yet clear. The results for rubber below 20° and for GRS can be explained by a relaxation theory. The behavior of the elastic losses also reflects the existence of a second-order transition, below which rotation of chain segments is hampered.

## 1. INTRODUCTION

AMONG the theories of elastic losses in solids, the so-called relaxation theory has lately received considerable attention.[1] According to this theory the reaction of a body to an applied strain is not instantaneous but requires a finite time which is determined by the molecular constitution of the material.[2] The time which is characteristic of the speed with which molecules will move towards their new equilibrium position when a stress is set up is called the relaxation time. This theory is the analogue to Debye's[3] theory of anomalous dispersion of dielectrics, and has been discussed for simple and more complicated models in many publications. It will suffice, here, to recall that according to this theory the elastic losses—defined as energy loss per cycle (often called $Q^{-1}$)—should rise linearly with frequency $\omega$ for low frequencies, and decrease as $1/\omega$ for high frequencies. The shape of the maximum in the intermediate region depends on the number of relaxation processes and, therefore, on the relaxation times that are present. This analogy between dielectric and elastic properties has been emphasized particularly in a recent publication of Kirkwood,[4] in which he applied to elastic phenomena a treatment which he formerly had applied to dielectric behavior where he calculated the distribution of relaxation times on the basis of a diffusion process of the single groups of the long chain molecules in high polymer substances.[5]

So far, little experimental evidence for the existence of this relaxation phenomena has been found, at least in experiments in which the elastic losses under alternating stresses are measured.[6] The aim of the work here presented was to find cases in which the relaxation theory would apply. High polymer molecules seem particularly suited for such a study because these molecules show a high degree of mobility, and their motion seems to be sufficiently slow so that it can be hoped that a relaxation time may be found in a low frequency region. It is also known from dielectric measurements that such relaxation phenomena do exist in these substances.

As a starting point the series of polyvinyl chlorides were chosen because Fuoss[7] observed dielectric relaxation in a region around 1000 c.p.s. However as will be discussed later, no elastic

relaxation was observed. More success was obtained with elastomers, in particular with synthetic rubber. The experimental procedure and results will be discussed in the following.

## 2. EXPERIMENTAL PROCEDURE

Three different methods for the determination of the elastic losses were used: (a) The observation of the half-widths of the resonance curve of a reed in forced vibration, (b) the measurement of the damping properties of a free vibrating body, and (c) the measurement of the (elastic) hysteresis loop.

The first and second methods are only applicable if the damping is relatively low. The last method is, in principal, free from this restriction, but the interpretation of the measurements is easier for high damping. The last method has the advantage, that it permits the measurement of the elastic losses over a wide range of frequencies, without need for changing the sample, while for methods (a) and (b) samples of different lengths have to be studied, in order to measure the elastic losses at different frequencies.

In all three cases, the sample, in the form of a reed approximately 2 mm thick and 4–15 mm wide, and of appropriate length, was clamped on one end, while an alternating force could be applied to the other end. In the first experiments this force was applied by an electrostatic method: One side of the reed was covered with a very thin metal foil and opposite the reed, separated by a few mm, was placed an electrode so that an alternating potential could be applied between the reed and this electrode. This gives rise to an alternating force of twice the frequency of the applied potential. (If a d.c. potential is superimposed, it is possible to create an alternating force of the same frequency.) In later measurements a small coil was attached to the end of the reed, and the reed was so mounted that this coil is in the air-gap of a strong speaker magnet. An alternating current set up in the coil then creates an alternating force on the reed.

The motion (vibration) of the end of the reed is observed by an optical method. The end of the reed protrudes into a light beam. If the reed vibrates, this light beam is thus modulated, and in falling on a photo-cell creates an a.c. signal proportional to the amplitude of vibration. This signal is then amplified. Figure 1 shows diagrammatically the optical arrangements and the attachment of the coil to the reed, in (a) for a lateral vibration, and in (b) for a longitudinal vibration. In the later experiments the whole device was made as small and compact as possible in order to avoid outside disturbances. Figure 2 reproduces a photo of the complete assembly mounted on a solid base plate. This picture represents the case of longitudinal vibration. For flexual vibrations a different clamping block is used. The screws on top of the light-bulb holder serve to adjust the light beam so that maximum modulation and, therefore, maximum sensitivity are obtained. For the study of variations with temperature the complete system was put in an automatically controlled constant-temperature box. (This arrangement is, of course, only workable for temperatures not higher than approximately 70°C.)

With the compact optical system as shown in Fig. 2, it was necessary to define the end of the reed more sharply by attaching to it a thin metal edge. The photo-current is first amplified by a preamplifier driven by batteries, and then by a conventional audiofrequency amplifier. The driving potential or current was delivered by an audio oscillator, and kept constant over the whole frequency range. The frequency could be recorded within 1 percent.

In case (a) (resonance curve), the output of the photo-amplifier was read on an a.c. meter giving a direct measure of the amplitude of vibration, which, when plotted as a function of frequency, gives a resonance curve whose half-width is easily determined. This method is precise for low or moderately high damping. For higher damping, the resonance peak becomes very wide and may be distorted by higher harmonics or parasitic reasonances in the system.

In case (b) (free vibration), the reed is deflected from its rest position by a d.c. potential or current. By opening a switch, the current or potential is interrupted and the reed returns to its equilibrium position executing a damped vibration. The output of the photo-amplifier is applied to the deflecting plates of an oscilloscope. At the time, the switch is opened, starting the vibration of the reed, a linear sweep of adjustable speed is applied to the other set of the plates of the oscilloscope. Thus, on the screen appears the picture of the damped vibration, from which the logarithmic decrement can be calculated by measuring successive amplitudes. Figure 3 reproduces two sets of pictures obtained with two materials of different constitution. The four pictures in each set represent different frequencies of vibration as indicated by the time-scale. The set at the left represents a material in which the damping increases very strongly with increasing frequency, whereas in the set at the right the damping is nearly independent of frequency. Again, this method is only usable for low damping.

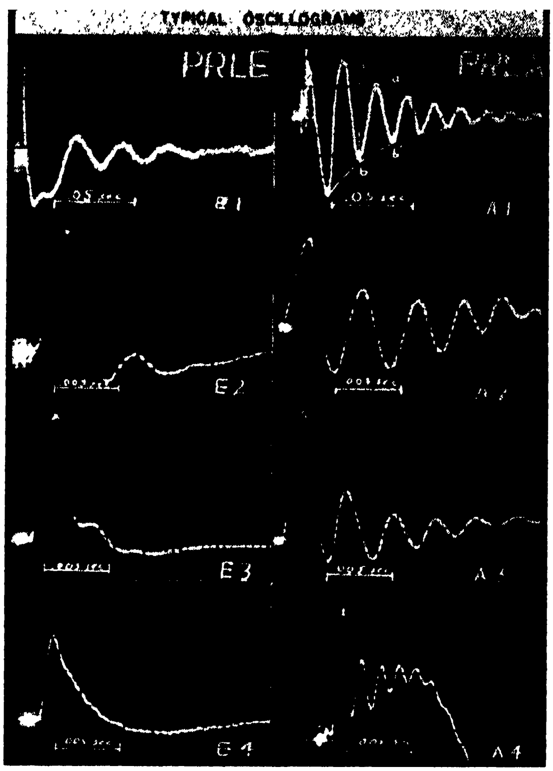

FIG. 3. Examples of damped free vibrations: butadiene-styrene, left 50/50, right 70/30.

In case (c) (hysteresis loop), the procedure is somewhat more complicated. The output of the photo-amplifier is again applied to one set of plates of the oscilloscope. To the other pair of plates a potential is applied which is taken across a resistor in series with the driving coil. Since the driving force is proportional to the current in the coil, this signal is proportional to the force. Thus there will appear on the screen the elastic hysteresis loop of the material (stress-strain diagram). The area of this hysteresis loop is a measure of the damping qualities of the material. In fact, if divided by the square of the amplitude, it is proportional to the energy dissipated per cycle divided by the total energy of vibration. In this method, the two signals must appear on the oscilloscope screen without phase differences caused by the electric system. As phase differences in amplifiers are unavoidable, a phase shifter is added to the system. This phase shifter is calibrated for each frequency by replacing the sample by a metal reed. It is known that for a metal like brass the phase shift between the vibration and the applied force is near 0 or 180°, except for a narrow region around resonance. If with this metal reed the stress-strain curve appearing on the oscilloscope screen is not a straight line, then there exists a phase shift in the electrical system, and it can be compensated for by an adjustment of the phase shifter. The accuracy of this phase adjustment proved to be one of the main difficulties of this method, especially for measurements at frequencies far away from resonance.

In order to have a relative measure of the amplitude, another signal derived from a resistance in series with the coil is passed through the photo-amplifier system. As the current in the coil is kept constant, a variation of this signal as it appears on the oscilloscope screen is a measure of the change in amplification of the photo-amplifier.

The pattern on the oscilloscope screen is photographed, and the area of the hysteresis loop measured with a planimeter. This area is then divided by the square of the maximum amplitude as determined with the help of the calibration line mentioned above.

## 3. INTERPRETATION OF MEASURED QUANTITIES

The quantities determined by the three sets of experiments are: the half-width of the resonance curve $\Delta\omega/\omega_r$ (where $\Delta\omega$ is the difference in frequency for two points where the amplitude of vibration is $\frac{1}{2}$ the amplitude at resonance frequency $\omega_r$); the logarithmic decrement $\delta$; and the energy $W$ dissipated during one cycle, divided by the square of the amplitude $y$, i.e., $W/y^2$. In order to discuss the elastic properties in terms of molecular properties, it is necessary, first, to relate the measured quantities to material constants. In the case of forced vibrations this can be done by introducing a complex modulus of elasticity, e.g., a complex Young's modulus for longitudinal vibrations, $E'+iE''$, which might be frequency dependent. For small damping $(E''/E'\ll 1)$ the same complex modulus can be used in treating the case of free vibrations. In the case of $(E''/E')\ll 1$, the following relations exist $\Delta\omega/\omega_r=\sqrt{3}(E''/E')$; $\delta=\pi(E''/E')$, where $E''$ and $E'$ have the values at the resonance, or free vibration frequency, respectively. $W/y^2$ is proportional to $E''$, with a proportionality constant which depends, in contrast to the two other formulas, on the dimensions of the reed, the boundary conditions etc. (For a free-clamped, thin reed of length $l$ this constant is $\pi^2/8l$.) This proportionality is only valid for frequencies below a certain frequency, which is low for low damping and high, for high damping. For frequencies beyond this limit, deviations from proportionality occur that have to be calculated for each particular case. The same complication arises for the other two methods if the damping is no longer small. In all these cases of nonproportionality it is necessary, in order to calculate the higher approximations to know the exact mechanism which gives rise to the losses, and which determines the frequency dependence of the elastic modulus. These calculations were made under the assumptions of a thin reed, clamped at one end, and acted upon by the external force on the other end, whose motion was observed. The damping mechanism was assumed to be of the viscous type, and the frictional force was written as $K(\partial\epsilon/\partial t)$, where $\epsilon$ is the deformation. In this case $E''=K\omega$. Further calculations were made with putting $E''=\text{const.}$, without specifying the mechanism that would yield this type of loss, since such a mechanism is not yet known. The experimental results were then corrected with the help of the formulas thus derived. Since the assumptions are only approximations to the real case, no data were used where the corrections exceeded 30 percent.

In the hysteresis loop method, the evaluation of $W/y^2$ in absolute units is rather cumbersome. Therefore the width of the resonance curve was measured simultaneously, at least at one temperature. This value was used to calculate the proportionality constants. The results were expressed directly in terms of $\Delta\omega/\omega_r$, and are plotted in these terms in the figures. ($E''(\omega)$ is then the value taken from the graph multiplied by $E'$ at the resonance frequency and at the temperature where resonance is observed, and divided by $\sqrt{3}$.)

## 4. EXPERIMENTAL RESULTS AND DISCUSSION

### (a) Generalities

In all the experiments the amplitude of vibration was so small that the maximum strain was not bigger than 0.1 percent. Under these conditions it proved that all the effects are linear. With the exciting force varying by a factor 5 to 10 in amplitude, no change in the losses was observed. Also the vibration remained sinusoidal (no appearance of harmonics). Furthermore the hysteresis loop has the form of an ellipse within a very good approximation (deviations from the ellipse

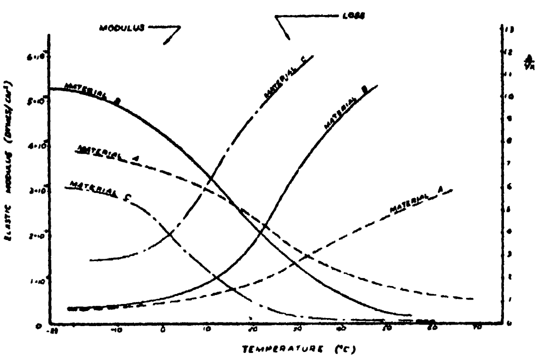

FIG. 4. Young's modulus and elastic losses of polyvinylchloride with 20 percent ($A$), 30 percent ($B$) and 40 percent ($C$) plasticizer.

correspond to an harmonic content of not more than 1 or 2 percent).

The influence of the "tightness" of clamping appears to be negligible for the loss measurement.

The metal foil glued to the reed in the electrostatic method, and the coil and coil supports used in the electrodynamic method, were replaced by similar attachments of different weight or geometric form, and proved to have no influence upon the measured elastic losses.

In most cases measurements were repeated, if possible with reeds of different width or length. Good reproducibility was observed. The error for the losses is approximately ±10 percent.

As will be seen later, very high losses, of an equivalent of approximately 100 for $\Delta\omega/\omega$, were observed under certain conditions. Such high values have to be interpreted with caution, as they mean that all the energy supplied by the outside force is dissipated in a very small region near the point where the force acts, and it is not excluded that the way in which the coil is connected to the reed has an effect; also the formula used for the calculation will probably receive additional correction terms, which cannot be evaluated exactly.

### (b) Polyvinyl Chlorides

Three samples were measured.[8] Material $A$ contained 80 percent polyvinyl chloride and 20 percent tricresyl phosphate, $B$, 70 and 30 percent, and $C$, 60 and 40 percent. All measurements were made by the first method (resonance curve). In Fig. 4 the results for Young's modulus and the half-widths of the resonance curve are indicated as a function of temperature. Young's modulus was calculated from the measured resonance frequency assuming a free-clamped, thin reed (or a clamp-clamped reed) in flexural vibration. By choosing different lengths of the reed, and by vibrating it as free-clamped or clamp-clamped, a series of resonance frequencies are obtained in the range of approximately 100 to 1400 c.p.s. The values obtained at these different frequencies agree within the experimental error with the curves drawn in Fig. 4. We can, therefore, conclude that in this frequency range, no dispersion occurs. This means that in our experiments we do not find a relaxation phenomena as it would have been suggested by the dielectric measurements made by Fuoss on the same substances in the same frequency and temperature range. This does of course not necessarily mean that such relaxation phenomena are absent, but if they are present, they are masked by other processes which are of greater importance and yield frequency independent losses.

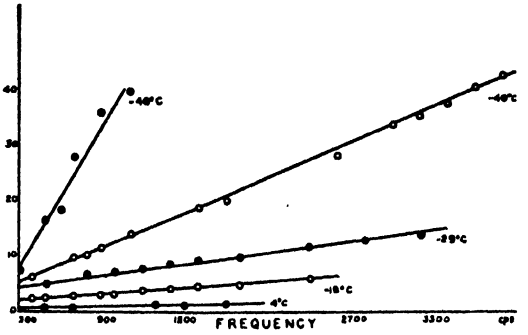

FIG. 5. Losses of natural rubber.

From Fig. 4 it can be seen that Young's modulus decreases with increasing temperature, while the losses increase. This can be explained by the "loosening" of the structure, and the increased tendency to flow. It should also be mentioned that static measurements of Young's modulus, at room temperature and with small stresses, were made, which yielded from 4 to 10 times higher values than those obtained by the vibration method. This seems to indicate that a dispersion zone must be present below the frequency range here studied.

---

[8] We are obliged to Dr. Fuoss, at that time at General Electric, for providing us with these samples.

### (c) Natural Rubber

The sample studied was natural gum stock with 3 percent sulphur. For temperatures between 5 and 55°C measurements were made with all 3 methods, yielding identical resuts; for lower temperature, down to $-46$°C, only the hysteresis-loop method proved workable. The frequency range was 20 to 900 c.p.s. for the first two methods, and 300 to between 1500 and 3500 (depending on the temperature) for the third method. Figure 5 reproduces the results for temperatures below 4°C, and shows that the losses rise linearly with frequency (but the line does not go through the zero). Measurements at temperatures above 10°C are not included in the diagrams. They yield for 20 to 1300 c.p.s., a constant value of 0.2 for 22°C, and slightly lower for higher temperature. (A slight rise of approximately 10 percent would also be compatible with the measurements.)

Where a comparison can be made, our results are in good agreement with those of Stambaugh,[9] and other earlier investigators. The frequency independent losses at higher temperatures can be represented, in a formal way, by a constant $E''$. However, as mentioned, no simple mechanism is known that would yield this result. Some speculations concerning this mechanism were given earlier,[10] but no new evidence in favor of or against it has been obtained. The losses at lower temperatures can be represented by the superposition of a frequency independent part and a viscous term, $E''=K\omega$, where $K$ could be called a coefficient of viscosity. The same frequency dependence would result from a relaxation phenomenon with measurements made below the relaxation time (or zone of relaxation times). In fact, for low frequency, the relaxation theory gives a molecular picture of viscous flow. Figure 6 shows how this coefficient of viscosity increases with decreasing temperature.

Resonance frequencies could be observed above $-18$°C. These values indicate that Young's modulus is rising slightly with decreasing temperature (20 percent increase from 22°C to $-18$°C).

### (d) Butadiene-Styrene Polymers

The samples[11] were unloaded and contained 1 percent sulphur, 0.5 percent BLE and 0.3 percent tetramethylthiuramonosulfide. The content of butadiene to styrene was 70/30; 65/35; 60/40; 55/45; 50/50. For the first 4 samples, at 22°C, all 3 methods were used, and gave identical results. The last sample at all temperatures, and the others below 22° were only investigated by the hysteresis-loop method. As an example Fig. 7 reproduces a set of curves observed for the 60/40 sample. For higher temperatures than those given in the figure, the losses are lower, and the bending is less pronounced. In Fig. 6 the slope of the linear part (low frequencies) is given as a function of temperature for this sample, and for 70/30 and 50/50. It appears that the temperature variation of this slope has the same shape, but is shifted to higher temperatures wih higher styrene content.

The characteristic feature in Fig. 7 as compared to the figure for natural rubber (Fig. 5) is the

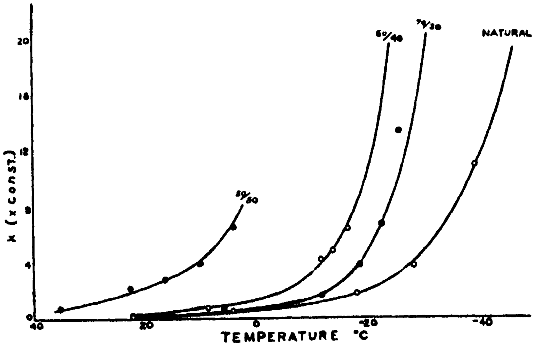

Fig. 6. Temperature dependence of "viscosity coefficient" (slope of loss-frequency curve).

[11] These samples were kindly given to us by the U. S. Rubber Company.

appearance of a peak in the curve. Again, the other samples show a similar behavior, except that the temperature at which the bending of the curve occurs, in the frequency range here studied, is higher for higher styrene content. For the 70/30 sample it does not yet occur above −26°C, while for 50/50 the bending is already pronounced at 16°C. This appearance of a peak can be interpreted as the result of a relaxation phenomenon, though the curves do not correspond exactly to those calculated with a single relaxation time.

Finally it is of interest to note that while at a constant frequency the losses increase first slowly and then more and more rapidly with decreasing temperature, this trend is reversed at very low temperatures (approx. −40°C for 60/40), and the losses decrease again. This fact stands out particularly well in looking at the change of the resonance curve. In lowering the temperature the resonance becomes wider, then is no longer observable, reappears again and becomes narrow. This characteristic temperature is higher for higher styrene content; for 70/30 it could not be observed above −50°C, the lower limit of our temperature range. This characteristic temperature is approximately the second-order transformation temperature of these substances.[12] As it is assumed that below the transformation point the segments of the chain-molecules "freeze in," and are no longer able to orient as freely as above this temperature, we may conclude that the relaxation phenomena observed are linked to this segment mobility. In agreement with this is the observation that the loss-frequency curve below this temperature has a different character from that above, and does not show the characteristic peak, at least not in our frequency range.

# Electrical Conductivity of GR-S and Natural Rubber Stocks Loaded with Shawinigan and R-40 Blacks*, **

P. E. Wack, R. L. Anthony, and E. Guth
*University of Notre Dame, Notre Dame, Indiana*

Measurements have been made of the direct current conductivity of rubbers loaded with carbon black. Shawinigan and Continental R-40 blacks compounded in natural rubber and GR-S were studied, and the resistivities were determined as functions of time, temperature, concentration and elongation. Resistance decreased with time, at first very rapidly, then more slowly, approaching an equilibrium value. This behavior seems to be independent of the type of black used. Temperature coefficients of resistance (at 50°C) were positive for Shawinigan stocks, negative for samples containing R-40, and tended to increase with increasing concentration of black and with increasing extension of the sample. At low concentrations, R-40 gave higher conductance in GR-S than did Shawinigan. At high loadings, Shawinigan gave the higher conductance in both GR-S and natural rubber. Resistance increased with elongation for all stocks containing R-40. The Shawinigan GR-S samples showed an inversion; for small elongations the resistance increased on stretching, but for higher extensions the resistance decreased. The results are interpreted on the assumption that the carbon black tends to form chains in the rubber matrix.

## I. INTRODUCTION

Carbon black has been used as a reinforcing agent in rubber-like materials for many years. In recent years special grades of carbon black have been developed which serve the purpose of not only reinforcing these materials but also of imparting to them some electrical conductivity. However, our knowledge of the exact mechanisms or processes, which are responsible for this reinforcing action and greatly increased electrical conductivity, is still far from complete. Both effects are closely related, and increased knowledge of one will aid our understanding of the other.

The reinforcing action of fillers has been dis-

cussed in a series of theoretical papers by Rehner,[1] Smallwood,[2] and Guth.[3] A general discussion of the effects of various types of carbon black in GR-S has recently been given by Parkinson.[4] The apparent tendency of the carbon black particles to form chains in the rubber, and possibly even a network structure at high carbon black concentrations has been pointed out by the aforementioned authors and others. Parkinson, in particular, has noted that, in some instances, there is strong evidence that the forces between carbon particles are greater than the forces between the carbon particles and the rubber. The possibility that in some cases the chain of carbon black particles may serve as the major reinforcing agent rather than the individual carbon black particles, was suggested by Guth.[3]

Past studies of the electrical conductivity produced in rubbers by carbon blacks have been confined chiefly to investigations of the effects resulting from varying the type of black, the particle size of the black, and the concentration of the black in the rubber. Cohan and Mackey[5] and Cohan and Steinberg[6] have shown that the specific resistance of a rubber compound at 20% volume concentration decreases with increasing purity of the black, decreases with increasing graphitic structure, and decreases exponentially with decreasing particle size. The progressive decrease in resistance with decreasing particle size had also been noted by Amon and Brown[7] in a study of the electrical resistance of carbon black inks. Hall, Buckley, and Griffith[8] have studied the dependence of the electrical resistance upon the concentration and structure of the black, using Shawinigan black in natural rubber and in GR-S. Bulgin,[9] in one of the most comprehensive papers published to date on this subject, discussed the dependence of the electrical conductivity in conducting rubbers upon the concentration of the black in rubber, its dependence upon the temperature, and its dependence upon the extension. Bulgin[9] employed a large variety of blacks and studied the behavior of these blacks in GR-S, GR-I, and in natural rubber.

In the work reported here, the conductivity has been studied much more completely than in any previous work as a function of time, temperature, extension, and concentration of the black in the rubber. The behavior of two types of conducting blacks, Shawinigan and Continental R-40, in both GR-S and in natural rubber, has been studied. The conductivity of the blacks themselves was also investigated as a function of temperature, under a pressure of approximately 2000 lb. per square inch.

This more complete study was carried out in the expectation that the results might indicate the state of aggregation of the black particles in the rubber and thus lead to conclusions about the relative strength of the carbon black-carbon black and the carbon black-rubber interaction. Since rubber is an insulator, appreciable conduction in a rubber stock loaded with conducting carbon black spheres can take place only if these spheres form a chain. Such chains in turn may form a lattice or network. Our results can be understood on the basis of a simple picture of the formation and breaking up of chains of carbon black particles. Carbon black particles are colloidal in size. To a first approximation, we may neglect the forces between them. Then we can consider the chain formation as a purely

kinetic phenomenon regulated only by chance. The probability of formation of a chain becomes appreciable only when the loading is sufficiently high. Changes in temperature and elongation cause a modification of structure of the carbon black chains. This will also change with time. It should be pointed out that the carbon black particles are connected to each other by the flexible long rubber molecules. In the unstretched state, the rubber molecules are curled up, in accordance with the kinetic theory of rubber elasticity. The flexibility of the rubber molecules will permit almost free translational kinetic (Brownian) motion of the carbon black particles, up to the limit given by the length of the rubber molecules. According to this picture, stretching of a loaded stock will limit the region in which the carbon black particles can move, and at sufficiently large extensions, the positions of the carbon black particles are more or less rigidly fixed.

## II. EXPERIMENTAL PROCEDURE

All stocks were mixed on a small laboratory size mixing mill and cured in a small platen press. The following base formulae were used for all stocks: Four different loadings of Shawinigan and of R-40 were employed in the GR-S and natural rubber stocks. These were 136.9 g, 80 g, 50 g, and 36.9 g. These loadings gave volume concentrations of 40 percent, 28 percent, 19 percent, and 15 percent, respectively, for the GR-S stocks, and 39 percent, 27 percent, 19 percent, and 15 percent, respectively, for the natural rubber stocks, the slight difference at the two highest loadings being caused by the difference in densities of GR-S and natural rubber. The volume concentration is defined here as the ratio of the true volume of the carbon black to the total volume of the cured rubber. The carbon black volume was calculated from its weight, employing the standard density value of 1.80 g/cm³. The densities (and volume) of the cured rubber stocks were determined by hydrostatic weighing at room temperature. It is of interest to note that the volume of cured loaded stock is equal to the sum of the volumes of the cured gum stock and of the carbon black, to within 1 percent or better, when the carbon black volume is calculated from the density value of 1.80 g/cm³. This was checked

by hydrostatic weighing of gum stocks and loaded stocks.

The tensile strength, elongation at break and Shore hardness are given in Table II below for the eight GR-S stocks, and in Table III for the eight natural rubber stocks.

Figures 1 and 2 show stress-strain curves at 30°C for the 19 percent and 28 percent concentrations in GR-S, and for the 19 percent and 27 percent concentrations in natural rubber. It is seen that for each loading the R-40 gives higher rigidity in both natural rubber and GR-S at low extensions than does the Shawinigan. At high extensions, the situation is reversed. An explanation for the higher rigidity of Shawinigan stocks at higher extensions will be suggested in connection with the interpretation of resistivity-extension curves (cf. Fig. 14). The data shown in Figs. 1 and 2 were taken with the fast stress-strain machine described in an earlier paper.[10]

The rubber was cured in the form of standard tensile sheets 6 inches square by $\frac{1}{16}$ inch thick. After an aging period of 24 hours or more, the samples for investigation were die-cut from these sheets. These samples were in the shape of square headed dumb-bells, the straight center sections having a width of 0.25 inches and a length of 2 inches. The ends of the samples were placed in flat aluminum clamps which covered only the enlarged end portions of the samples. The clamps served simultaneously as a means of stretching the rubber and also as electrical contacts to the sample. Resistivities of (stretched) samples were measured in the direction of the stretch. The coating of the sample ends with Aquadag before clamping made no appreciable difference in the over-all resistance measurements. After clamping, the samples were mounted in an oven by means of a rack capable of holding eighteen samples, each sample being individually mounted in a horizontal Pyrex glass tube. One end of each sample was held fixed at one end of the glass tube, the other end being attached to a copper rod which protruded through the door of the oven. The elongation of each sample could be adjusted and measured by means of these rods. The time required, after a temperature change, for equalization of temperature throughout the oven, including the interior of the samples themselves, was checked by means of a differential thermocouple. This waiting time was approximately 15 minutes after reaching the desired temperature, as read on a mercury thermometer centrally located in the oven. Good air circulation was maintained by means of a small fan mounted in the base of the oven. Resistances were measured with the aid of a Leeds and Northrup Type H.S. galvanometer and a 2-volt storage battery. For low resistance samples a Leeds and Northrup Testing Set, Model 5430, was also used. Specific resistances were then calculated for each sample from the known sample dimensions.

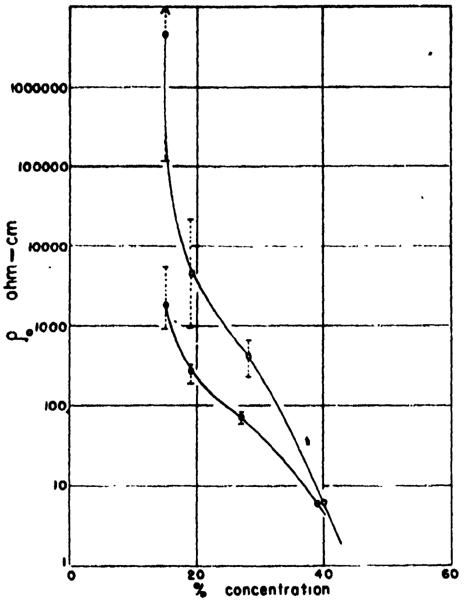

FIG. 5. Resistivity *versus* volume concentration of Shawinigan black at 70°C. Open circles denote GR-S stocks, and black circles denote natural rubber stocks.

The measurements on the carbon black were made in the oven by inserting the powder in a small Bakelite tube and maintaining a pressure of approximately 2000 lbs./in.$^2$ on the black by means of a piston and tension spring device. This pressure, along with considerable tamping down of the black while inserting it in the cylinder, gave apparent densities ranging from 0.36 g/cm$^3$ to 0.39 g/cm$^3$.

Figure 3 shows the oven with its door opened, and the rack in which the samples are placed. Figure 4 is a view of the oven with its door closed and shows the copper rods projecting through the door. The device employed in measuring the temperature coefficients of resistivity for the carbon blacks is seen in front of the oven.

Reversal of the direction of current flow during the measurements, as well as several checks employing 60 cycle current, gave no evidence of any important polarization effects, either in the rubber or in the carbon black.

## III. RESULTS

### A. Dependence of Resistivity Upon Carbon Black Concentration and Upon Time

Initial measurements of the resistivities of several samples showed that the resistivity for each sample was a function of the time which had elapsed after the sample had been cut out and mounted in the clamps in an unstretched condition. In all cases the resistance decreased with time, at first quite rapidly, and then more slowly, and appeared to be approaching a stable value. This behavior is easily explained using our picture of the rubber-black system. As the samples were molded, cured, and cut, strains were set up in their interior. These strains caused a breakage in the carbon black chains, thus leading to an increase in the resistance. In the course of time kinetic (Brownian) motion of the carbon black particles will lead to a re-forming of the chain structure and thus to a decrease in the resistivity. Any small temporary distortion of the sample, for example a small extension followed by an immediate retraction to zero extension, produced a relatively large increase in the resistance, which then decayed in the same manner with time again to a semi-equilibrium value. This behavior had been noted much earlier by Evans[11] and has since been pointed out by Bulgin and others. The approach to a steady state value of the resistance can be greatly accelerated by "annealing" the samples at elevated temperatures. This effect would seem to indicate that any sudden change in

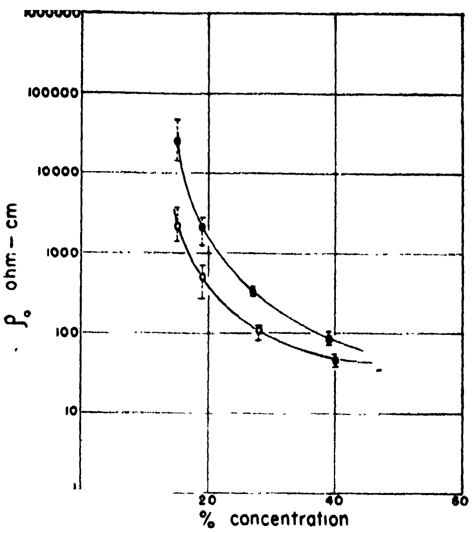

FIG. 6. Resistivity *versus* volume concentration of R-40 black at 70°C. Open circles denote GR-S stocks, and black circles denote natural rubber stocks.

---

[11] R. D. Evans, Paper presented at the meeting of the Ohio Academy of Science in 1930 and kindly made available to us by W. W. Vogt.

strain disrupts existing carbon networks, which subsequently tend to reform themselves. In the work described here all samples were annealed, in an unstretched condition, for a period of 10 hours at 70°C after they had been mounted in the oven. The value of the resistivity attained at the end of this initial annealing period is denoted by $\rho_0$ in this work. (It should be noted here that this value of resistivity is not really constant but rather continues to decrease slowly with time. However, the important consideration is that the rate of change of resistance with time must be so small that it cannot appreciably alter the results of some additional experiment.) Preliminary measurements also indicated wide variations between the resistivity values for samples which were supposed to be identical. Resistivities for samples cut from the same tensile sheets were found to vary, in some cases, by as much as a factor of ten. This was particularly true for the Shawinigan black– GR-S stocks at low carbon concentrations. The Shawinigan black—natural rubber stocks were somewhat more uniform. However, the continental R-40 stocks were much superior in this respect. At high concentrations the variations in resistivity values were much smaller for all stocks.

The dependence of $\rho_0$ upon the volume concentration of the carbon black in the rubber is shown in Figs. 5 and 6. Figure 5 shows the effect on resistivity of four concentrations of Shawinigan in both GR-S and natural rubber, and Fig. 6 shows the behavior of R-40 in these two rubbers. In these two figures each point is an average value of a large number of separate determinations on individual samples. The vertical line drawn through each point shows the range of $\rho_0$ values for each stock. Comparison of Figs. 5 and 6 shows that at low loadings R-40 gives better conductivity (lower resistivity) in GR-S than does Shawinigan. At the high loadings, Shawinigan gives better conductivity in both GR-S and natural rubbers. The R-40 natural rubber stocks have higher resistivities than the R-40 GR-S stocks. In the case of the Shawinigan black, however, the situation is reversed and here the GR-S stocks have the higher resistivities. The very rapid decrease of resistivity with increasing concentration of Shawinigan black at low concentrations, may explain in part the wide variations found in the resistivity values for identical stocks in this region. Slight variations in concentration of the Shawinigan, from sample to sample, might thus be expected to produce large changes in resistivity in the region of low loadings. Large variations in the resistivities of supposedly identical rubber stocks loaded with Shawinigan black were also found by Hall, Buckley, and Griffith.[8] They suggest that the effect may be due to variations in the degree to which the structure of the Shawinigan black has been broken down during the milling and curing processes.

To minimize the effects of variations in the value of $\rho_0$ and thus make possible better comparisons between different samples, when studying the dependence of resistivity upon extension, temperature and time, the relative resistivity, $\rho/\rho_0$, is employed in this work rather than the actual resistivity, $\rho$. Figure 7 shows the decrease in the relative resistivity with time during the annealing period for 19 percent volume concentrations of R-40 and Shawinigan in natural rubber. Figure 8 shows the decrease in this ratio

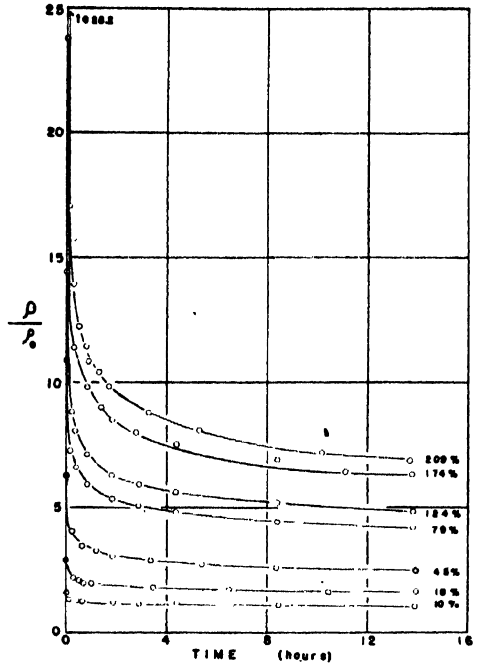

FIG. 9. Decay of resistivity with time at various extensions for a 19 percent volume concentration of R-40 in GR-S. Temperature = 70°C.

with time, during the annealing period, for the same concentrations of these blacks in GR-S. In general, this relative decrease with time was found to be larger for the GR-S stocks than for the natural rubber stocks, and it became progressively smaller for both stocks as the loadings were increased.

## B. Dependence of Resistivity of Loaded Stocks upon Extension

At the end of the 10-hour annealing period, the samples were stretched to various elongations, and the temperature was maintained at 70°C for an additional 14 hours. During this period the decay of resistivity with time was again observed. Figure 9 shows the decrease in the relative resistivity with time, at various extensions, for a GR-S stock containing a 19 percent volume concentration of R-40. These curves have been cross-plotted at times of 30 seconds and 14 hours to show the dependence of the resistivity upon the extension. This dependence is shown in Fig. 10. Figure 11 shows the decrease in $\rho/\rho_0$ with time, at various extensions, for a 19 percent concentration of R-40 in natural rubber. The

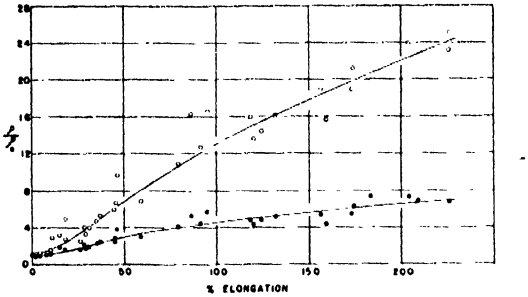

FIG. 10. Cross-plot of Fig. 9 showing the dependence of resistivity upon extension at times of 30 sec (open circles) and 14 hours (black circles).

corresponding dependence of $\rho/\rho_0$ upon the extension, at times of 30 seconds and 14 hours, is shown in Fig. 12. A very similar behavior was observed for the 15 percent and 28 percent concentrations of R-40 in GR-S and also for the 15 percent and 27 percent concentrations of R-40 in natural rubber. It was not possible to obtain data as a function of extension for the 40 percent loadings in GR-S nor for the 39 percent loadings in natural rubber, because of the extreme stiffness of these stocks.

Figure 13 gives the dependence of $\rho/\rho_0$ upon time for various extensions of a GR-S stock containing a 19 percent volume concentration of Shawinigan. A very pronounced inversion in the value of the relative resistivity as a function of

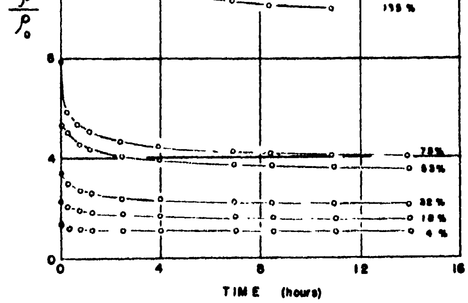

FIG. 11. Decay of resistivity with time at various extensions for a 19 percent volume concentration of R-40 in natural rubber. Temperature = 70°C.

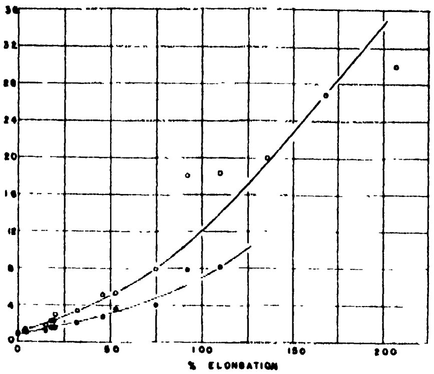

FIG. 12. Cross-plot of Fig. 11 showing the dependence of resistivity upon extension at times of 30 sec (open circles) and 14 hours (black circles).

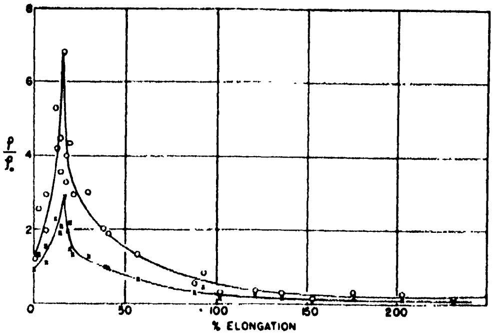

FIG. 14. Cross-plot of Fig. 13 showing the dependence of resistivity upon extension at times of 30 sec (open circles) and 14 hours (crosses).

extension is apparent in the range of low extensions. These curves have been cross-plotted at times of 30 seconds and 14 hours to show the dependence of $\rho/\rho_0$ upon the extension. This dependence is shown in Fig. 14. Examination of Figs. 13 and 14 shows that for high extensions the resistivities are almost immediately reduced to values which are very considerably less than the values which existed just before the extension. At extensions in the vicinity of 15 percent to 20 percent the resistivities, immediately after stretching for the first time, tend to become quite large and are extremely sensitive to slight differences in extension. Reproducibility of relative resistivities in this region was poor. The general behavior shown in Figs. 13 and 14 is strongly suggestive of a maximum in the resistivity *versus* extension relationship in the region of low extensions. This might, perhaps, be caused by a general breakdown of the carbon black network structure at these extensions, followed by a forced realignment of the carbon chains in the direction of the extension at higher elongations caused by the orientation of the rubber molecules. A process of this nature would account for the increased conductivity in the direction of the extension and might even be accompanied by a reduction in the conductivity in the direction perpendicular to the stretch. The latter possibility has not yet been checked, since the equipment employed in this work was designed to measure resistivities (and conductivities) in the direction of the extension.

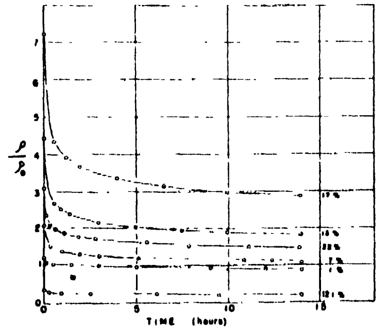

FIG. 13. Decay of resistivity with time at various extensions for a 19 percent volume concentration of Shawinigan in GR-S. Temperature = 70°C.

A probable explanation of the different behavior of Shawinigan and of R-40 at large extensions may be given. At large extensions of the material the rubber molecules most firmly bound to the carbon black particles will be subject to exceptional high extensions and will make abnormally high contributions to the rigidity. Therefore, we would expect carbon black to increase the rigidity of the material more when it is more firmly bound to the rubber molecules. That this is the case with Shawinigan is indicated by the decrease in resistivity below the initial value at high extensions. However the larger size of the Shawinigan particles may also be of importance both for the increase of rigidity and for the decrease of resistance with increasing extension.

An anisotropic conduction of the type suggested above has been shown by Habgood and Waring[12] to occur in extruded stocks containing

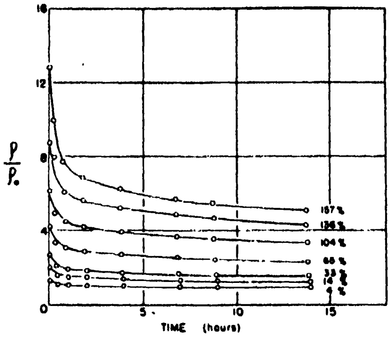

FIG. 15. Decay of resistivity with time at various extensions for a 19 percent volume concentration of Shawinigan in natural rubber. Temperature = 70°C.

Shawinigan black. A similar asymetry in graphite electrodes was also noted by Buerschaper.[13]

The behavior of Shawinigan black in GR-S for the 28 percent loading was similar to that shown in Figs. 13 and 14 for the 19 percent loading. In the case of the 15 percent loading of Shawinigan black in GR-S, the resistivities of the extended samples were too high for measurement with the present equipment. A similar inversion in the resistivity *versus* extension relationship was found for the 27 percent loading of Shawinigan in natural rubber, but was not perceptible for the 15 percent and 19 percent loadings in natural rubber. Figures 15 and 16 show the dependence of relative resistivity upon extension and time for the 19 percent volume concentration of Shawinigan in natural rubber.

## C Dependence of Resistivity of Loaded Stocks upon the Temperature

After the samples had been maintained in an extended condition for a time of 14 hours at 70°C, the temperature was lowered in steps to about 30°C and the corresponding values of resistivity were noted. The temperature was then increased in steps, and readings were taken as a function of increasing temperature. In general the resistance *versus* temperature relationship so obtained was not a linear one, and the two branches of the curve did not coincide. Figures 17, 18, 19, and 20 show the temperature dependence of resistivity at zero extension for all loadings of Shawinigan and R-40 in both natural rubber and GR-S. In general, the agreement between data obtained with decreasing and increasing temperatures becomes better as the loadings are increased. This is particularly true for the Shawinigan stocks. The temperature coefficients of resistivity were determined by constructing tangents to these curves at 50°C, this temperature coefficient being defined as

$$\alpha_{50^\circ\mathrm{C}} = \frac{\Delta\rho}{\Delta T \cdot \rho_{50^\circ\mathrm{C}}}.$$

The dependence of $\alpha_{50^\circ\mathrm{C}}$ upon carbon black concentrations is shown in Fig. 21 for GR-S and in Fig. 22 for natural rubber. Each plotted point is an average of four separate determinations. It is seen that $\alpha_{50^\circ\mathrm{C}}$ is positive for all Shawinigan stocks, and increases with increasing loadings. With one exception, namely, the 40 percent volume concentration in GR-S, the temperature coefficient for the R-40 stocks is negative and also increases with increasing loadings. Since the temperature coefficients at 100 percent concentration should correspond to those of the carbon blacks themselves, the possible trend at higher concentrations is indicated in Figs. 21 and 22 by dotted line extensions of the curves.

Figures 23, 24, 25, and 26 show the dependence of the resistivity-temperature relation upon extension for 19 percent volume concentration of both blacks in GR-S and natural rubber. Average temperature coefficients over the range from 30°C to 70°C have been calculated from these curves as follows. Let $A$ be the average value of $\rho/\rho_0$ at 70°C and $B$ the value of this ratio at 30°C.

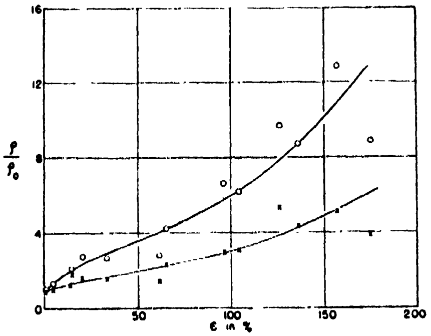

FIG. 16. Cross-plot of Fig. 15 showing the dependence of resistivity upon extension at times of 30 sec (open circles) and 14 hours (crosses).

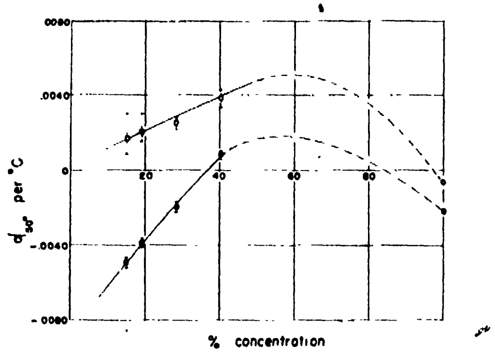

FIG. 22. Dependence of temperature coefficient of resistance upon volume concentration in natural rubber. Open circles denote Shawinigan and black circles R-40.

Then

$$\bar{\alpha}_{50°C} = \frac{A-B}{40\frac{(A+B)}{2}} = \frac{A-B}{20(A+B)}.$$

The dependence of this temperature coefficient upon extension for 19 percent volume concentrations of R-40 and Shawinigan is shown in Fig. 27 for natural rubber and in Fig. 28 for GR-S. This coefficient increases with increasing extension in all cases. It is positive for the Shawinigan stocks and negative for the R-40 stocks. A similar behavior was found for the other loadings.

These results show that the temperature coefficient of the resistivity of the loaded stocks depends strongly upon the concentration and upon the extension. The positive coefficient is probably connected with the breaking and reforming of carbon black chains. Such a kinetic effect will, in general, increase with increasing temperature, in contrast to the resistivity of the black itself, which will decrease with rising temperature. The explanation of the negative coefficient at lower black concentrations needs further consideration. It will also be noted that when a run is made first decreasing the temperature and then increasing it again to the original value the final resistivity is (with one exception: 19 per cent concentration Shawinigan in GR-S) larger than the starting value. This fact and the presence of hysteresis effects in general indicates that any disturbances of the material, whether thermal or mechanical, tends to break up some chains and thus increase the resistivity temporarily. This effect is simply superimposed on the other trends which would be observed if measurements could be made on samples in complete statistical equilibrium. The decrease of the area of hysteresis loops on elongation for R-40 and Shawinigan in GR-S may be explained as due to the fixation of black particles as explained in connection with the effect of elongation on resistivity in general.

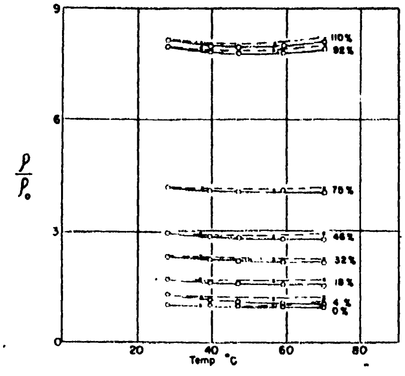

FIG. 23. Relative resistivity *versus* temperature at various extensions for a 19 percent concentration of R-40 in natural rubber.

### D. Dependence of Resistivity of the Carbon Blacks upon Temperature

The temperature dependence of the blacks was measured with the aid of the apparatus described in Section II, a pressure of 2000 lbs./in.$^2$ being maintained on the blacks during the measurements. The dependence of the resistivity upon the temperature is shown in Fig. 29 for both blacks. The temperature coefficients of resistivity at 50°C, as determined from these curves, are $-0.0021$/°C for R-40 and $-0.0006$/°C for Shawinigan.

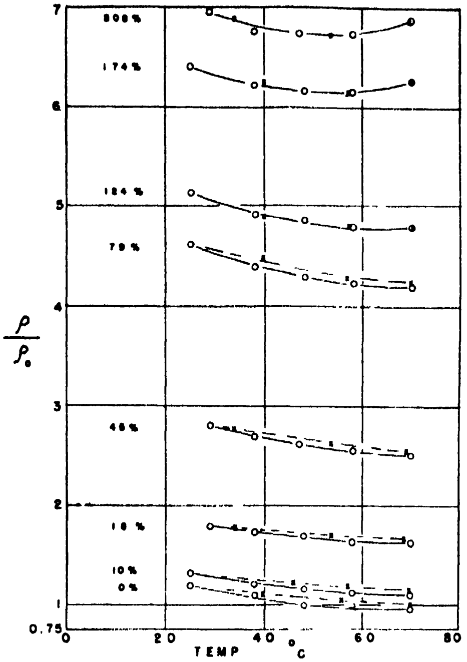

FIG. 24. Relative resistivity *versus* temperature at various extensions for a 19 percent concentration of R-40 in GR-S.

It is interesting to note that even at a pressure of 2000 lbs./in.$^2$ the apparent density of the carbon black ranged from about 0.36 g/cm$^3$ to 0.39 g/cm$^3$, whereas the apparent density of the carbon black in the rubber at the highest loadings was about 0.7 g of carbon black per cubic centimeter of cured rubber. It had originally been expected that pressures of from 1000 to 2000 lbs./in.$^2$ would result in a stable value of resistivity for the carbon black, since a previous study of the decrease in resistance of the carbon black with increasing pressure seemed to indicate a leveling off of resistance values in the region of about 1000 lbs./in.$^2$ On the basis of this expectation, these resistivity values were at first included in the plots of the logarithm of the resistivity *versus* volume concentration shown in Figs. 5 and 6, as points corresponding to a 100 percent volume concentration. This led to an approximate linear relationship for the R-40 black in GR-S and in natural rubber when log resistivity was plotted *versus* log concentration. However, it has since been discovered that the resistivity of the black itself depended strongly upon its apparent density and that even at constant pressure a wide variation in apparent densities can be obtained by tamping down the black while it is being loaded in the cylinder. Since the carbon black volume, calculated from the density value of 1.8 g/cm$^3$, plus the gum rubber volume has been shown to be equal to the volume of the cured loaded rubber, it follows that the "apparent" density of the carbon black corresponding to a 100 percent volume loading should be 1.8 g/cm$^3$. This density value is much greater than any we have been able to produce, and the corresponding resistivity value is therefore unknown. This strong dependence of resistivity upon apparent density of the black has been noted by Benson,

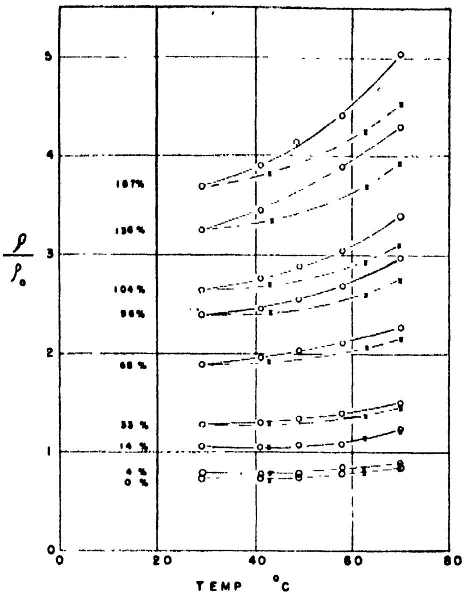

FIG. 25. Relative resistivity *versus* temperature at various extensions for a 19 percent concentration of Shawinigan in natural rubber.

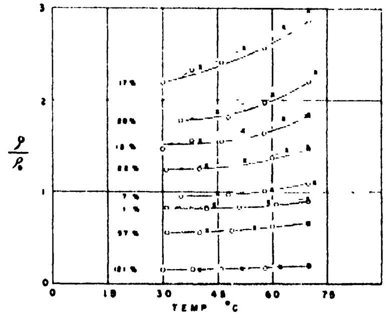

FIG. 26. Relative resistivity *versus* temperature at various extensions for a 19 percent concentration of Shawinigan in GR-S.

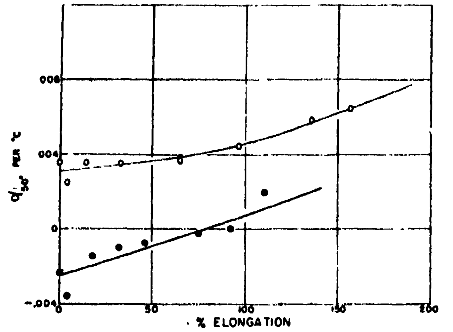

FIG. 27. Dependence of temperature coefficient of resistivity upon extension for 19 percent concentrations of R-40 (black circles) and Shawinigan (open circles) in natural rubber.

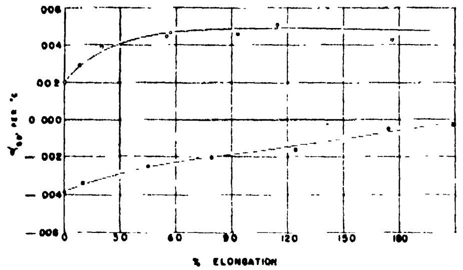

FIG. 28. Dependence of temperature coefficient of resistivity upon extension for 19 percent concentrations of R-40 (black circles) and Shawinigan (open circles) in GR-S.

Gluck, and Kaufmann.[14] They also showed that the density of the black measured at a constant pressure could be increased by as much as a factor of two by various densifying processes, for example by ball-milling.

In contrast to the large variations in the resistivity of the blacks produced by variations in pressure and density, the temperature coefficients of resistivity were found to be nearly independent of pressure and density, provided neither the pressure nor the density was too low. Accordingly these values have been included in Figs. 21 and 22.

## IV. SUMMARY

The behavior of two types of conducting blacks, R-40 and Shawinigan, has been studied in natural rubber and in GR-S. A series of four loadings of each black in each type of rubber was employed. These loadings ranged from about 40 grams of black per 100 grams of raw rubber to 140 grams of black per 100 grams of raw rubber, the corresponding true volume concentrations ranging from 15 percent to 40 percent. The resistivities of these stocks were studied as functions of time, temperature, extension, and loading. The following results were observed:

### A

Fast stress-strain curves show that in both natural rubber and GR-S, the R-40 black gives the better reinforcement at low extensions, but that Shawinigan gives the better reinforcement at the high extensions.

### B

Any small strain produces an increase in resistivity which then decays with time in a nearly exponential fashion. In particular the process of cutting out the samples and mounting them in clamps produces such strains. Annealing the samples at elevated temperatures accelerates the approach to an initial steady-state resistance value. Accordingly, in this work all samples were annealed for 10 hours at 70°C in an unstretched condition. The resistivity value attained at the end of this time is denoted by $\rho_0$.

### C

At the lowest concentrations, R-40 gave better conductivity in GR-S than did Shawinigan, the log resistivity *versus* concentration curve being very steep for the Shawinigan black in this region. At the high loadings Shawinigan gave higher conductance in both GR-S and natural rubber. The R-40 GR-S stocks were better conductors than the R-40 natural rubber stocks. For Shawinigan black, however, the natural rubber stocks were better conductors than the GR-S stocks.

### D

For the R-40 stocks, stretching a sample produced an increase in the resistivity, which then decayed with time while the sample was held at a fixed extension. The Shawinigan stocks behaved differently, however. In the case of the 19 percent and 28 percent concentrations in GR-S and also the 27 percent concentration in natural rubber, an inversion was found in the resistivity *versus* ex-

---

[14] G. Benson, J. Gluck, and C. Kaufmann. In paper presented before the Toronto Meeting of the Electrochemical Society, October 16 to 19, 1946.

tension relationship. The resistivity increased with increasing extensions up to about 20 percent extension and then decreased for higher extensions. For sufficiently high extensions, the resistivities were immediately reduced to values which were very considerably less than the unstretched values. All resistivities were measured along the length of the sample and hence in the direction of the extension.

### E

The dependence of resistivity upon temperature was observed for all stocks over the temperature range from 30°C to 70°C. In general, the average temperature coefficient, calculated at 50°C, was positive for the Shawinigan stocks and negative for the R-40 stocks. It increased with increasing carbon black concentration and also increased with increasing extension of the sample.

### F

Temperature coefficients of resistivity were also measured for the two blacks at 50°C. The blacks were compressed under a pressure of about 2000 lbs./in.$^2$ This pressure was maintained during the measurements, the "apparent" densities ranging from 0.36 to 0.39 g/cm$^3$. The observed temperature coefficients were −0.0021/°C for the R-40 black, and −0.0006/°C for Shawinigan black.

Our results can, in general, be understood on the basis of a simple picture of the formation and the breaking up of chains of carbon black particles. Thermal and mechanical disturbances both lead to a breakage of the chains and thus to an increase in the resistance. In the course of time Brownian motion of the carbon black particles will re-form the chain structure and thus decrease the resistivity as a function of time. This explains the decrease of resistance with time of freshly cured and cut and of stretched samples, the increase of resistivity on stretching in general, the fact that the ascending branch of the resistivity-temperature curve lies above the descending branch and a positive temperature coefficient of resistivity. In the case of Shawinigan the greater increase of rigidity and the decrease of resistivity (below the initial value), both at high extensions, is probably determined by the greater strength of the rubber-carbon black bond and the larger size of the black particles as compared with R-40.

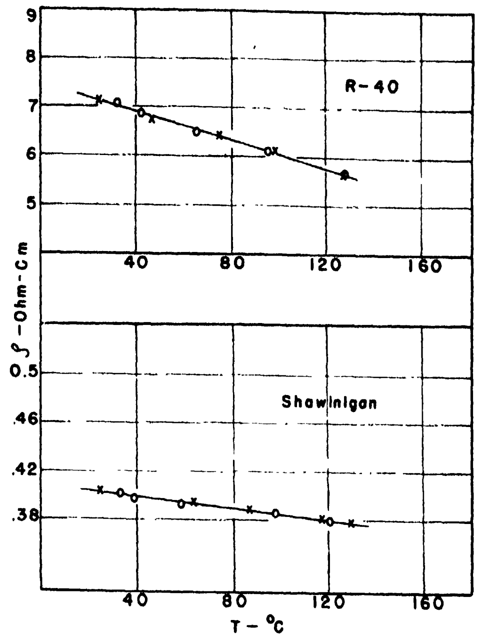

FIG. 29. Dependence of carbon black resistivity upon temperature at a pressure of 2000 lbs./in.$^2$

It is a pleasure to thank Professor Hubert M. James for frequent consultation and many valuable suggestions in connection with this study.

# Elastic Properties of Cork

## II. Stress-Temperature Relationship of Compressed Cork

S. L. Dart and Eugene Guth
*Polymer Physics Laboratory, University of Notre Dame, Notre Dame, Indiana*

(Received October 14, 1947)

In the first paper of this series it was shown that for cork, held at constant compression, the stress as a function of compression, temperature, and time was separable into two factors, one factor representing the load-compression curve and the other describing the decay of stress with time. In the present paper the dependence of the load-compression curve upon temperature is studied. After the sample has relaxed at constant temperature and compression for a time sufficiently long so that the change of stress with time may be neglected, stress-temperature curves were obtained. These curves showed a linear dependence of the stress upon the temperature. From the stress-temperature curves the resolution of the stress into its additive components due to internal energy and entropy was carried out. The physical significance of this resolution is discussed. The experiments were carried out with a refined version of the apparatus described in the first paper. In particular, the apparatus was corrected for rate of thermal expansion.

### INTRODUCTION

In a previous paper[1] an account was given of the stress relaxation of cork as a function of compression, temperature, and time. In particular it was shown that the stress decayed to zero in about 1000 years at room temperature and in about 1000 minutes at 200°C, independent of compression. This independence of the decay time on compression was also checked at 80°C and at 130°C. It was also demonstrated that the compressive stress $Z$ as a function of compression, temperature, and time was separable into two factors,

$$Z(\epsilon, T, t) = F(\epsilon, T)\cdot G(t, T), \tag{1}$$

where the factor $F(\epsilon, T)$ is essentially the load-compression curve of cork and the factor $G(t, T)$ describes the decay of stress with time and temperature. In the previous paper it was proved that $G(t, T)$ has the form

$$G(t, T) = a - b \log t \tag{2}$$

where $a$ and $b$ depend on $T$ only. In particular $a$ and $b$ were thrown into the form

$$a = 1$$
$$b = \beta/(\alpha - T)$$

giving as a final equation

$$Z(\epsilon, T, t) = A(\epsilon, T)[1 - [\beta/(\alpha - T)] \log t]. \tag{3}$$

However, the dependence of $A(\epsilon, T) = F(\epsilon, T)$ upon $T$ was left open. The present paper fills in the gap and brings the fundamental stress-temperature relationship for cork.

### EXPERIMENTAL METHOD

The apparatus used was described in the previous paper. It consisted of a lever arm for compressing the sample which was automatically kept balanced through a chainomatic drive. Through this drive the force was recorded as a function of time on a clock-driven drum.

The apparatus was carefully rechecked for possible errors in the thermal expansion correction and was also corrected for rate of thermal expansion. This latter is very important in connection with the measurement of stress as a function of temperature at constant compression, since the compression must be maintained constant during the temperature change as well as during the temperature equilibrium. The procedure used was patterned after that of Anthony, Caston, and Guth.[2] That is, the sample was allowed to relax[1] until the rate of change of stress was small enough to make the stress-relaxation negligible during the subsequent stress-temperature determination. The preliminary relaxation time used was 1000 minutes. After this

---

[1] Dart and Guth, J. App. Phys. 17, 314–318 (1946).

[2] R. L. Anthony, R. H. Caston, and E. Guth, J. Phys. Chem. 46, 826 (1942). Reprinted in Rubber Chem. Tech. 16, 297 (1943).

preliminary relaxation period the temperature was lowered in steps and the corresponding stress changes were noted. Using this procedure one can find the temperature behavior of the stress at temperatures less than the relaxation temperature.

Figure 1 shows the results of such an investigation at the compressions indicated and with the common relaxation temperature of 80°C. It is seen that within the experimental error the stress depends linearly on the temperature. Thus, we may express this by the equation

$$Z(\epsilon, T) = M(\epsilon) + N(\epsilon)T, \tag{4}$$

where $M(\epsilon)$ and $N(\epsilon)$ are functions of compression alone. We will defer the discussion of the significance of this relation to a later section.

This then gives us the stress as a function of compression and temperature, exclusive of time effects. That is, this Eq. (4) gives us the temperature dependence of the factor $A(\epsilon, T)$ or $F(\epsilon, T)$ in Eq. (3). Before we write down an equation expressing all the experimental results presented, we must recognize that we have measured time effects and temperature effects separately, i.e., time effects were measured at constant temperature and *vice versa*. Let us call the constant relaxation temperature $T^*$ and the temperature which is changed, $T$. $T^*$ is really a variable separate from $T$ because in order to specify the state of the system one must specify not only the actual temperature $T$, but also the temperature $T^*$ at which the relaxation took place. This situation was discussed in more detail by Guth, Anthony, and Wack[3] for the case of rubber in extension. They showed, experimentally, that certain ratios (cf. Eqs. (13a, b, c, and d) of their paper) are constant. The constancy of these ratios implies the validity of "generalized similarity and separability" expressed by the equation

$$Z(\epsilon, T, T^*, t) = F(\epsilon, T) \cdot G(T^*, t). \tag{5}$$

It seems reasonable to assume that "generalized similarity" will also hold for cork, though this was not checked directly. Taking into account (3) we can then identify more explicitly the factors $F$ and $G$.

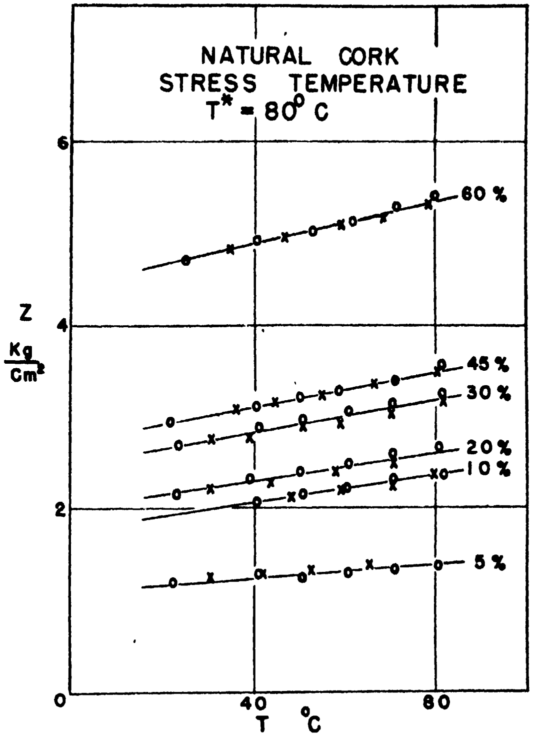

FIG. 1. Stress-temperature curves for cork previously relaxed at $T^* = 80°C$ for 1000 minutes. Circles indicate points obtained on lowering the temperature. Crosses are the points obtained on raising the temperature.

$$F(\epsilon, T) = M(\epsilon) + N(\epsilon) \cdot T;$$
$$G(T^*, t) = \{1 - [\beta/(\alpha - T^*)] \log t\}. \tag{6}$$

Then our generalized equation of state takes the form

$$\begin{aligned} Z(\epsilon, T, T^*, t) &= [M(\epsilon) + N(\epsilon)T] \\ &\quad \times \{1 - [\beta/(\alpha - T^*)] \log t\} \qquad (7) \\ &= F(\epsilon, T) \cdot G(T^*, t). \end{aligned}$$

## DISCUSSION OF EXPERIMENTAL RESULTS

### A. Stress Relaxation

The discussion so far has been concerned solely in presenting the experimental results of our investigation of the elastic properties of cork. We shall now try to give a more fundamental discussion of these results in the light of present day theories. Consider first, the stress relaxation. The general equation for the time dependency of stress as given by Boltzmann has been generalized for the non-Hookean case, by Guth, Wack,

---

[3] E. Guth, P. E. Wack, and R. L. Anthony, J. App. Phys. **17**, 347 (1946).

and Anthony.[3] This may be written as follows:

$$Z(t)=F[\epsilon(t)]-\beta'\int_{-\infty}^{t}\phi(t-t')F[\epsilon(t')]dt',\qquad(8)$$

where $\beta'$ is a small constant, $F=F(\epsilon)$ gives the stress-strain relationship, and $\beta'\phi(t-t')$ is the memory function of Boltzmann. For relaxation we have $\epsilon(t)=\epsilon(t')=0$ for $t<0$ and $\epsilon(t)=\text{constant}$ for $t>0$. Thus, Eq. (8) becomes

$$Z(t)=F(\epsilon)[1-\beta'\psi(t)],\qquad(9)$$

where

$$\psi(t)=\int_{0}^{t}\phi(t-t')dt'.\qquad(9a)$$

It is to be noticed that Eq. (9) is identical in form with the experimental Eq. (3). Thus, we can describe the time dependency by means of the generalized Boltzmann theory. Also, for the case of cork, comparison of (3) and (9) shows that

$$\beta'\psi(t)=[\beta/(\alpha-T)]\log t,\qquad(10)$$

while (9a) shows that

$$\phi(t-t')=1/(t-t').\qquad(10a)$$

A relation of the type (10) holds for many materials in a limited range of $t$ values. The remarkable result for cork is the validity of the relation (10) over a very wide range of $t$ values. As a matter of fact, (10) is valid for cork in the range $t=1$ min. We plan to discuss the theoretical significance of this fact at a later time.

If the stress-time curve is an exponential in $t$, we have

$$Z=Z_0\exp(-K't),\qquad(11)$$

where $K'$ is given by

$$K'=(kT/h)e^{-\Delta H/RT}.$$

Here $\Delta H$ is the activation energy and $kT/h$ is the rate factor as given by Eyring.[4] This equation is a straight line on a $\log Z$ *vs.* $t$ plot. Such a plot was tried on a relaxation run at 200°C and 4.86 percent compression and the result was far from linear. However, activation energies were calculated using a straight line portion of the curve and also using the time for the stress to drop to a value $1/e$ times the first value. These activation energies were 38.0 and 36.8 kilocalories per mole, respectively. These results are slightly larger than the corresponding values for rubber-like materials, which have activation energies of about 32 kilocalories per mole.

In Eq. (3), $F(\epsilon,T)$ designates the value of the stress at $t=1$ min. Expressing this fact more explicitly, Eq. (7) may be written

$$Z(\epsilon,T,T^*,t)=F(\epsilon,T)\times\{1-[\beta/(\alpha-T^*)]\log t/t_0\},\qquad(12)$$

where $t_0=1$ min. For $\alpha\leq T^*$ Eq. (12) was not established experimentally and it cannot be extrapolated to this range without further considerations. At any rate theoretical arguments show that a logarithmical relationship of the type of Eq. (12) will not hold for very small times, i.e., for times much smaller than 1 min.

In the first installment of this series[1] the time $\tau$ needed for the stress to decay to zero, for a sample held at constant compression, was shown to be independent of the compression strain. To show the dependence of $\tau$ upon the relaxation temperature $T^*$, a plot of $T^*$ *versus* $\log\tau$ was used. The curve so obtained was a straight line.

Instead of a $T^*$ *vs.* $\log\tau$ plot, a $\log\tau$ *vs.* $1/T^*$ plot may also be used. A straight line does not fit in the latter representation as well as the former one, but still gives a reasonable fit, if one considers the unavoidable experimental errors. We then have the relation

$$1/T^*=a+b\log\tau.$$

Solving for $\tau$ we obtain

$$\tau=\tau_0\exp(V/RT^*),\qquad(13)$$

i.e., an infinite decay time at absolute zero, which is reasonable. The constants in Eq. (13) have the values

$\tau_0=1.6\cdot10^{-3}$ min.,
$V=9$ kilocalories per mole.

### B. Stress-Temperature

Concerning the stress-temperature relationship, we can proceed as follows:

We start from the well-known energy equation of thermodynamics

$$\left(\frac{\partial U}{\partial V}\right)_T=T\left(\frac{\partial P}{\partial T}\right)_V-P.\qquad(14)$$

---

[4] Cf. for instance, S. Glasstone, K. Laidler, and H. Eyring, *The Theory of Rate Processes* (McGraw-Hill, New York, 1941).

Using the Maxwell relation

$$\left(\frac{\partial P}{\partial T}\right)_V=\left(\frac{\partial S}{\partial V}\right)_T, \tag{15}$$

we can write

$$\left(\frac{\partial U}{\partial V}\right)_T=T\left(\frac{\partial S}{\partial V}\right)_T-P. \tag{16}$$

Applying this to our case of unilateral compression we must substitute $1-\epsilon$ for $V$, and $Z$ for $P$, since we plot actually the pressure or the negative of the tension stress. This gives

$$-\left(\frac{\partial U}{\partial \epsilon}\right)_T=-T\left(\frac{\partial S}{\partial \epsilon}\right)_T-Z$$

or

$$Z=\left(\frac{\partial U}{\partial \epsilon}\right)_T-T\left(\frac{\partial S}{\partial \epsilon}\right)_T=Z_U+Z_S, \tag{17}$$

where $Z_U$ is the contribution of the internal energy to the stress, $Z_S$ is the entropy contribution, and $Z$ is, of course, the total stress. (Actually the experiments are carried out at constant pressure and constant compression. Nevertheless, Eq. (17) is valid in sufficient approximation, when derivatives are taken at constant temperature and constant pressure.) Equation (17) has the same form as our experimental Eq. (4). Thus, using the curves shown in Fig. 1 we can calculate $Z_U$ and $Z_S$ as a function of $\epsilon$. In doing this one must remember that the $T$ in Eq. (17) is absolute temperature. The results of such a calculation are shown in Fig. 2. Here one can see that the entropy is responsible for most of the stress in the first two regions, i.e., for the stiffness of the sample at small compressions and during the breakdown of the structure. However, when the actual material of the cell walls begins to be compressed, at 60 percent or so, the internal energy contribution becomes appreciable.

The negative internal energy contribution in the first range of (small) compressions is at least partly caused by the thermal expansion of the uncompressed cork. This is similar to the behavior of rubber at small extensions. The internal energy contribution is partly caused by the thermal expansion of the unstretched rubber.

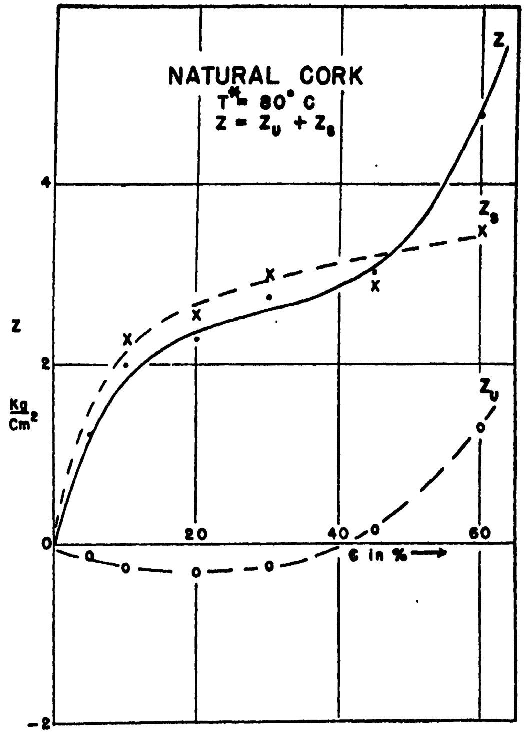

FIG. 2. Resolution of the stress of Fig. 1 at $T=25°C$ into its components $Z_U$ and $Z_S$ due to internal energy and entropy, respectively.

The large contribution to the stress due to entropy is presumably connected with the bending of the cell walls. The material of the cell walls is likely to consist of long chain molecules with at least some degree of free rotation. On this basis a large entropy contribution can be understood. The increase of internal energy, on further compression, is presumably caused by intermolecular forces coming into prominence as compression increases.

## ACKNOWLEDGMENT

The authors wish to express their appreciation to Dr. H. A. Robinson, Chief Physicist, Armstrong Cork Company, for valuable discussions and for furnishing the samples used in this investigation. They also wish to express their appreciation to Mr. E. Claxton, Director of Research, and to Dr. R. B. Rohrer, Assistant Director of Research, Armstrong Cork Company, for the benefit of valuable discussions and for the support of this work.

# Elastic Properties of Cork

## III. Hydrostatic and Ordinary Load-Compression Curves for Cork

S. L. DART,* HOWARD A. ROBINSON,** AND EUGENE GUTH*

(Received October 14, 1946)

Load-compression curves were taken for natural cork. The S-shape of the curves is discussed and a theoretical fit is made for the high end of the curve, assuming an initial stiffness and an incompressible part of the cork material. A comparison is made between repeated compressions, with and without a recovery period of time.

Pressure-volume curves were also taken and their significance discussed in connection with the load-compression curves leading to an evaluation of Poisson's ratio.

DETERMINATION of the load-compression curves of cork under various experimental conditions is of great theoretical and practical interest. The load-compression curves for cork show a peculiar S-shape. The proper interpretation of this S-shape should throw considerable light on the structure of cork. A knowledge of the structure of cork, in turn, will facilitate the design of corky materials for practical applications, and enable one to predict their behavior under a great variety of conditions.

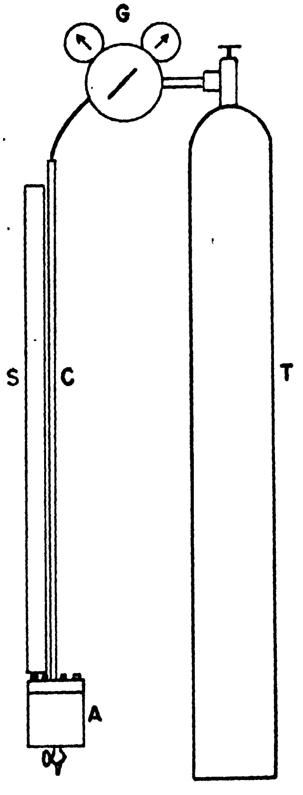

FIG. 1. Apparatus for hydrostatic compression of cork. *T*: high pressure tank; *G*: gauge and reducing valve; *S*: scale; *C*: glass capillary tube; *A* : compression chamber.

In this paper an attempt is made to interpret the S-shaped load-compression curve of cork as the result of the cellular structure and of the two-phase structure of cork, namely, the corky material *and* the air trapped in the cork cells. Load-compression curves were obtained in two ways: in the ordinary way, and second, by measuring the change in volume caused by hydrostatic pressure.

These two methods lead actually to somewhat different load-compression curves; their mutual relation will be explained in this paper in the section on hydrostatic curves.

### DESCRIPTION OF THE EXPERIMENTAL METHOD

#### A. Ordinary Load-Compression Curves

These curves were obtained by means of the apparatus described in a previous paper[1] (cf. Fig. 1 there). The same sample was used to obtain the complete load-compression curves up to 70 percent compression by gradually increasing the load, and reading the corresponding compressions on the dial gauge.

#### B. Hydrostatic Volume-Pressure Curves

These curves were obtained on an experimental arrangement shown in Fig. 1. A cork

sample of about six cubic centimeters volume is placed in the compression chamber which is then bolted shut. Water is then forced into the stopcock at the bottom until it rises near the top of the glass tube and scale. The stopcock is then closed and any air bubbles are made to rise to the top of the tube by tapping. Care must be taken to get all air bubbles out as they would cause an error in the volume-pressure curve. A zero reading on the scale is taken of the water level, and the whole unit is connected through a reducing valve to a high pressure tank (of nitrogen in our case). The pressure is then increased in units of 5 p.s.i. every 30 seconds, and the corresponding water-level readings on the scale are taken at the end of each 30-second period. This procedure was used in order to simulate as closely as possible the procedure used in taking an ordinary load-compression curve. The pressure was read from the reducing gauge and the volume change was calculated from the scale readings (knowing the diameter of the glass tube). It was interesting to note that there was a great deal of flow of the cork during a run, as is the case during an ordinary load-compression run. This implies that the flow is caused by the cork structure itself and not by the escape of air from the cells, which would be impossible in the hydrostatic case.

## ORDINARY LOAD-COMPRESSION CURVES FOR CORK

Figure 2 represents load-compression curves obtained at the Armstrong Research Laboratories. Up to the breaking point the extension branch of this curve is also given for cork. The crosses indicate the load-compression curve for cork obtained by repeating the loading a second and a third time on the same sample. Twenty-four hours elapsed between consecutive loadings.

Figure 3 shows a somewhat more extensive study of the repeated load-compression curves carried out at Notre Dame. The consecutive curves were taken one after the other without giving time for the sample to recover. Complete hysteresis loops were obtained.

Figures 2 and 3 reveal a series of interesting features important for the interpretation of the load-compression curves.

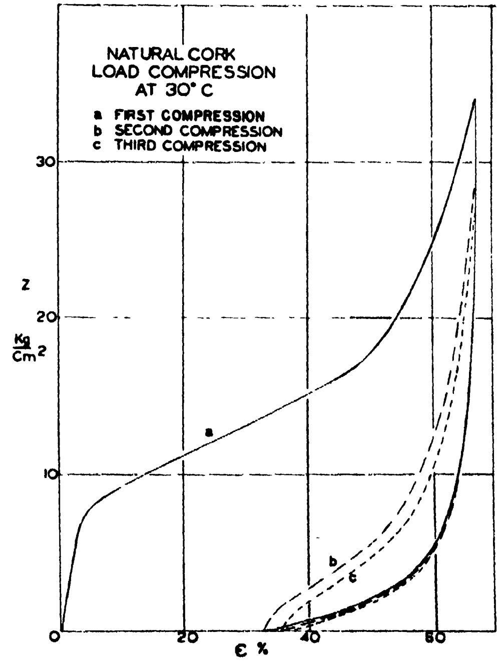

FIG. 3. Load-compression curves for repeated compressions including hysteresis loops.

The extension branch is monotonic. The tensile strength and breaking elongation are low. They

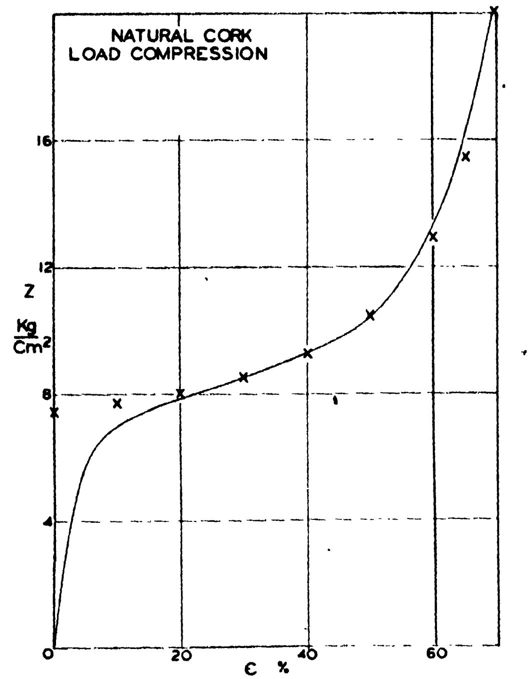

FIG. 4. Load-compression curve of cork. Crosses indicate theoretical Eq. (1) of text.

are chiefly determined by the cuts or cracks invariably present in cork, and the propagation or growth of these cracks. The tensile strength may be compared with the tear resistance of a compact material like rubber, the tear being natural and unavoidable for cork.

The compression branch shows a characteristic S-shape. On repeated compression the S-shape tends to be washed out and the curve approaches somewhat the monotonic behavior shown by GR-S tread.[3] This is shown with particular clarity in Fig. 3, but to a lesser degree in Fig. 2 because of the recovery of the sample between consecutive loadings.

A simple explanation of the S-shape may be based on the known cellular and two-phase structure of cork: the corky material (including various organic substances) constituting the cell walls and the air trapped in the cells. We notice that the knee of the compression curve occurs roughly at a compression corresponding (on inversion at the origin) to the breaking elongation, and for a load somewhat smaller than the negative of the tensile strength. On repeated stretching the knee occurs for a lower critical load. The equal order of absolute magnitude of the critical load and compression of the knee and of the tensile strength suggest that a certain breakdown of the cells may have taken place at the knee. The difference in the lowering of the knee as shown in Fig. 2 with recovery period between repeated loadings, and in Fig. 3 without a recovery period, indicates that the breakdown of the cells is partially reversible.

For the part above the knee of the compression curve we have tried a preliminary quantitative representation. That part of the compressive stress $Z$ may be represented fairly accurately by the equation

$$(Z-a)(L-l_0)=\text{const}; \qquad (1)$$

$L$ is the relative length, $a$ and $l_0$ are constants. The quantity $a$ should be independent of the compression, and represents the critical stress necessary for the partial destruction of the cork structure (*not* the *cells*).

The plateau after the knee is interpreted as largely caused by the failure of the resistance of the cork (through buckling of the cell walls for instance). The upward turn is interpreted as a compression of the almost incompressible part of

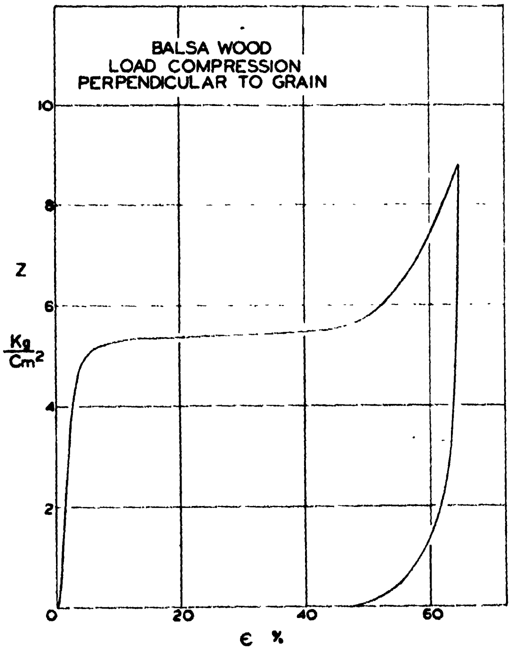

FIG. 5. Load-compression loop for balsa wood.

---

[3] Synthetic rubber compound containing carbon black as used for the tread surface of tires.

cork. Of course, the van der Waals $b$ of the air comes in also. The constant on the right side of Eq. (1) should be of the order $RT$. According to this equation, $Z$ should be a linear function of the temperature at constant compression (since the constant on the right side of Eq. (1) should be proportional to $T$)

$$Z = M(L) + N(L) \cdot T. \qquad (2)$$

This conclusion was checked in the second paper of this series by our relaxation method. Equation (1) checks well with a load-compression curve, as shown in Fig. 4. However, the true significance of this apparent agreement has not been established. For some samples the plateau above the knee was practically straight. The possible significance of this finding, at some variance with Eq. (1), needs further study.

It is interesting to note that balsa wood, when compressed perpendicular to the grain, also shows a pronounced S-shaped load-compression curve, with an almost horizontal plateau, as shown in Fig. 5. The large set (46 percent) after compression disappears almost completely when the sample is soaked in water.

### LOAD COMPRESSION CURVE OF HIGHLY COMPRESSED CORK

In connection with the interpretation of the S-shaped load-compression curve it was interesting to see how a high hydrostatic pressure would change the shape of the load-compression curve. At our request Dr. P. W. Bridgman[3] was kind enough to apply to cork a pressure of 29,000 kg/cm² in isopentane. The initial dimensions of the sample on April 11, 1945, were 0.324″×0.319″ ×0.312″. After exposure to high pressure the dimensions were 0.297″×0.301″×0.283″. On February 6, 1946, the dimensions were 0.302″ ×0.306″×0.287″. In view of the magnitude of the hydrostatic pressure employed in the test, it is remarkable that the permanent set of the linear dimensions was only about 8 percent on the average immediately after the exposure. After ten months' rest the permanent set was somewhat less.

In Fig. 6 the dotted line shows the load-compression curve taken in June, 1946, on the same piece of cork which had been subjected to the high pressure by Dr. Bridgman on April 11, 1945. The full line shows the load-compression curve of Fig. 2, which was obtained on a piece of cork not previously compressed. It is seen that the initial part of the two curves is almost the same. We interpret this initial part as resulting from the initial bending of the cell walls. The comparison of the two curves exhibits nicely the fact that the cells were not crushed by the high hydrostatic pressure. The plateau of the curve for the pre-compressed sample is, however, much less developed than in the case of the previously uncompressed sample. We attribute this plateau to the failure of the resistance of the cork cells. The comparison of the two curves shows that the hydrostatic compression must have driven a large amount of the air out of the cells. The steep part of the two curves has about the same slope, as one would expect.

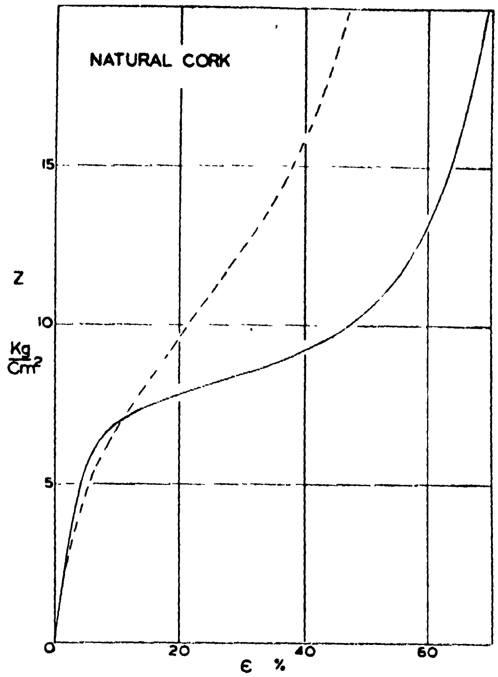

FIG. 6. Comparison of load-compression curves for cork; dashed line shows curve for sample hydrostatically compressed by P. W. Bridgman, applying a pressure of 29,000 kg/cm². Full line shows behavior of a sample which was not previously compressed.

### HYDROSTATIC CURVES

It is clear from the description of this method in the first section that hydrostatic compression

---

[3] Jefferson Physical Laboratory, Harvard University, Cambridge, Massachusetts.

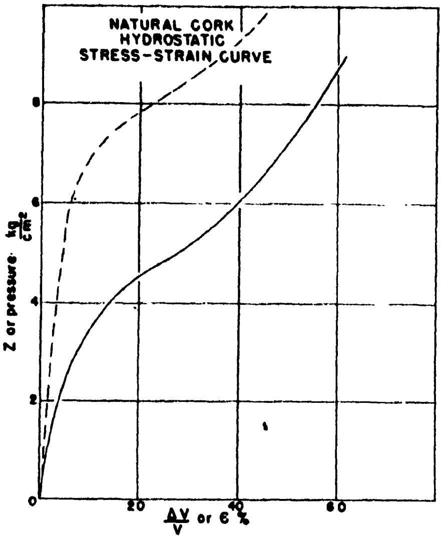

FIG. 7. Comparison of hydrostatic (full line) and ordinary load-compression (dashed line) curves for cork.

leads to a pressure-volume relationship, different from the ordinary load-compression relation. The connection between these two types of relations may be exhibited simply and quantitatively, referring to the elements of the theory of elasticity. The slope at the origin of a load-compression curve $Z=Z(\epsilon)$ is Young's modulus

$$dZ/d\epsilon=E. \tag{3}$$

Similarly, the slope at the origin of the pressure-volume relation, $P=P(V)$, is the bulk modulus $K$

$$VdP/dV=K. \tag{4}$$

Now according to the theory of elasticity, Young's modulus, $E$, and the bulk modulus $K$ are connected as follows:

$$E=3K(1-2\mu), \tag{5}$$

where $\mu$ is Poisson's ratio (ratio between lateral contraction and longitudinal extension). Knowing $E$ and $K$ Eq. (5) enables us to obtain $\mu$.

$$\mu=\tfrac{1}{2}(1-E/3K). \tag{6}$$

Figure 7 shows a hydrostatic pressure-volume change curve with the corresponding load-compression curve for cork. When inserted into Eq. (6), comparison of the slopes of the two curves yields

$$\mu=0.04. \tag{7}$$

Another method of obtaining $\mu$ is to measure the change of volume on ordinary compression. According to the theory of elasticity the following relation holds:

$$\Delta V/V=\epsilon(1-2\mu). \tag{8}$$

This relation permits one to compute $\mu$ if $\Delta V/V$ is measured for a given compression $\epsilon$. This method, however, was not used in the present work.

## A Cold Cathode Rectifier

WILLARD H. BENNETT*

(Received October 21, 1946)

A cold cathode rectifier is described in which corona discharge is used at atmospheric and higher pressures in hydrogen and nitrogen free of electron-attaching impurities. This kind of tube has advantages where the current demands upon a rectifier are small.

IN the course of some experimental studies of corona discharge, methods were found for producing and maintaining conditions for free electron discharge in gases at pressures of the order of magnitude of atmospheric and higher. The very large difference in mobility between free electrons and positive ions is illustrated in Fig. 1, in which are shown the negative and positive corona current-voltage characteristics for a 1-mil tungsten wire-end discharging in hydrogen at atmospheric pressure towards a plane electrode at a distance of 3 cm. Characteristics for wire sizes between 0.4 and 3 mil, and for distances to the plane electrode between 0.3 cm and 10 cm were measured and are summarized in an earlier report.[1]

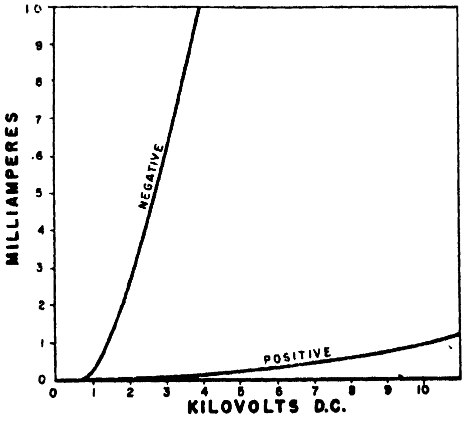

FIG. 1. Current-voltage characteristics for negative and positive corona.

As will be seen from the figure, the very large difference between the mobilities of electrons and positive ions is quite unusual for corona discharges. These can only be attained by using means for eliminating electron-attaching components from the gas in the tube to a degree estimated as less than one part per hundred million and keeping the gas free of these components to this degree.

Cold cathode rectifiers were developed taking advantage of this large difference in mobilities. It is believed that these rectifiers have peculiar advantages over conventional types of rectifiers in many applications, particularly where the

[1] Willard H. Bennett, Phys. Rev. 58, 992–997 (1940), see Figs. 2 and 3, p. 994. The abscissae in those figures were incorrectly labelled and should have been "kilovolts difference" instead of "log voltage difference."

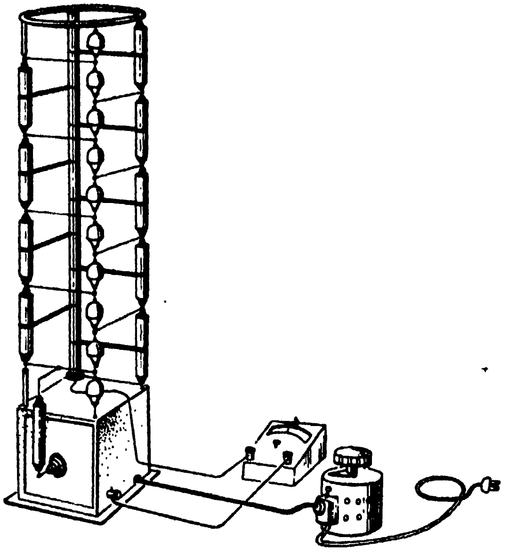

FIG. 3. A representative type of rectifier using ten tubes of the type shown in Fig. 2b. The condensers are 0.5 microfarad each and rated at 20 kilovolts d.c. each. The multiplier can be a spiral ink line resistor on a Bakelite or formica cylinder with 100 megohms per stage.

current requirements are small, and that a description of this kind of rectifiers would be of interest.

## GENERAL DESCRIPTION

Some representative types of tube are illustrated in Fig. 2. In these tubes, the discharge electrodes are one- or two-mil tungsten wire-ends. The collecting electrode in each is an Aquadag coating on the glass wall shown as the shaded area in the broken sections.

The tubes in Figs. 2a and 2b are filled with hydrogen at atmospheric pressure. The tube in Fig. 2c is filled at eight atmospheres with 30 percent hydrogen and 70 percent nitrogen.

Because there is no filament heating requirement with a tube of this kind, rectifiers built using these tubes are simpler, lighter, and more compact, than rectifiers using conventional types of tubes. As an illustration, Fig. 3 shows a rectifier supplying 100 kilovolts using a 10 kilovolt transformer in a Cockcroft-Walton circuit. In this kind of circuit, if conventional types of tubes were used, the need for filament heating current at each stage would make necessary a filament transformer with high voltage insulation between primary and secondary for each stage. Such a requirement would make necessary a bulkier and more complicated equipment than that shown in Fig. 3.

There is no requirement for filament heat-up time and no devices are needed for tube protection on this account.

Rectifiers can readily be designed with clips for holding the tubes so that simply reversing the tubes in the clips reverses the output polarity of the rectifier.[2]

Although these tubes do not waste electric power in heating a filament, they suffer from loss of efficiency from another cause. Under normal conditions of operation, there is a small positive-ion current on the reverse half-cycle. This effect together with the fact that even the high free electron mobilities are not sufficient to give as high current densities as are obtainable with electrons in vacuum, has served to hold these tubes to an efficiency of about 20 percent to 50 percent which is lower than most conventional types of rectifier unless no greater output currents are required than can be adequately supplied by these cold cathode tubes.

In Figs. 4 and 5 are shown some efficiency data taken on a rectifier using the type of tube shown in Fig. 2c. In Fig. 4, the transformer supplies 10 kilovolts a.c., and in Fig. 5, the supply is 20 kilovolts a.c. Observations were obtained for hydrogen (shown with full lines) and a mixture of 30 percent hydrogen and 70 percent nitrogen (shown with dashed lines). War work prevented completing these data, but from some observations in a single wire experimental tube, a good estimate was obtained for 20 percent deuterium and 80 percent nitrogen (shown with the dotted lines). From mobility data[3] it is to be expected that the efficiency would be still higher for a mixture of 5 percent deuterium and 95 percent nitrogen. For comparison purposes, representative curves for a vacuum-tube rectifier are included.

## PREPARATION OF A TUBE

As discharge electrodes, wire-ends with any diameter between about 0.4 mil and 3 mils seem

---

[2] Additional engineering data is given in Trans. A.I.E.E. 64, 164–7 (1945); and Electronics Industries, p. 106 (November, 1945).

[3] W. H. Bennett and L. H. Thomas, Phys. Rev. 62, 41–47 (1942).

to be about equally effective. The reason for this is that in the initial conditioning of the tube, there is an etching of the wire-ends to a sharp conical tip whose radius of curvature is of the order of magnitude of 0.2 mil.[4] In tubes containing six or more wire-ends, the maximum number that can usefully be grouped with bases adjoining is six, and even with six wires in a group, the maximum current per wire-end that can be drawn without arc-over is less than six times the current that could be drawn from a single wire, the other electrode spacings being the same but the other five wires removed. The discharge spreads laterally from a wire-tip and adjacent discharges interfere with each other to some extent.[5]

It is important that the electric field diverge all the way to the collecting electrode. Aquadag or metal collecting electrodes can be used.

After filling the tube with gas and sealing the tube, a.c. voltage is applied directly. The resulting discharge eliminates the electron-attaching impurities and sharpens the wire-ends, slowly at first. The current rises quite rapidly during the last stages of the conditioning, however, and unless a circuit breaker is used in the a.c. supply, the tube may be greatly over-heated.

This does not complete the conditioning. If the tube is allowed to stand, it will probably decondition to some extent after a day, that is, the electron mobilities will have decreased by a large amount. This is probably caused by the liberation into the gas of some electron-attaching impurities from the walls of the tube and from the electrodes. For this reason, immediately following the first run-up, the tube is put on a reduced a.c. voltage sufficient to maintain a current of about 100 microamperes per wire. After about three hours, the tube is permanently conditioned.

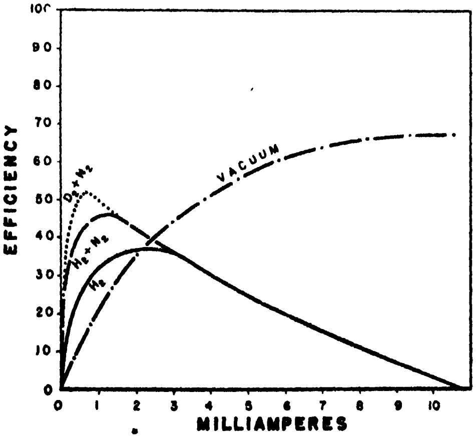

FIG. 4. Efficiency with 10 kv a.c., applied.

## OPERATION

One of the convenient features of this kind of tube is that the full rated voltage can be thrown on without any preliminaries.

There is a definite output voltage at which a tube arcs over and the maximum d.c. output rating of the tube can be given as about 10 percent under that value. The tube never "arcs-back" at unexpectedly low voltages as some of the conventional mercury vapor tubes do occasionally.

There is no observable consumption of discharge electrodes or other materials in these tubes and there is no known reason for these tubes to have other than an indefinitely long life when operated within the ranges of rated current and voltage.

Surges in the high voltage a.c. supply, caused by opening or closing the primary circuit, cannot puncture the tube with cold emission because the tube is filled with gas.

The small positive-ion current on the inverse half-cycle serves a useful purpose. When the output of the rectifier is being smoothed with a condenser, resetting the input a.c. voltage to a

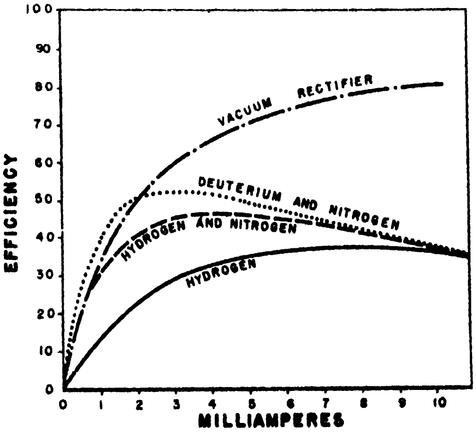

FIG. 5, Efficiency with 20 kv a.c., applied.

---

[4] Willard H. Bennett, Phys. Rev. 61, 55 (1942). See also reference 1.

[5] Willard H. Bennett, Phys. Rev. 61, 53–56 (1942).

lower value results in the condenser voltage dropping correspondingly because of the positive-ion current in the tube.

As long as the rated inverse voltage is not exceeded with these tubes, no damage results from drawing more than the rated current through the tubes momentarily. The only damage that eventually occurs is caused by over-heating the tube as a whole and this takes at least several minutes for all types of tubes. The largest tubes, containing part nitrogen, decondition at currents of about 0.2 milliampere per wire because of a slow formation of ammonia. Operation at 0.06 milliampere per wire slowly disassociates the ammonia and reconditions the tube.

At the higher values of current, ionization by collision occurs between the sheath and the collector in a tube and a high pressure glow discharge makes its appearance. This glow discharge has a positive resistance characteristic for currents up to a higher order of magnitude than the limiting current for the corona discharge, and is not to be confused with normal high pressure arcs. This is not a disruptive kind of arc (that is, it is not abruptly initiated with a streamer and a spark) because of the absence of electron-attaching gaseous components.[6]

In tubes containing part nitrogen, at currents of the order of ½ milliampere per wire-end, the wire-ends become heated, and at currents of between 1 and 5 milliamperes per wire-end, the wire-ends attain temperatures as high as 2000°C. The energy necessary to produce these temperatures cannot be accounted for by the impact energies of positive ions striking the wire-ends following their last free paths. Such heating does not occur in discharges in pure hydrogen at the same currents.[7] It appears that either an active state of nitrogen, or else an excessive concentration of atomic hydrogen caused by the presence of nitrogen, is produced in the ionization sheath and is responsible for this excessive heating which occurs only in part nitrogen.

When the wire-ends heat to more than about 1000°C, a reduction in sheath drop in potential[1] occurs both for positive and negative discharge because of the thermal reduction in gas density immediately adjacent to the wire-end. There is a corresponding reduction in arc-over voltage for the tube on the inverse half-cycle. This effect is reduced by using the finest wires (0.4 mil) but is not entirely overcome by this means.

## CONCLUSION

It is not believed that the full potentialities of this kind of discharge in a rectifier have been realized. Further studies of the diffuse kinds of arcs which occur in these gases should prove profitable. It is thought that a wider appreciation of the advantages of a cold cathode gas-filled rectifier may bring an increased interest in studies of the properties and methods for control of these arcs.

# The Hydrodynamic Lubrication of Finite Sliders

Charles P. Boegli
*Springfield, Ohio*

(Received December 17, 1946)

Two approximations are made in the solution of Reynolds' lubrication equation for the case of a finite slider. These approximations lead to a series of equations that are easy and rapid to use for flat sliders, and which are also applicable to curved sliders. Examples of their use are presented, and a number of calculations are made to determine the range of slider proportions to which they may be applied with sufficient accuracy. The method is of special value for wide sliders which are difficult or impossible to analyze by other methods.

## INTRODUCTION

THE solution of the basic Reynolds differential lubrication equation for the case of a slider bearing of finite width has always been beset with great difficulties. Reynolds[1] did not succeed in finding a general solution to the

---

[1] O. Reynolds, "On the theory of lubrication and its application to Mr. Beauchamp Tower's experiments," Phil. Trans. Roy. Soc. 177, part 1, 157–234 (1886).

equation, and it was not until nineteen years after his presentation that Michell[2] provided a satisfactory attack to the problem.

Michell's method involves no assumptions that affect the accuracy of the solution for the specified conditions. It is, however, applicable only to sliders with flat surfaces, and even for such simple cases the solution is so tedious that only a very small amount of data has yet been computed. R. O. Boswall, working with an assumption credited to Stodola, succeeded in developing an approximate method[3] that gives results negligibly different from those of the exact method in cases where comparisons are possible. Here again the analytical solution can only be made for flat sliders; for other shapes resort is had to a graphical method that actually consists in estimating by eye the shape of one of the pressure distribution curves.

More recently, Muskat, Morgan, and Meres published another solution to the original differential equation.[4] They presented their solution as a series of graphs that serve better for the solution of problems of operation than problems of design. Again, only bearings with flat surfaces are considered.

There is great need for a set of equations that will provide, with a minimum of effort, a good approximation to the actual behavior of a wider variety of sliders than can now be handled. The need for a very high degree of accuracy is, for several reasons, not great. One reason is that it is never possible to predict closely the behavior of the viscosity of the lubricant as it passes through the bearing; the assumption of constant viscosity is generally made, and the practical value of the solution is limited by this approximation. Also, it would be very difficult actually to construct a bearing in exact conformity with a specified design; such a small difference, for example, as a slight rounding of the leading edge, would have considerable effect upon the performance. Therefore, a solution that predicts to a fair degree of accuracy the performance of a great many types of slider bearings would be at least as valuable as one that predicts very closely the performance of only a narrow range.

Such a solution is provided through two simple assumptions. The first is that used by Boswall in his derivation of an approximate method; namely, that the pressure functions along the length and width of the slider are independent. The second is that the pressure function along the length of the slider (that is, the dimension in the direction of motion) is the *same as that for an infinite slider.*

This paper presents analyses based upon these two assumptions; an analytical solution for the case of the flat slider and an arithmetical method for curved sliders. Since with any approximate method some estimate of the accuracy and range of applicability is desirable, the report also presents a comparison of the results obtainable with the new method to any available data found in other manners.

## ANALYSIS

The general differential equation of Reynolds serves as the starting point for this analysis of slider lubrication.

$$\frac{\partial}{\partial x}\left(\frac{1}{\mu}\frac{\partial P}{\partial x}h^3\right)+\frac{\partial}{\partial z}\left(\frac{1}{\mu}\frac{\partial P}{\partial z}h^3\right)=6\frac{d}{dx}Uh. \quad (1)$$

In this equation $\mu$, $h$, $U$, and $P$ are the oil viscosity, the oil-film thickness, the slider velocity, and the oil pressure at any point on the slider surface. If the substitutions are made:

$$x=x_0+Lx_1,$$
$$z=Bz_1,$$
$$h=h_0\beta,$$

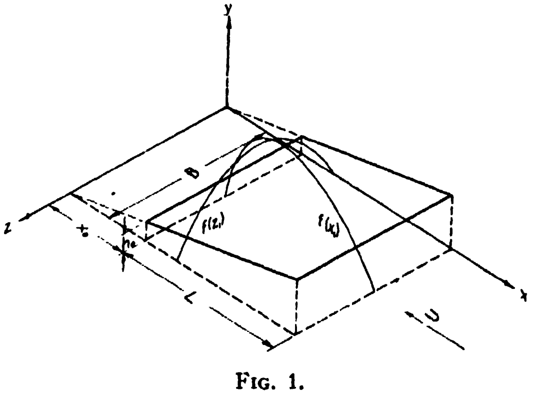

FIG. 1.

---

[2] A. G. M. Michell, "The lubrication of plane surfaces," Zeits. f. math. Physik **50**, 1073–1099 (1904).

[3] R. O. Boswall, *The Theory of Film Lubrication* (Longmans, Green, and Company, New York, 1928), pp. 141–158.

[4] Muskat, Morgan, and Meres, "Studies in lubrication. VII. The lubrication of plane sliders of finite width," J. App. Phys. **11**, 208–219 (March 1940).

where $L$ and $B$ are the length and width of the slider, $h_0$ represents the oil-film thickness at the outlet edge, and $\beta$ is a function of $x_1$ (see Fig. 1); and if viscosity is assumed constant, the equation becomes

$$\frac{\partial}{\partial x_1}\left[\beta^3\frac{\partial P}{\partial x_1}\right]+N^2\beta^3\frac{\partial^2 P}{\partial z_1^2}=A\frac{d\beta}{dx_1}. \tag{2}$$

In Eq. (2), $N$ is the ratio of slider length to slider width ($L/B$) and $A$ is the product $6\mu UL/h_0^2$ containing all the dimensional terms. The new variables $x_1$ and $z_1$ are the fractional distances along the length and width of the slider, and range in value from 0 to 1.0.

It will now be assumed, following the method in reference 3, page 141, that the pressure at any point can be expressed as the product of two functions

$$P=A\cdot f(x_1)\cdot f(z_1). \tag{3}$$

This product is substituted for $P$ in Eq. (2), yielding

$$\frac{\partial}{\partial x_1}\left[\beta^3 f(z_1)\frac{df(x_1)}{dx_1}\right]+N^2\beta^3 f(x_1)\frac{d^2f(z_1)}{dz_1^2}=\frac{d\beta}{dx_1}. \tag{4}$$

To find the form of $f(z_1)$ Eq. (4) is solved along the line where $f(x_1)$ is a maximum; that is, where $df(x_1)/dx_1$ is zero. This yields

$$\frac{d^2f(z_1)}{dz_1^2}+\frac{\left[\frac{1}{f(x_1)}\frac{d^2f(x_1)}{dx_1^2}\right]_{x_m}}{N^2}f(z_1)=\frac{\left[\frac{1}{\beta^3 f(x_1)}\frac{d\beta}{dx_1}\right]_{x_m}}{N^2}, \tag{5}$$

in which $x_m$ indicates the value of $x_1$ for which $f(x_1)$ is a maximum. This equation can be simplified by considering that since $f(x_1)$ is the same as that for an infinite slider, this being the second basic assumption, this function was derived from the differential equation

$$\frac{d}{dx_1}\left(\beta^3\frac{dP}{dx_1}\right)=A\frac{d\beta}{dx_1},$$

which, upon substitution of $P=A\cdot f(x_1)$ and performance of the indicated differentiation, gives

$$3\beta^2\frac{df(x_1)}{dx_1}+\beta^3\frac{d^2f(x_1)}{dx_1^2}=\frac{d\beta}{dx_1}.$$

Where $f(x_1)$ is a maximum, this equation shows that

$$\left[\frac{d^2f(x_1)}{dx_1}\right]_{x_m}=\left[\frac{1}{\beta^3}\frac{d\beta}{dx_1}\right]_{x_m} \tag{6}$$

and consequently Eq. (5) is reduced to

$$\frac{d^2f(z_1)}{dz_1^2}+\frac{M}{N^2}f(z_1)=\frac{M}{N^2}$$

where $M$ is equal to the expression on either side of Eq. (6) divided by $f(x_m)$. The solution is

$$f(z_1)=1-\left(\frac{e^n-1}{e^n-e^{-n}}\right)(e^{-nz_1}+e^{-n(1-z_1)}), \tag{7}$$

where

$$n^2=-\frac{M}{N^2}.$$

Up to this point the treatment has been general, and applicable to both flat and curved sliders. In the case of flat sliders,

$$\beta=1+bx_1$$

and

$$M=-\tfrac{1}{2}\frac{(b+2)^4}{(b+1)^2}$$

while $f(x_1)$ is simply[5]

$$f(x_1)=\frac{bx_1(x_1-1)}{(b+2)(bx_1+1)^2}. \tag{8}$$

For curved sliders, an arithmetic or graphical evaluation of $f(x_1)$ is usually preferred to an analytical solution. Such methods result in a series of tabulated values of the function for various values of $x_1$, and it is necessary to find $x_m$ and $f(x_m)$ from this table. An excellent method of finding the required values is presented in *Empirical Formulas.*[6] To evaluate $n$, the value of $M$ must be known; it can be calculated from the expression on the right side of Eq. (6), which is to be preferred to the quantity on the left, because the former does not require the finding of second derivatives from graphical data.

The important equations and constants are

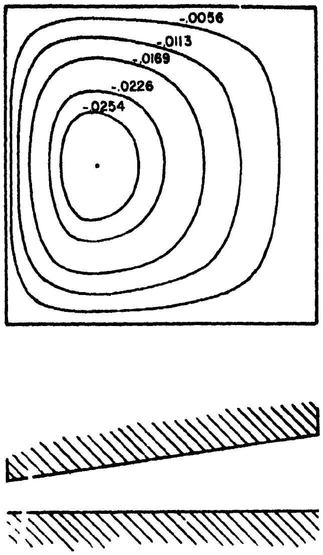

FIG. 2.

summarized below:

$$P = A \cdot f(x_1) \cdot f(z_1) \tag{3}$$

$$f(z_1) = 1 - \left( \frac{e^n - 1}{e^n - e^{-n}} \right) (e^{-nz_1} + e^{-n(1-z_1)}) \tag{7}$$

$$f(x_1) = \frac{bx_1(x_1 - 1)}{(b+2)(bx_1+1)^2} \quad \text{for flat sliders only} \tag{8}$$

in which

$$A = \frac{6\mu UL}{h_0^2}$$

$$n^2 = -\frac{M}{N^2}$$

$$M = \left[ \frac{1}{f(x_1)} \frac{d^2 f(x_1)}{dx_1} \right]_{x_m} = \left[ \frac{1}{\beta^3 f(x_1)} \frac{d\beta}{dx_1} \right]_{x_m}$$

$$= -\tfrac{1}{2} \frac{(b+2)^4}{(b+1)^2} \quad \text{for flat sliders only}$$

$$N = L/B.$$

## EXAMPLES OF FLAT-SLIDER ANALYSIS

To illustrate briefly the use of the equations, let it be desired to analyze the lubrication of a slider for which $N = 1.0$ and $b = 1.5$. For this slider, $M = -12.0$ and $n$ is thus found to be 3.46. The pressure functions are then

$$f(x_1) = \frac{1.5x_1(x_1 - 1)}{(3.5)(1.5x_1+1)^2}$$

$$f(z_1) = 1 - 0.97(e^{-3.46z_1} + e^{-3.46(1-z_1)}).$$

Graphs of these two functions can be drawn, and by finding curves of constant $f(x_1) \cdot f(z_1)$ the isobars over the slider surface can be located. This has been done in Fig. 2. The numbers on the isobars are values of $f(x_1) \cdot f(z_1)$. The actual pressure at each isobar is, of course, this value of $f(x_1) \cdot f(z_1)$ multiplied by the quantity $A$.

For the case of wide sliders, where $N$ becomes small, the analysis by means of the rigorous equations, or even by the approximate treatment in reference 3 becomes more difficult, but that with the new equations becomes simpler. For a slider where $N = 0.01$ and $b = 1.5$, $M$ is still $-12.0$ but $n$ is now 346. Then,

$$f(z_1) = 1 - (e^{-346z_1} + e^{-346(1-z_1)}).$$

It is observed that the value of this function, although zero at $z_1 = 0$ and 1.0, rises very rapidly to 1 between these endpoints; at $z_1 = 0.02$ or 0.98, for example, the value of $f(z_1)$ is 0.999. The function $f(z_1)$ may therefore be considered as a correction to be applied to the ends of a slider which would otherwise be considered infinite. Under such conditions, the value of $f(z_1)$ should be directly dependent upon $z_1/N$, the actual width represented by $z_1$; that this is actually the case is illustrated by finding the point at which $f(z_1) = 0.999$ for a slider for which $N = 0.0001$ and $b = 1.5$. This value turns out to be $z_1 = 0.0002$, which is 0.01 times that for a slider of $N = 0.01$. Since, however, this second slider is 100 times as wide, the actual distance from the ends of both sliders to the points at which $f(z_1) = 0.999$ is the same. This type of relationship in fact exists up to the point where the quantity

$$(e^n - 1)/(e^n - e^{-n})$$

becomes significantly different from 1.0.

## EXAMPLE OF CURVED-SLIDER ANALYSIS

For purposes of illustration, a slider will be analyzed for which $\beta = (2.50)^{x_1}$ and $N = 0.5$. The

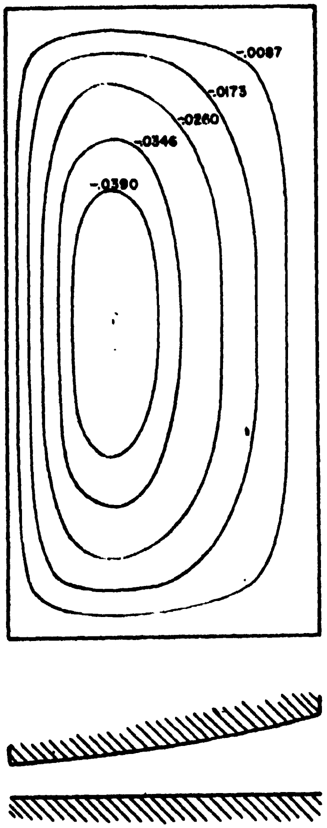

FIG. 3.

customary approximate method leads to a series of values for $f(x_1)$:

| $x_1$ | $\beta$ | $f(x_1)$ |
|---|---|---|
| 0.0 | 1.000 | 0.0000 |
| 0.1 | 1.096 | −0.0273 |
| 0.2 | 1.201 | −0.0414 |
| 0.3 | 1.316 | −0.0466 |
| 0.4 | 1.443 | −0.0459 |
| 0.5 | 1.582 | −0.0414 |
| 0.6 | 1.733 | −0.0349 |
| 0.7 | 1.899 | −0.0273 |
| 0.8 | 2.081 | −0.0192 |
| 0.9 | 2.281 | −0.0112 |
| 1.0 | 2.500 | 0.0000 |

By the use of Lagrange's interpolation formula, $x_m$ is found to be 0.338 and $f(x_m) = -0.0470$. At this point $\beta = 1.363$ and $d\beta/dx_1 = 1.249$

$$M = \frac{1.249}{(-0.0470)(1.363)^3} = -10.50.$$

The value of $n$ is then

$$n = (10.50)^{\frac{1}{2}}/0.5 = 6.482.$$

All the necessary constants have now been calculated. The shapes of the isobars over the surface are illustrated in Fig. 3. The value marked on each isobar gives, when multiplied by $A$, the magnitude of the pressure at that isobar.

TABLE I.

|  | $b=1.0$ |  |  | $b=2.0$ |  |  |
|---|---|---|---|---|---|---|
| $N$ | $W/W_\infty$ (new) | $W/W_\infty$ (actual) | Error % | $W/W_\infty$ (new) | $W/W_\infty$ (actual) | Error % |
| 0 | 1.000 | 1.000 | 0 | 1.000 | 1.000 | 0 |
| 0.5 | 0.687 | 0.695 | −1.2 | 0.735 | 0.714 | 2.9 |
| 1.0 | 0.421 | 0.434 | −3.0 | 0.493 | 0.460 | 7.2 |
| 1.5 | 0.259 | 0.279 | −7.2 | 0.322 | 0.297 | 8.4 |
| 2.0 | 0.168 | 0.185 | −9.2 | 0.219 | 0.208 | 5.3 |

## APPLICABILITY OF EQUATIONS

Although the new equations are especially useful in analyzing cases that are difficult or impossible to solve by the more exact and involved methods, the only available accurate data are for flat sliders, and these must consequently serve as a basis for estimating the accuracy of the solutions obtained by the new method. The comparison thus made is presumed to hold also for curved sliders.

### $W/W_\infty$ Ratio

By $W/W_\infty$ ratio is designated the ratio of the total load carried by the slider to that which would be carried by an equal length of an infinitely wide slider. Since $f(x_1)$ in the new equations is the same as that for an infinite slider, the $W/W_\infty$ ratio is merely the integral of $f(z_1)$ (Eq. (7)), which is

$$\frac{W}{W_\infty} = 1 - \frac{2}{n}\frac{(1-e^{-n})^2}{(1-e^{-2n})}. \qquad (12)$$

Values computed from this equation are compared to those computed by Michell's method for $b=1.0$ and 2.0 in reference 3, page 137 (Table I).

TABLE II.

| $b=2.0$ | $N$ | $D$ (new) | $D$ (actual) | Error % |
|---|---|---|---|---|
|  | 0 | −0.0246 | −0.0246 | 0 |
|  | 0.5 | −0.0181 | −0.0175 | 3.4 |
|  | 1.0 | −0.0122 | −0.0113 | 8.0 |
|  | 1.5 | −0.0079 | −0.0073 | 8.2 |
|  | 2.0 | −0.0054 | −0.0051 | 5.9 |

It will be shown later that the error in the $W/W_\infty$ ratio is of the same magnitude as that in many other derived characteristics of the slider bearing. Figure 4 compares values of $W/W_\infty$ obtained with the new equations to those found by several investigators with various methods, for $N=0.5$, 1.0, and 2.0. The values due to Kingsbury are from "Optimum Conditions for Journal Bearings"[7] and those credited to Muskat, Morgan, and Meres were actually found by a series of graphical calculations with the charts in *Lubrication*,[8] pages 162–66. The latter cannot therefore be considered extremely accurate, but they extend over a greater range than the other published values.

It can be seen that the ratio given by the new equations is in good agreement with those computed by other methods.

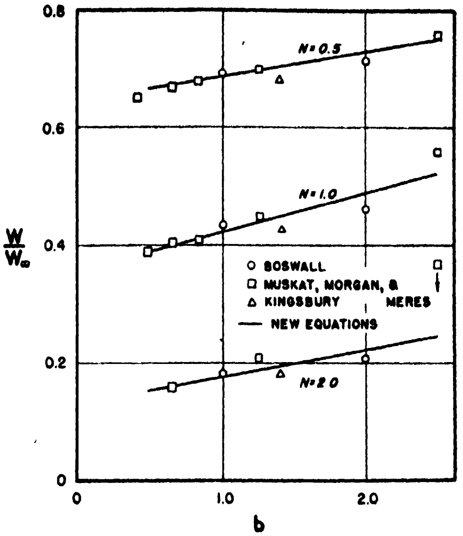

FIG. 4.

### Total Load

The total load carried by the slider is given by the expression

$$W=ALBD,$$

following the notation of Boswall. The new method yields, for the value of $D$,

$$D=\int_0^1 f(z_1)dz_1 \int_0^1 f(x_1)dx_1,$$

because the variables $x_1$ and $z_1$ are independent. Comparison of the values of $D$ from the new and from the Michell solution is sufficient because the factors $A$, $L$, and $B$ are the same for both methods. The accurate data are again obtained from reference 3, page 137 (Table II). It could have been expected that the error in total load be somewhat greater than that in $W/W_\infty$ ratio, because here the variation of $f(x_1)$ from the actual form is also taken into account. Nevertheless, the accuracy is still surprisingly good.

TABLE III.

| $b=2.0$ | $N$ | $\bar{x}_1$ (new) | $\bar{x}_1$ (actual) | Error % |
|---|---|---|---|---|
| | 0 | 0.392 | 0.392 | 0 |
| | 0.5 | 0.392 | 0.386 | 1.5 |
| | 1.0 | 0.392 | 0.374 | 4.9 |
| | 1.5 | 0.392 | 0.359 | 10.5 |
| | 2.0 | 0.392 | 0.341 | 12.6 |

### Center of Pressure ($\bar{x}_1$)

The center of pressure is the value of $x_1$ at which the integrated effect of the pressure is directed. It is thus the line along which the slider would be pivoted. This depends, in the new method, only upon $f(x_1)$ which keeps the same form regardless of $N$. The value of $\bar{x}_1$ is therefore a constant depending only upon $b$, and is equal to $\bar{x}_1$ for an infinite slider. It is, of course, known that the value of $\bar{x}_1$ is actually dependent upon $N$, but the error introduced by assuming it constant remains to be found. The actual values are obtained from the same source previously quoted (Table III). The error in $\bar{x}_1$ is still not excessively great, and the assumption of the constant value would lead to no serious difficulty in most cases.

TABLE IV.

| $b=2.0$ | $N$ | $H$ (new) | $H$ (actual) | Error % |
|---|---|---|---|---|
| | 0 | 1.82 | 1.82 | 0 |
| | 0.5 | 2.00 | 2.02 | −1.0 |
| | 1.0 | 2.30 | 2.38 | −3.4 |
| | 1.5 | 2.74 | 2.83 | −3.2 |
| | 2.0 | 3.23 | 3.32 | −2.7 |

TABLE V.

| $b=2.0$ | $N$ | $V_0$ (new) | $V_0$ (actual) | Error % |
|---|---|---|---|---|
| | 0 | 0.288 | 0.288 | 0 |
| | 0.5 | 0.225 | 0.227 | −0.9 |
| | 1.0 | 0.169 | 0.172 | −1.8 |
| | 1.5 | 0.126 | 0.130 | −3.1 |
| | 2.0 | 0.100 | 0.115 | −14.0 |
| $b=2.0$ | $N$ | $V_i$ (new) | $V_i$ (actual) | Error % |
| | 0 | 0.288 | 0.288 | 0 |
| | 0.5 | 0.313 | 0.313 | 0 |
| | 1.0 | 0.306 | 0.299 | 2.3 |
| | 1.5 | 0.274 | 0.262 | 4.7 |
| | 2.0 | 0.240 | 0.245 | 2.0 |

## Frictional Force

In reference 3, page 145, the frictional resistance is given by the equation

$$R=W\left(\frac{\mu_0 U}{W_1}\right)^{\frac{1}{2}}H,$$

where $H$ is an expression involving integrals of $f(x_1)$ and $f(z_1)$. As in the case of total load, a comparison of values of $H$ is sufficient, since the remaining terms are identical for both methods (Table IV). Here, the error is very small indeed.

## Quantity of Lubricant

The following expressions are given for the quantity of lubricant in reference 3:

$$V_1=\tfrac{1}{2}(6D)^{\frac{1}{2}}\left[\beta_1-\frac{\beta_1^3}{\epsilon}G_1\int_0^1 f(z_1)dz_1\right]$$

where

$$G_1=\left[\frac{df(x_1)}{dx_1}\right]_{x_1=1},$$

$$V_0=\tfrac{1}{2}(6D)^{\frac{1}{2}}\left[1-G_0\int_0^1 f(z_1)dz_1\right]$$

where

$$G_0=\left[\frac{df(x_1)}{dx_1}\right]_{x_1=0}.$$

$V_1$ and $V_0$ are the inlet and outlet quantities, respectively. Substitution of the proper values into these equations yields the results given in Table V. The error in $V_0$ is too large at $N=2.0$ but is certainly sufficiently small at $N=1.5$. The error in $V_1$ is small enough over the entire considered range of $N$.

TABLE VI.

| $b=2.0$ | $N$ | $W/W_\infty$ | $D$ | $\bar{x}_1$ | $H$ | $V_i$ | $V_0$ |
|---|---|---|---|---|---|---|---|
| | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| | 0.5 | 2.9 | 3.4 | 1.5 | −1.0 | 0 | −0.9 |
| | 1.0 | 7.2 | 8.0 | 4.9 | −3.4 | 2.3 | −1.8 |
| | 1.5 | 8.4 | 8.2 | 10.5 | −3.2 | 4.7 | −3.1 |
| | 2.0 | 5.3 | 5.9 | 12.6 | −2.7 | 2.0 | −14.0 |

## Estimation of Error

It was noted previously that the value of $W/W_\infty$ is very easily calculated by the new method, and it would be desirable to use the error in this quantity as a criterion of the accuracy of the method. For purposes of comparison, then, the errors are tabulated in Table VI. It is considered that the $W/W_\infty$ ratio forms a fair, if not slightly pessimistic, criterion of the accuracy of $D$, $H$, and $V_1$, while for $\bar{x}_1$ and $V_0$ the error is likely to be greater in magnitude than that estimated from $W/W_\infty$ when $N$ becomes large. For the great majority of sliders, for which $N\leqslant 1.0$, the $W/W_\infty$ criterion is satisfactory.

Since Fig. 4 shows good agreement between actual and computed $W/W_\infty$ ratios even at $N=2.0$, it can be concluded that the new equations hold with good accuracy for all sliders for which $N$ is 1.0 or less, and they provide an excellent basis for estimating the behavior of even narrower sliders.

## ACKNOWLEDGMENTS

The original work on this project was carried out at the National Advisory Committee for Aeronautics, Aircraft Engine Research Laboratory, Cleveland, Ohio, and was published as ARR E4122. The present report constitutes a refinement in treatment and a considerable expansion of that work.

The assistance of Miss Thelma Bresser in reading the proofs is gratefully acknowledged.

## Measurements of Base Pressure on a Missile in Free Flight*

F. K. Hill and R. A. Alpher
*Applied Physics Laboratory, The Johns Hopkins University, Silver Spring, Maryland*
February 24, 1947

In a series of experiments now under way, missiles of simple geometry (see Fig. 1), differing only in length, are rocket-launched to supersonic velocities; telemetering installed in the missiles transmits to a ground receiver the aerodynamic data measured during flight. Among the significant data being obtained are base pressures; such data are important in the extrapolation of wind-tunnel studies on models to full-scale performance of missiles, where large Reynolds numbers are encountered under ordinary atmospheric conditions.

The missiles have a 14-caliber ogival nose joining tangentially to a cylindrical body of 4-inch diameter, the base of the cylinder being flat and closed. Four fins of bi-convex section are added to give flight stability. The yaw of the missile (in the plane including the missile axis and base pressure measurement port) with respect to the flight path is determined by differential pressure measurements near the nose tip. These differential pressure measurements may be correlated with yaw by means of laboratory experiments in an open supersonic jet or in wind tunnels, as well as by calculations based on linearized supersonic flow theory. It is found in these experiments that the yaw angles encountered are of the order of 1° or less and that no measurable effects caused by angle of attack are observed on base pressure data here reported. Missile velocities are obtained both by an optical tracking system and by stagnation pressure measurement on the missile with a Pitot tube.

Base pressures were measured at a 0.040″ port located ⅜″ from the center line of the missile. Observed base pressures were converted to pressure coefficients by dividing them by the dynamic head (namely, $\frac{1}{2}\times$density$\times$velocity$^2$); corrections caused by change in altitude during flight were made. Coefficients thus computed are shown (Fig. 2) for missiles of the first two lengths of the series to be studied. It is to be noted that the coefficients show at most a small variation with Mach number in the supersonic range covered by the tests, where the value is about 0.3. This result is significantly different from previously used theoretical values.[1] While present information indicates that pressure is essentially independent of position on the base of such missiles, an experimental check of this will be made in free flight.

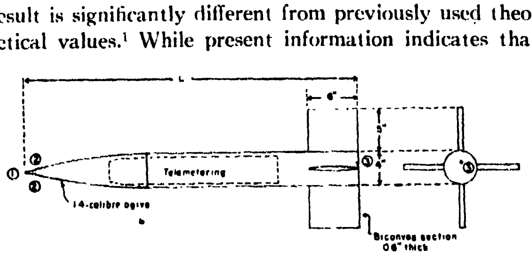

Fig. 1. Scale effect test missile. Telemetering to record: (1) Pitot tube stagnation pressure, (2) differential pressure at nose ports, (3) base pressure at port ⅜″ from center. All pressure ports in the same plane through missile axis.

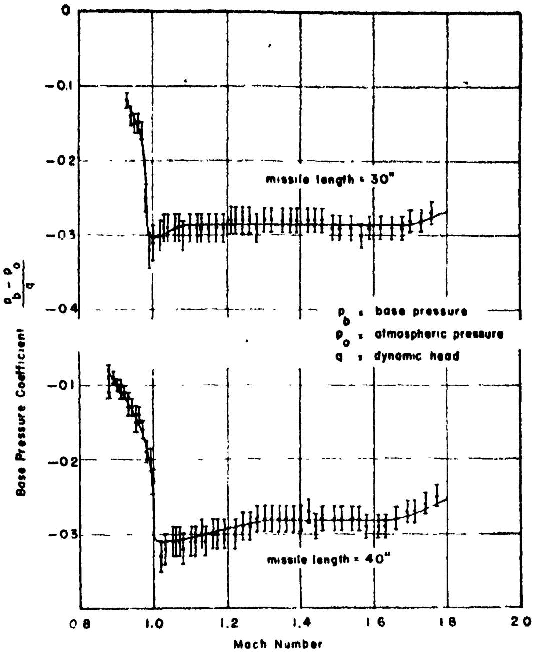

Fig. 2. The probable errors indicated are based upon fairly well-known inaccuracies in the determination of the dynamic head and static pressure throughout flight, and an assumed inaccuracy in the telemetering records based on laboratory tests. All errors are believed to be random.

Similar missiles with lengths up to 120″, as well as a series differing only in diameter, and a series of homologous models, are to be studied, with maximum velocities corresponding to Mach number 3.

This study is part of a general investigation of scale effects which is to be reported in detail after completion of all the tests. It provides the first direct measure of base pressure on such high speed missiles.

## Direction of Maximum Crystal Elongation during Metal Cutting

G. H. Townend
*Metropolitan-Vickers Electrical Company, Ltd., Manchester, England*
March 17, 1947

In an interesting paper by Dr. M. E. Merchant on "Mechanics of the Metal Cutting Process,"[1] an error was made in the expression connecting shear angle, rake angle, and direction of maximum crystal elongation (Eq. (1), page 269). I have written to Dr. Merchant and he confirms the new expression derived below.

Let $\alpha$ = rake angle,
$\phi$ = the angle between the shear plane and the surface of the workpiece.

Consider a section of the workpiece $ABCD$ such that $\angle CBD = 90°$. Then after shearing this section will become the parallelogram $BFEC$. The dimension perpendicular to the shear plane must be unchanged during shearing.

$$\therefore \quad BD = BH = a.$$

Consider a line $CG$ in the chip making an angle $\psi$ with the plane of shear. Then the corresponding line in the workpiece is $DJ$. The condition that $CG$ shall be the direction of maximum crystal elongation is that $CG/DJ$ is a maximum.

$$CG = a \operatorname{cosec}\psi,$$
$$DJ = \{a^2 + (a \cot\phi - a \cot\psi + a \tan(\phi - \alpha)^2\}^{\frac{1}{2}}.$$

The condition is that

$$\{\sin^2\psi + (\cot\phi \sin\psi - \cos\psi + \tan(\phi - \alpha) \sin\psi)^2\}^{-\frac{1}{2}}$$

is a maximum. That is,

$$\sin^2\psi + \{\sin\psi(\cot\phi + \tan(\phi - \alpha) - \cos\psi\}^2$$

is a minimum. Let

$$\cot\phi + \tan(\phi - \alpha) = \epsilon,$$
$$\epsilon^2 \sin 2\psi - 2\epsilon \cos 2\psi = 0.$$

If $\epsilon \neq 0$

$$2 \cot 2\psi = \epsilon,$$
$$2 \cot 2\psi = \cot\phi + \tan(\phi - \alpha).$$

Alternatively it is easily shown that a circle on the workpiece becomes an ellipse on the chip and that the principal axes of the ellipse make an angle $\psi$ with the shear plane, where

$$2 \cot 2\psi = \cot\phi + \tan(\phi - \alpha).$$

# Here and There

### Printing Electronic Circuits

According to a recent release from the National Bureau of Standards prepared by Cledo Brunetti and Philip J. Franklin, new techniques, developed by the National Bureau of Standards in cooperation with electronic manufacturers, for electronic devices promise to simplify production methods and to accelerate the manufacture of cheaper, more compact, and more uniform electronic equipment. These techniques, representing the perfection of a method of printing wiring and circuit components on an insulated surface, is one of the new processes and techniques evolved from research and development during the war.

The methods are applicable in the design of numerous industrial and commercial devices where extreme ruggedness and small size are imperative. By means of the printing process the electronic circuit of a conventional radio—now characterized by a maze of wires, resistors, inductors, and condensers—may be replaced by a compact circuit printed on a small flat plate, eliminating much of the third dimension and making it simple to check and repair. Other specific applications lie in the fields of pocket radios, personal radio telephones, miniature hearing aids, meteorological instruments, and various miniature electronic control circuits.

Present investigations at the National Bureau of Standards of the various means available for reducing the size of electronic assemblies and for mechanization of chassis wiring reveal a number of feasible and practical electronic printing methods. Variations of the stenciled screen-printing process include hand printing or spraying of the components and leads on suitable surfaces. Another method involves the use of photography and an abrasive blast. A third is an adaptation of the chemical methods of silvering mirrors. Mechanical processes include metal spraying, metal sputtering or evaporation, the use of foils, and stamping. As an example, loop antennas are now stamped out in a single operation by a variation of the printed wiring techniques and have shown improved performance over wire-wound loops in addition to reduced cost of production. The principal effect of these methods is to reduce electronic circuit wiring to two dimensions. The effect is enhanced where it is possible to employ sub-miniature tubes and compact associated components.

### New Appointments

Leonard I. Schiff, theoretical physicist who worked on the Los Alamos atom bomb project, has joined the faculty of Stanford University as associate professor of physics.

H. B. G. Casimir, co-director of the Philips Research Laboratories, Eindhoven, Holland, is delivering a series of invitation lectures at Johns Hopkins University on the properties of matter at low temperatures and on problems in quantum electrodynamics.

Leo L. Beranek, formerly director of the electro-acoustic and systems research laboratories of Harvard University, has been appointed associate professor of communications engineering in the Department of Electrical Engineering of the Massachusetts Institute of Technology.

Alfred J. Reis, Austrian-born scientist, was recently appointed a research specialist in the Engineering Experiment Station at Rutgers University. He will conduct a series of studies in the engineering properties of materials and in powder metallurgy.

John A. Hipple has been named chief of the Atomic Physics Section at the National Bureau of Standards.

John L. Abbott recently joined North American Philips Company, Inc., as application engineer in the industrial x-ray division.

### Awards

James I. Hoffman of the National Bureau of Standards has been awarded the 1946 Hillebrand Prize for significant contributions to chemical science.

The John Price Wetherill and the Howard N. Potts medals of The Franklin Institute of Philadelphia were awarded at ceremonies on April 16. Kenneth S. M. Davidson of Stevens Institute of Technology received the Wetherill medal for his contributions to the improved design of ships through experiments on ship hull models. Vladimir K. Zworykin, director of electronic research of the Radio Corporation of America, and Robert H. Kent, associate director of the ballistics research laboratories, Aberdeen Proving Ground, were each awarded a Potts medal. Zworykin received the medal for his inventions of the iconoscope and kinescope, which are essential to modern commercial television. Kent was honored for contributions to the science of ballistics and particularly for his effective operation of the Aberdeen Wind Tunnel, which is doing a large part of the supersonic testing for the armed forces.

The seven winners of Frank B. Jewett fellowships for research in the physical sciences for 1947–1948, announced by the American Telephone and Telegraph Company, are as follows: M. G. Ettlinger of California Institute of Technology and Austin, Texas; Wallace D. Hayes of California Institute of Technology and Palo Alto, California; Paul Olum of Harvard University and Winchester, Massachusetts; Aadne Ore of Yale University and Oslo, Norway; Alfred Schild of the Carnegie Institute of Technology and Pittsburgh, Pennsylvania; Robert L. Scott of the University of California and Santa Ana, California; and Edwin H. Spanier of the University of Michigan and St. Paul, Minnesota. Two of the winners are chemists, two physicists, two mathematicians, and the seventh is an aeronautical engineer.

### General Electric-Yale University Joint Research

At the Dunham Laboratory of Electrical Engineering at Yale University, research is being conducted on controls for a flight simulator or dummy rocket for duplicating flight characteristics of a rocket missile, as part of General Electric Company's long-range rocket research program. The project at Yale is under the direction of John L. Bower, Assistant Professor of Electrical Engineering.

### Biological Photographic Exhibition

An international exhibition of biological photography of interest to all photographers in the scientific field will be held September 10–27, 1947, under the sponsorship of the Biological Photographic Association at the Rochester Public Library, Rochester, New York. Three judges who are prominent in their fields will select all entries. Membership in the Association is not a requisite for participation in the exhibition. Entry blanks for contributors may be obtained from Mr. H. Lou Gibson, 343 State Street, Rochester 4, New York. The entry fee is $1, and the last day for receiving entries is August 1, 1947.

Information concerning the convention program of the Biological Photographic Association to be held September 10–13 may be obtained from Mr. John V. Butterfield, 635 St. Paul Street, Rochester 4, New York.

### General Electric Educational Fund Awards

Research fellowships totaling $20,500 have been awarded to fourteen graduate students by the General Electric Educational Fund. Eight of the winners received Charles A. Coffin Fellowships awarded for research in the fields of electricity, physics, and physical chemistry. The other six young men obtained Gerard Swope Fellowships for advanced study in industrial management, engineering, the physical sciences, and other scientific and industrial fields.

### M.I.T. Summer Session in Applied Mathematics

Massachusetts Institute of Technology has announced a special summer session in applied mathematics from August 4 to September 19, 1947. The following graduate courses will be offered:

1. **Theory of Plates and Shells.** By Professors F. B. Hildebrand and E. Reissner.
2. **Theoretical Hydromechanics.** By Professors E. Reissner and C. C. Lin.
3. **Advanced Topics in Applied Mathematics.** By Professors J. L. Synge, H. Reissner, W. Prager, F. B. Hildebrand and P. D. Crout.
4. **Tensors in Mechanics.** By Professor D. J. Struik.

Further information concerning the program may be obtained by writing to Department of Mathematics, Massachusetts Institute of Technology, Cambridge 39, Massachusetts.

### Centenary of Association of Engineers

The Association of Engineers, with headquarters at the University of Liége in Belgium, celebrates this year its 100th anniversary. For the occasion it is sponsoring a congress and an exhibition to which engineers and industry representatives are cordially invited. The congress will take place in Liége from August 30 to September 13, and is entitled "Past, Present and Future of Our Industry." For further information address Association des Ingenieurs, 12, Quai Paul Van Hoegaerden, Liége, Belgium.

### National Electronics Conference

The National Electronics Conference, Inc., whose purpose is to serve as a national forum on electronic developments and their application, is sponsored jointly by Illinois Institute of Technology, Northwestern University, American Institute of Electrical Engineers, Institute of Radio Engineers, and the University of Illinois, with the Chicago Technical Societies Council a cooperating organization. Plans are now being formulated for the 1947 National Electronics Conference, which will be held on November 3, 4, and 5 at the Edgewater Beach Hotel, Chicago.

### Course in Statistical Quality Control

An advanced eight-day course in quality control by statistical methods is to be presented June 27 through July 5 at Purdue University, Lafayette, Indiana. It is intended for those who already have some acquaintance with statistical quality control from such a course as the War Production Board organized during the war. Anyone desiring further information should write to Professor I. W. Burr at Purdue.

### Marconi Anniversary

An International Congress will celebrate the fiftieth anniversary of the discovery of radio by Marconi, September 28 to October 5, 1947, in Rome, Italy. The event is being organized by the Italian National Council of Research. It aims at providing a complete picture of the progress of radio in the world from the scientific, technical, and industrial point of view, and giving world radio experts the opportunity of meeting and studying plans for a future international collaboration.

### The Bulletin of Mathematical Biophysics

Following is the table of contents for *The Bulletin of Mathematical Biophysics* for June 1947:

**Mathematical Theory of Motivation Interactions of Two Individuals: II.** ANATOL RAPOPORT

**A Theory of Membrane Permeability: III. The Effect of Hydrostatic Pressure.** INGRAM BLOCH

**The Mechanism of the Middle Ear: II. The Drum.** MARTINUS H. M. ESSER

**A Mathematical Description of Metabolizing Systems: II.** HERMAN BRANSON

**Outline of a Matrix Calculus for Neural Nets: II.** H. D. LANDAHL

The University of Chicago Press, Chicago, Illinois, Volume 9, Number 2.

### Meeting of the Division of Solid State Physics

A Division of Solid State Physics in the American Physical Society, recently authorized by the Council, is in the process of formation and a corresponding announcement is being sent out to the members of the society. The organizing committee of the division is planning for a meeting of the division in conjunction with the Montreal meeting of the American Physical Society June 19 to 21, 1947. In view of the fact that the American Society for X-Ray and Electron Diffraction is having a meeting near Montreal starting Monday, June 23, the meeting of the division will take place on Saturday, June 21, so as to make it convenient for those interested in solid state to attend both meetings.

The program will be composed of four invited papers:

"Diffraction of Neutrons in Crystals," F. SEITZ.

"Theory of Crystal Rectifiers with Application to Copper Oxide," J. BARDEEN.

"The Relaxation Spectrum of Metals," C. ZENER.

"Nuclear Magnetic Resonance Absorption in Solids and Liquids," E. M. PURCELL,

and contributed papers in the field of solids. It is suggested that those who have papers in the field of the division would present them at the June meeting in Montreal.

The Organizing Committee of the Division of Solid State:

| | |
|---|---|
| T. A. Read | S. Siegel |
| F. Seitz | R. Smoluchowski |
| W. Shockley | C. Zener |

### Calendar of Meetings

**May**

| | |
|---|---|
| 26–27 | Institute of Aeronautical Sciences, Detroit, Michigan |
| 31 | American Physical Society, New England Section, Amherst, Massachusetts |

**June**

| | |
|---|---|
| 1–6 | Society of Automotive Engineers, French Lick, Indiana |
| 8–10 | American Society of Refrigerating Engineers, Los Angeles, California |
| 9–13 | American Institute of Electrical Engineers, Montreal, Quebec, Canada |
| 9–14 | Symposium on Molecular Structure and Microscopy, Ohio State University, Columbus, Ohio |
| 12–14 | Canadian Association of Professional Physicists, University of Western Ontario, London, Canada |
| 16–19 | American Society of Mechanical Engineers, Chicago, Illinois |
| 16–20 | American Society for Testing Materials, Atlantic City, New Jersey |
| 18–20 | American Association of Physics Teachers, Regional Meeting, University of Minnesota, Minneapolis, Minnesota |
| 18–21 | Society for the Promotion of Engineering Education, Minneapolis, Minnesota |
| 23–25 | American Society for X-Ray and Electron Diffraction, Montreal, Quebec, Canada |

**July**

| | |
|---|---|
| 11–12 | American Physical Society, Stanford University, California |
| 16–19 | American Society of Civil Engineers, Duluth, Minnesota |

**August**

| | |
|---|---|
| 21–23 | Society of Automotive Engineers, Los Angeles, California (Transportation and Maintenance Meeting) |
| 26–29 | American Institute of Electrical Engineers, San Diego, California |

## New Booklets

Dow Corning Corporation, Midland, Michigan, has announced a new technical pamphlet, *DC Antifoam A*, which discusses a silicone compound recently developed for killing foam in aqueous systems. 4 pages.

The December 1946 issue of *The Frontier*, published by the Armour Research Foundation of Illinois Institute of Technology, Chicago 16, Illinois, includes the following articles: "A Unique Torquemeter," "Classification of Analytical Methods," "Processing and Use of Zircon for Refractory Electrical Insulating Compositions." 20 pages.

*Nickel Steel Topics* for February 1947, published by The International Nickel Company, Inc., 67 Wall Street, New York 5, New York, features an article on the "refrigerator car of the future," built largely of stainless and low nickel alloy steels. 12 pages.

Fish-Schurman Corporation, 230 East 45th Street, New York 17, New York, makers of raw optical, technical, and scientific glass and optical parts and specialties, recently issued bulletin MI-318 on *FS Multi-Layer Interference Films; Dichroic and Achromatic Beam Splitters*. 2 pages.

*The Aerovox Research Worker*, monthly house organ of the Aerovox Corporation, New Bedford, Massachusetts, in its December 1946 edition discusses "The Rectifier-Amplifier V. T. Voltmeter." 4 pages.

**Pittsburgh Plate Glass Company, Columbia Chemical Division, Fifth Avenue at Bellefield, Pittsburgh 13, Pennsylvania, has published *Form A-100*, a new Columbia Caustic Soda Book, 72 pages, printed in three colors. Many photographs. Write for a copy on your company letterhead.**

# Crystal Pattern Synthesis by an Approximate Summation of Fourier Series

JOSEPH S. LUKESH
*Crystallographic Laboratory, Department of Geology, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received February 10, 1947)

A faithful representation of the locations of the peaks of electron density maps can be obtained rapidly by determining for each point in the projected unit cell the algebraic sum of the amplitudes of those reflections which are contributing either a maximum or a minimum at each point. Since maxima and minima do not, in general, fall at the specific points of the grid, an approximation must be introduced. Using the semi-polar form of Fourier series, the approximate summation can be accomplished with the use of one hundred and fifty strips. The method was tested by determining the peak locations in the structure of diopside projected on 001. Potential applications of the approximate summation include rapid checking of the validity of assumed crystal structures.

## INTRODUCTION

CRYSTAL patterns can be synthesized conveniently by determining the projected electron density through the summation of a Fourier series of the following general type:

$$\rho(x, y) = (1/A)\sum_h \sum_k F_{(hk0)} \cos(2\pi/N)(hx+ky), \tag{1}$$

which gives the projection normal to the *c* axis. Other axes are treated by appropriate choice of the indices, *h*, *k*, or *l*. Equation (1) is valid only when the projection is centrosymmetrical. The non-centrosymmetrical case will not be considered here; however, it can be treated in a similar manner by applying the same reasoning to the sine terms. The form of the contribution of a given reflection, *hk0*, to the total electron density is invariant, regardless of the actual crystal structure. It consists of a sinusoidal alternation of positive and negative density. Actually it is a cosine surface whose periodicity in each axial direction is given by the appropriate index. The different distributions of electron density in different crystals arise from varying amplitudes of the cosine surfaces and from different arrays of contributing reflections. Obviously, in order that an accumulation of electron density occur at any point in the projected unit cell, the sum of the positive solutions of the terms of Eq. (1) must be greater than the sum of the negative solutions. In order that a high peak occur, not only must a large number of reflections give positive solutions, but also they must be near their maxima. Similarly, in order that there be little or no accumulation of electron density, either most reflections are contributing very little, or those near their maxima are compensated for by others near their minima. This suggests that if one were to list for each point in the unit cell the amplitudes of all reflections that are contributing a maximum and all that are near a minimum, one might obtain a faithful representation of the electron density distribution merely by subtracting the negative terms from the positive. If this hypothesis is valid, the labor of computation is reduced to the listing and totalling of the appropriate amplitudes. Of course, detail will be lost in the regions of low electron density, but these regions are unimportant in at least the early stages of crystal structure analysis. In many cases, location of the strongest peaks will be of material aid in the solution of a crystal structure.

## THEORY

In an earlier paper the writer[1] developed a semi-polar form of the series of Eq. (1). This concept, while not essential to the approximate method to be discussed, offers a number of advantages in computational simplicity and will be followed in this report. If the point, $x, y$, is specified by the coordinate, $x$, and the slope, $c$, of the line from the origin to the point, Eq. (1) may be written:

$$\rho(x, c)=(1/A)\sum_h \sum_k F_{(hk0)} \cos(2\pi/N)x(h+ck). \tag{2}$$

The half-unit cell for which the summation is to be made is divided into four segments, and the form of the cosine term varies for each. For a given plane and a given radial line, Eq. (2) reduces to

$$\rho(x, c)=(1/A)\sum_h \sum_k F_{(hk0)} \cos(2\pi/N)Cx, \tag{3}$$

where $C$ is a constant and $x$ is an integer. In the article cited[1] it was pointed out that the conventional rectilinear grid is inconvenient, since the slopes of the lines from the origin to the various points are not suited for easy calculation. Furthermore, only a few points occur along any one line. For these reasons, a semi-polar grid was described in which the points at which Eq. (3) is to be evaluated are defined by the intersections of radial lines and either the $x$ or $y$ coordinates. If the axes are divided into thirty points (a sufficient number since the projection is only an approximation), the number, $N$, in Eq. (3) is thirty. For this spacing of points, it is convenient to choose radii whose slopes are .1, .2, .3, etc., and the constant, $C$, can be determined from the indices of a plane merely by inspection. Thus, for the reflection, 320, the constant along the radius whose slope is .4 is equal to 3 plus .4(2), or 3.8.

If Eq. (3) is plotted as a function of $x$ for a given amplitude, $F$, and a given constant, $C$, a cosine curve results. This is the form of the density contribution of a reflection, $hk0$, along a radial line of slope, $c$. The amplitude is determined by $F$ and the periodicity by $C$. It is obvious that maxima and minima occur at various points along the radius. Since the positions of the maxima and minima depend only on the indices of the reflection and on the slope of the radius, they can be determined in advance and tabulated for use in all structure determinations. Because, as was pointed out in the article previously cited,[1] there are only one hundred and fifty independent values of $C$ for the grid chosen, the table will not be extensive.

In general, the maxima and minima will not occur at integral values of the coordinate, $x$. This necessitates the introduction of an approximation, since it is at the integral values of $x$ that the summation is being made. For the purposes of this report, it has been assumed, quite arbitrarily, that a plane contributes to the electron density only at those points where its amplitude times the appropriate value of the cosine is fifty or more percent of the maximum. Similarly, a plane subtracts from the density only when the product is fifty or more percent of the minimum. In other words, a reflection is assumed to be ineffectual when the product of its amplitude times the cosine is between zero and either plus or minus one-half of $F$. Furthermore, it is assumed that a plane contributes or subtracts the entire value of $F$ when it is effective. This latter assumption eliminates all calculation, and the summation consists of tabulation of the amplitudes of the effective planes at each point and their summation.

## EXAMPLE OF THE APPROXIMATION

In order to test the hypothesis developed above, computations have been made of the electron density of diopside projected on (001). Data for the amplitudes of the various reflections and a map of the conventional summation have been reported by Bragg.[2] Because of the high symmetry of diopside in this projection, only one-eighth of the cell need be considered. However, in order to test the approximation, computations were made for one-quarter of the cell.

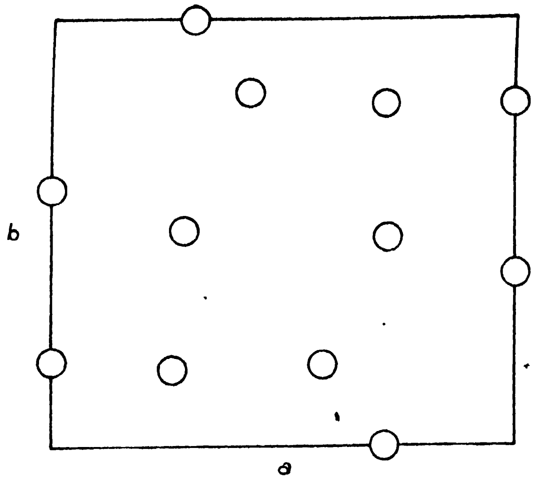

FIG. 1. Peak locations in the 001 projection of diopside determined by the approximate summation, Case I (equal amplitudes).

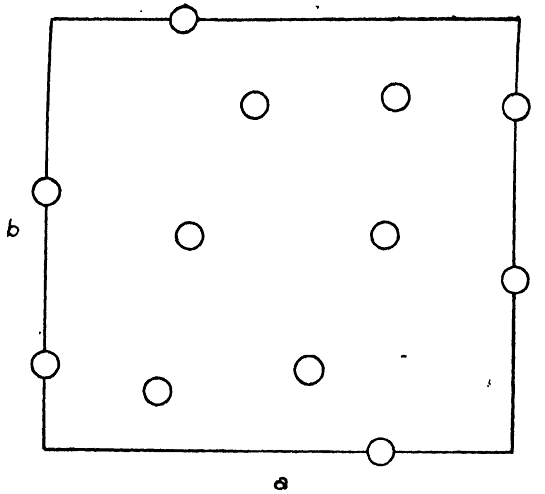

FIG. 2. Peak locations in the 001 projection of diopside determined by the approximate summation, Case II (estimated amplitudes).

Since the quarter-cell is in itself centrosymmetrical, the amount the major peaks depart from centrosymmetry will be a test of the value of the approximation. Three electron density maps have been computed. In the first, only the signs of the amplitudes have been used, all magnitudes being considered equal. In the second, estimated magnitudes have been introduced; and in the third, the actual measured values were used.

In Table I are listed the one hundred and fifty values of the constant, $C$, of Eq. (3) and the corresponding values of $x$ for which maxima and minima, as defined previously, occur. To compute the summation it is only necessary to list for each radial line the amplitudes of the reflections which are maximum and minimum at each point. As a typical example, the maxima and minima of the plane 570 along the radial line whose slope, $c$, is .4, will be determined. The constant, $C$, is equal to 5 plus .4(7), or 7.8. From Table I, opposite 7.8 it is found that maxima and minima occur at the following points:

Maxima—0, 4, 8, 11, 12, 15
Minima—2, 6, 9, 10, 13, 14

If the amplitude of the reflection, 570, is plus forty, the number forty is recorded in the columns of the worksheet corresponding to the coordinates, $x$, for which the contribution is a maximum. Similarly, minus forty is recorded in the columns corresponding to the minima. When the amplitude is negative, one must, of course, make appropriate sign changes.

## Case I—Equal Amplitudes

This example, which represents an exploration of the possibility of determining atomic locations from knowledge of the array of reciprocal lattice points, but not their relative weights, is of little

TABLE II. $F$ values of the reflections of the type $hk0$.*

| $hk0$ | $F$ | $hk0$ | $F$ |

| 820 | −17 | 370 | 0 |
| 130 | 13 | 570 | 40 |
| 330 | 50 | 080 | 0 |
| 530 | 37 | 280 | −32 |

* After W. L. Bragg, Zeits. f. Krist. **70**, 475 (1929).

Note: Because of symmetry, reflections of the types $\bar{h}k0$, $h\bar{k}0$, and $\bar{h}\bar{k}0$ have the same $F$ values as those of the type $hk0$.

practical importance, since one can always estimate the relative weights from a photographic film. It is included here because the results are rather striking.

The data used in this and succeeding cases were taken from Bragg[2] and are listed in Table II. The peaks of the "electron density" map drawn from the computations are represented in Fig. 1 by circles. (The actual map is, of course, distorted. In the interests of clarity, only the peak positions are shown.) Figure 1 should be compared with Fig. 4, which shows the peak locations taken from the conventional summation of Bragg.[2] It is important to note that the major peaks, representing heavy atoms or two or more atoms superimposed, are correctly positioned; small peaks are slightly displaced.

### Case II—Estimated Amplitudes

In this example, the amplitudes listed in Table II have been assigned weights of from one to five. Those from one to twenty-five, for instance, have been given the weight of one; those from twenty-six to fifty, two, etc. This was done in an attempt to simulate amplitudes that might be calculated from intensities estimated from an x-ray film. Figure 2 shows the locations of the peaks in the summation. Improvement is noted in the positions of the smaller peaks.

### Case III—Measured Amplitudes

In Fig. 3 are shown the peaks, with their relative heights indicated by contours, resulting from the approximate summation in which measured amplitudes were used. There is no appreciable change in the positions found in the previous case.

## DISCUSSION

The parameters of the peaks shown in Figs. 1 through 4 are listed in Table III. In all cases, the values obtained from the approximate summations are within .02 of those from the conventional summation. (The values for the conventional summation may or may not be in agreement with the actual parameters of diopside. Those listed were measured from the electron density map in order to present a fair comparison with those derived in the same manner from the approximate summations.) On the basis of this one test, it would appear that the electron density peaks can, indeed, be located with reasonable accuracy by considering only the maximum and minimum contributions at each point in the cell. One would, however, hesitate to recommend the approximate method until independent checks have been made. The choice of diopside may have been a fortuitous one.

One of the potential uses of the approximate method is in the checking of an assumed structure. If a logical structure can be deduced from crystal chemical knowledge, the phases of the strong reflections can be computed. An approximate summation, using only those reflections, might suffice to demonstrate whether or not the assumed structure is consistent.

## COMPUTATION BY MEANS OF STRIPS

Although the labor of computation is reduced in the approximate method to the addition of columns of numbers, it is still necessary to look up data in a table and to record them. This effort can be eliminated by preparing a series of strips, one for each value of the constant, *C*. Each strip has a space for each value of the coordinate, *x*, and those spaces where the function is a maximum are colored blue. Minima are indicated by red. The labor of summation involves only the selection of the strips, their arrangement on a suitable board, and the addition of the coefficients.

In checking an assumed structure, it is not necessary to perform the entire summation. Only those regions which should be high in density need be treated. Using the approximate method, the summation can be done in a very short time.

# Single Crystal Electron Diffraction by Micro-Crystalline Materials*

NORMAN DAVIDSON** AND JAMES HILLIER
*RCA Laboratories, Princeton, New Jersey*

(Received March 11, 1947)

It is shown that the double lens probe-type electron diffraction camera described earlier is capable of producing useful electron diffraction patterns of single microscopic crystals in the size range 200–2000A; the formation of an opaque carbonaceous deposit, which occurs when an electron probe is focused on a specimen, is prevented in the diffraction camera by previously exposing the specimen chamber to an electron spray. A number of examples of two-dimensional grating patterns and Kikuchi-line patterns obtained from such crystals are shown. From either type of pattern it is possible to obtain accurate values for some of the lattice spacings, while from the Kikuchi-line patterns it is possible to deduce accurately the orientation of the crystals relative to the electron beam. The results are shown to agree reasonably well with the predictions of the dynamical theory as presented by MacGillavry. It is concluded that a two-dimensional grating pattern is to be expected from a crystal oriented with an important lattice vector approximately parallel to the electron beam independent of slight disorders or warping of the crystal. Kikuchi-line patterns are to be expected for most other crystals which are not excessively thick or disordered. The theory also shows that both types of patterns may be obtained simultaneously.

## I. INTRODUCTION

THE study of the diffraction of fast electrons by single crystals has been pursued in several different ways up to date. Because of the limited penetration of the electron beam, work with macroscopic crystals which are readily manipulated and oriented is restricted either to reflection diffraction by a surface or, for transmission electron diffraction, to the relatively rare case of materials, such as mica, which can be obtained as thin sheets.

There would be many useful applications of an effective technique for obtaining single crystal electron diffraction patterns and thus determining the lattice constants of crystals of dimensions less than a micron—that is, crystals of dimensions appropriate to electron diffraction and electron microscopy. Some of these applications are:

(a) Identification of a material which has a complex powder pattern or which is present as a minor constituent of a mixture of crystals.

(b) The determination of crystal structure when single crystals of sufficient size for x-ray diffraction are not available.

(c) Further study of the fundamental phenomena of electron diffraction by crystals.

Various methods of observing the electron diffraction patterns from single micro-crystals have been reported in the literature. The observations of crystalline reflections in electron micrographs[1,2] have been used to confirm the dynamical theory of electron diffraction, to study the warping of crystals, and in general to provide information about strong reflections by properly oriented crystals. The method is limited to strong reflections.

Boersch has obtained electron diffraction patterns in which the collimated electron beam was restricted by an aperture to have a cross section of 0.005 mm at the specimen.[3] The spot patterns obtained for the various films examined were such that only one or a few crystals were responsible for the diffraction, but no correlation was possible between the morphology of the irradiated portion of the specimen and its diffraction pattern.

The same author has suggested a scheme in which a fine aperture moves in the image plane of an electron microscope.[4] When the aperture

is placed on the image of a particular crystal, the angular distribution of the transmitted rays provides information about the diffraction pattern of the particular crystal. Boersch used this technique to obtain diffraction patterns of 0.08-mm portions of gold foil. This method would be difficult to develop into a practical method for true micro-crystals because of the effects of spherical aberration on the diffracted rays, and of the decrease, caused by magnification, in angular aperture of an imaging pencil.

Ardenne has suggested several schemes for modifying the electron optical system of an electron microscope so as to obtain diffraction patterns from fields 1–10 microns in diameter.[5, 6]

The purpose of the present article is to report the phenomena observed using a mode of operation of the electron diffraction camera described by Hillier and Baker[7] wherein a beam of electrons reduced to a probe of *ca.* 200A cross section, and of maximum angular aperture *ca.* $7.5\times10^{-3}$ radian is diffracted by single micro-crystals. It is believed that this method offers a practical approach to the problem of obtaining electron diffraction patterns from single micro-crystals, and of correlating the morphology and orientation of a particular crystal with its diffraction pattern.

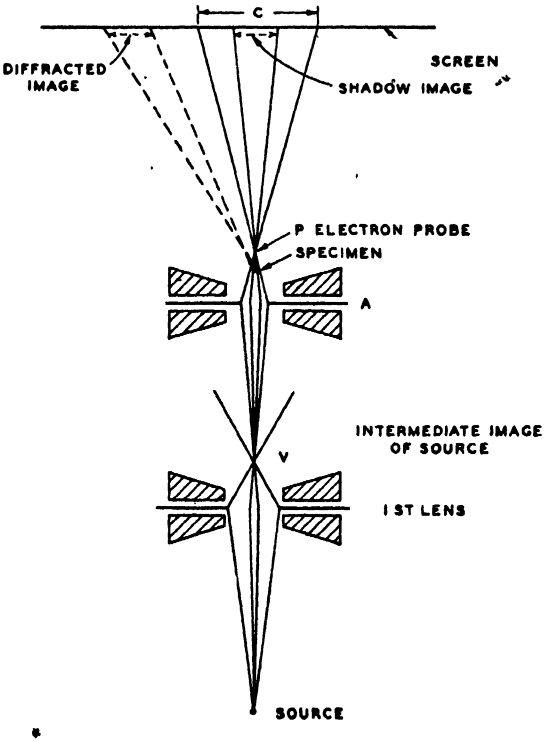

FIG. 1. Schematic diagram of lens system and ray paths in the electron diffraction camera as used for shadow microscopy and single crystal diffraction.

## II. EXPERIMENTAL TECHNIQUES

The double lens system of the electron diffraction camera can be used in the two following ways (Fig. 1):

(a) Using the first lens as a strong lens to form a reduced image, *V*, of the electron source, and the second lens to re-focus the image on the photographic plate or fluorescent screen, a focused electron diffraction pattern is obtained of an area of specimen determined by the size of the limiting aperture, *A*, of the second lens.

(b) When the focal length of the second lens is reduced, the image *V* of the source is re-focused to an electron probe *P*, somewhere between *A* and the image screen. A bright field shadow image of the specimen is formed on the image screen within the central cone of illumination, *C*. The rays diffracted out of *C* by crystalline material in the irradiated field are the subject matter of this article.

From the point of view of obtaining a conventional powder diffraction pattern, one is producing, in this mode of operation, a "defocused" electron diffraction pattern. The degree of defocusing may be expressed by the numerical value of the angular aperture of the convergent beam of electrons passing through crystalline material in the field of irradiation. It will be seen, however, that under some circumstances it is possible to obtain precise values of interplanar spacings and lattice constants from defocused patterns.

For the sake of clarity, some of the well-known facts about the operation of a shadow microscope[8, 9] should be mentioned before describing

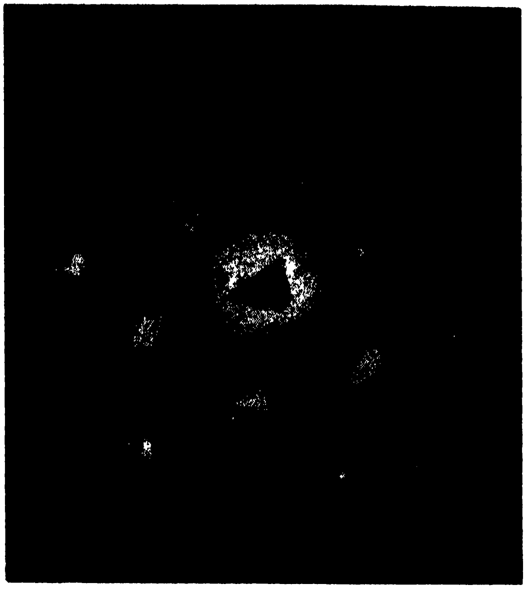

FIG. 2. Two-dimensional grating pattern from graphite, *kho*, reproduced from Hillier and Baker, reference 7, Fig. 15 (c). The bright field shadow image of the crystal has been printed on from a negative given a shorter exposure. Note the variation of reflecting power of different areas of the crystal for different reflections.

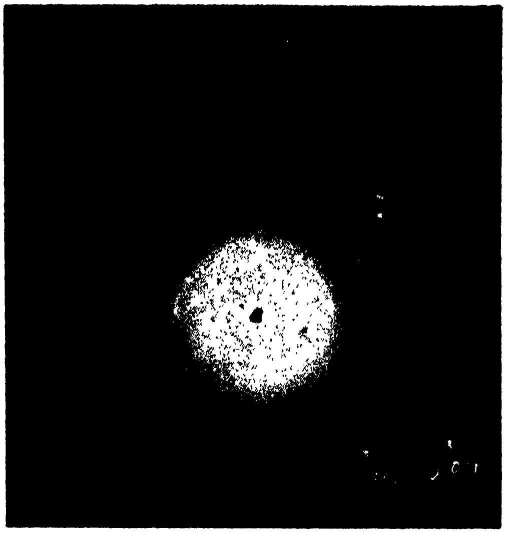

FIG. 3. Two-dimensional grating pattern, BeO (hexagonal), *hol*, $d_{100}=2.33$A, $d_{001}=4.38\pm0.02$A. (ASTM, 2.34A, 4.38A, respectively.) The bright field shadow image of the crystal has been printed on from a negative given shorter exposure. The $10\bar{4}$ reflection is relatively much brighter than for the x-ray case; the $\bar{3}01$ and $\bar{3}03$ are evident, although the calculated structure factor for these reflections is zero.

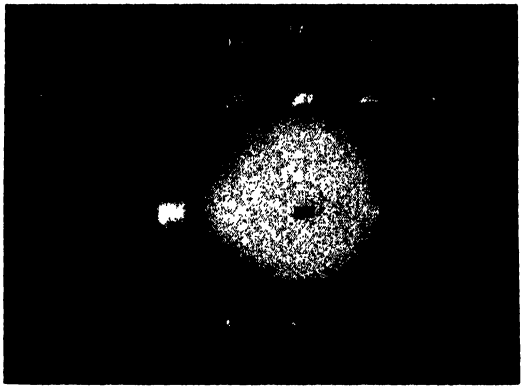

FIG. 4. BeO, *hhl*, $d_{110}=1.33_5\pm0.01$A, $d_{002}=2.20_5\pm0.01$A. (ASTM, 1.350A, 2.19A.) Note the intensity of the *hh*4 and $hh\bar{4}$ reflections. The central image of the crystal has been printed on from a shorter exposure.

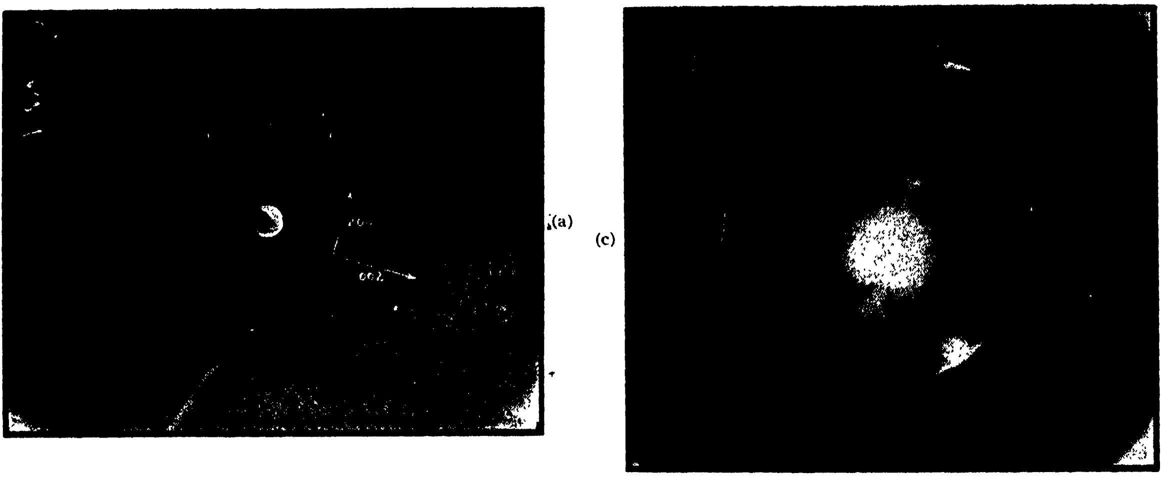
the diffraction results. The magnification and the resolving power of a shadow microscope are dependent on the probe position with respect to specimen and electron-recording screen and the probe size. To obtain a small probe, the focal length of the lens should be as short as possible. To obtain high magnification the probe should be reasonably close to the specimen. In practice a probe of minimum cross section of *ca.* 100–200A is obtainable with lenses of 2–3 mm focal length. While no precise tests of the resolving power of the present instrument have been made, resolutions less than 1000A and probably somewhat more than 200A have been obtained with magnifications of from $4\times10^3$ to $10^4$. With the pole piece configuration employed the focal point of the second lens for a probe of *ca.* 200A cross section was beyond the lens opening; it was, therefore, easy to mount the specimen close to the probe position. Under these conditions and with a 25-$\mu$ aperture for $A$, the maximum angular aperture of irradiation of the specimen was *ca.* $7.5\times10^{-3}$ radian. The angular aperture decreases rapidly as the separation of the probe and specimen is increased, and was $10^{-3}$ for most of the work described below.

When the probe is focused directly on the specimen, the magnification is infinite and no specimen image is observed, but rather a projection of the limiting aperture, $A$, provided the specimen is partially transparent. Actually, be-



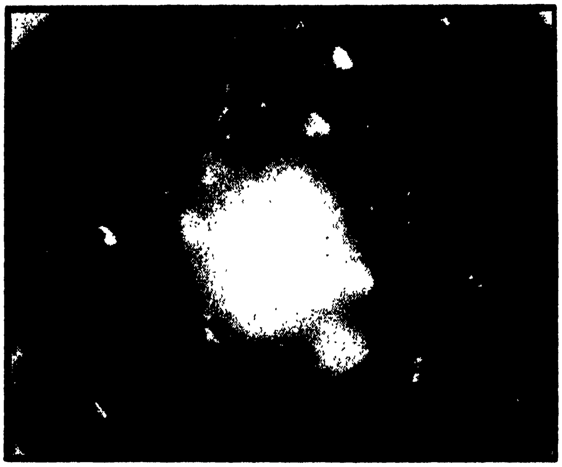


FIG. 5. Tip of $\alpha Al_2O_3 \cdot H_2O$ crystal (böhmite) (orthorhombic) $2h02l$, $d_{100} = 1.86 \pm 0.01A$, $d_{002} = 1.42 \pm 0.01A$. (ASTM, 1.86A, 1.43A.) (a) Short exposure showing image of crystal and one strong diffracted image, $\bar{2}02$. (b) Longer exposure showing full two-dimensional pattern and some $2h+1$, ?, $2l+1$ reflections. (c) Probe focused on specimen; each diffraction spot is an image of the defining aperture, some containing the striations discussed in the text. The Kikuchi-line pattern shows that the strongly diffracting $\bar{2}02$ plane is oriented at its Bragg angle with respect to the incident beam.

cause of asymmetries in the lens,[10] the image will first go to infinity in one direction, and then in another perpendicular to the first as the focal power is varied. Images observed at near infinite magnification were somewhat distorted because of this asymmetry.

The correlation of diffraction pattern with morphology and orientation of the crystal can be made on the basis of the electron shadow micrograph. Alternately, the shadow micrograph may be used for control purposes. With a little practice, the same crystal can be located in the field of view of a conventional magnetic electron microscope, which provides a higher resolution image of the crystal. One difficulty with the electron shadow microscope as used here is that the magnification, which varies with the exciting current of the magnetic electron lens, the position of the pole-piece material on its hysteresis loop, and the specimen-lens distance, was unknown for any particular photograph. It is estimated that most of the crystals shown here for which conventional micrographs are not shown were *ca.* 2000A–5000A in dimensions. The $\alpha Al_2O_3H_2O$ crystals are usually 5–10 microns long.

### III. EXPERIMENTAL RESULTS

The diffraction results are very similar to those observed by Kossel and Möllenstedt for the diffraction of a convergent beam of electrons by thin sheets of mica.[11] The present work is an extension of their results to single crystal analyses of *arbitrary* micro-crystals.

Two principal types of diffraction patterns were observed under the experimental conditions described above: (a) two-dimensional grating patterns and (b) Kikuchi-line patterns. Figures 2–7 are illustrations of two-dimensional grating

FIG. 6. Diffraction pattern from a pair of $Al_2O_3 \cdot H_2O$ crystals. In the short exposure (a), there is one strong diffracted image (002) from one of the crystals. One portion of this crystal diffracts much more strongly than the other. It is evident from the position of the Kikuchi line in the longer exposure (b) that the strongly diffracting region of the crystal makes the Bragg angle with the incident beam. A two-dimensional grating pattern is developing in (b) and became much more evident in longer exposures not shown here. Because the two crystals are not exactly parallel, the diffracted images are separated. Note the variation in reflecting power of neighboring parts of the crystal for a particular reflection, especially in the 002 and $20\bar{2}$ reflections. This was noted in the other images on longer exposure. An electron micrograph of the same pair of crystals is shown, for comparison, in (c). Because of the large field of view required to include both crystals, the shadow micrograph in (a) was not obtained with the highest usable magnification and the smallest probe size, and is not intended to illustrate the ultimate in performance of the shadow microscope.

patterns. In these cases, the probe was focused between the specimen and the electron-recording screen, so that a bright field shadow image of the crystal is formed in the central cone of illumination.

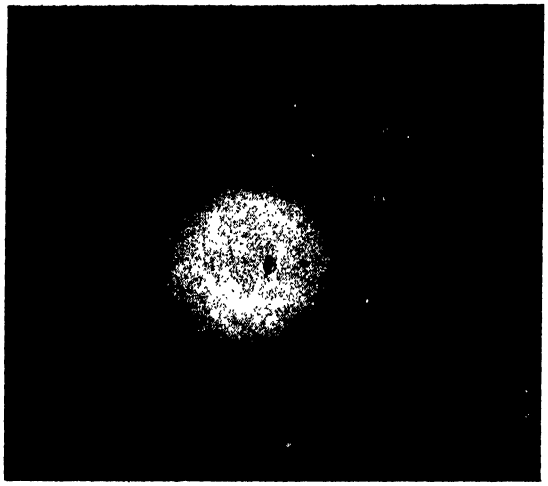

FIG. 7. ZnO (hexagonal), *hh*2, $d_{110} = 1.62 \pm 0.01$A, $d_{002} = 2.61 \pm 0.02$A. (ASTM, 1.61A, 2.61A.)

The field of view was adjusted so that only one crystal was present. Through any one point of the crystal passes a pencil of rays of very small angular aperture (*ca.* $10^{-4}$ radian, depending on the probe size and the specimen to probe separation). If only the rays passing through one portion of the crystal were diffracted, there would be an uncertainty in the diffraction angle proportional to the dimensions of the shadow image. Actually it is frequently observed in the two-dimensional grating patterns that each diffracted spot is a dark field shadow image of the diffracting crystal. Furthermore, the distances between corresponding points of a diffracted image and the central image correspond precisely to the angles of scattering deduced from the interplanar spacings of the crystal; the azimuthal directions of scattering are those of the normals to the corresponding planes of the crystal. The two-dimensional grating patterns may be considered as being formed by linear combinations (with integer coefficients) of two vectors, $\mathbf{b}_{hkl}$ and $\mathbf{b}_{h'k'l'}$, of the reciprocal lattice of the crystal. The total deviation of any ray that is diffracted must be twice the Bragg angle for a particular reflection.

When such two-dimensional grating (cross-grating) patterns are obtained, there is an apparent breakdown of the Bragg law for the diffraction of electrons by the crystal. Although the total deviation of a ray is invariably twice the Bragg angle for a particular reflection, the beam need not be incident on a crystal at precisely the Bragg angle with respect to the reflecting plane. It is sufficient that the ray be approximately parallel to the reflecting plane.

It is evident that in order for a cross-grating pattern to be possible, two of the shorter vectors of the reciprocal lattice must be approximately perpendicular to the electron beam; an equivalent statement is that an important lattice vector must be approximately parallel to the electron beam.

The method of specimen dispersion generally used[12]—spreading a drop of an amyl acetate solution of collodion containing a fraction of a milligram of the powdered specimen between two microscope slides by sliding them against each other—favors orientation of the crystals with well developed faces parallel to the collodion film. For the crystals used, this condition is equivalent to having an important lattice vector approximately parallel to the electron beam.

It should be emphasized that the intensity diffracted onto most of the spots observed in the cross-grating patterns is quite low—from 0.1 percent to 3 percent of the incident intensity. Sometimes one or two of the reflections are very strong containing practically all of the scattered intensity. The crystal is presumably oriented so that the beam makes an angle close to the Bragg angle with the plane responsible for these reflections. Figures 5 and 6 provide examples of this phenomenon.

As will be discussed in more detail later on, calculations based on the dynamical theory of electron diffraction indicate that diffracted intensities of the order of magnitude of from 0.1 percent to 3 percent are to be expected for each of a set of spots of a two-dimensional grating pattern when an electron beam is incident approximately parallel to an important lattice vector of a perfect crystal. In addition, any disorder or warping of the crystal will contribute to the development of a two-dimensional grating

---

[12] This technique was used in all the examples cited in this article except for the case of $\alpha Al_2O_3 \cdot H_2O$. An aqueous suspension of this material dries down on a collodion film with most of the crystals lying flat on the film.

pattern, a factor which is probably important for most of the patterns exhibited here.

Qualitatively, it is observed that the relative intensities of the various diffraction spots of a two-dimensional grating pattern are not the same as the x-ray diffraction intensities for the given material. In particular, reflections which are very weak for the x-ray case may have a much greater relative intensity for electron diffraction. Of course, these anomalous intensities have been observed frequently before in electron diffraction patterns.[13] A reflection which would be weak or vanishing by the structure-factor criterion, but which can be formed by the vector sum of two strong reflections will have appreciable intensity because it will be formed by the process of multiple scattering. This is possible for electron diffraction because a beam need not be incident at the Bragg angle with a plane to be strongly diffracted by that plane.

The most striking examples of this phenomenon of anomalous intensities among the samples studied occurred for BeO. The *h*04 reflections of Figs. 3 and 4 are as strong as the other reflections, although the *hk*4 reflections of BeO are extremely weak in the case of x-ray diffraction.[14] The 301 and 303 reflections are weak but evident (Fig. 3) although the structure factor for these reflections is zero. The 301 reflection, for example, may be considered as resulting from the combination of 200 and 101, or 300 and 001, etc., all of which are allowed and strong. However, in Fig. 4 there are only *hh* 2*l* reflections, and no *hh* 2*l*+1. In this case there is no way of combining two allowed reflections to obtain a forbidden reflection.

It should be recalled at this point that Bethe in his fundamental paper on the dynamical theory of electron diffraction[15] suggested the possibility of these "anomalous" reflections, resulting from the combination of two strong reflections.[16]

In the x-ray diffraction patterns from $\alpha Al_2O_3 \cdot H_2O$, the symmetry of the orthorhombic crystal prohibits all but the 2*h* 0 2*l* reflections of the *h*0 *l* series.[17] However, in longer exposures images appear in the middle of the rectangles that form the orthorhombic pattern. The lattice constants of $\alpha Al_2O_3 \cdot H_2O$ are $a = 3.72$A, $b = 12.5$A, $c = 2.83$A. Because of the large value of *b*, the *h*1*l* reflections occur through nearly the same angle, and at approximately the same angle of incidence as the *hol* reflections. Therefore, the indices of the "anomalous" spots are probably 2*h*+1, 1, 2*l*+1.

The second general class of phenomena observed are the production of Kikuchi-line patterns. In general, three requirements must be fulfilled in order for the Kikuchi-line phenomena to occur:

(a) The crystal must be sufficiently thick so that the primary process of incoherent scattering—to produce a cone of rays of much larger angular aperture than the incident cone of illumination—take place with sufficient probability to produce a general blackening of the entire photographic plate. In order that all the background scattering should contribute to the patterns, the electron probe is focused on the crystal in these experiments.

(b) The Bragg law must be satisfied for the diffraction of electrons by the crystal; that is, electrons incident upon a reflecting plane at the Bragg angle must be diffracted with much greater intensity than electrons incident at another angle.

(c) Some planes must be oriented approximately parallel to the axis of the electron beam. This requirement will usually be fulfilled because of the great number of reflecting planes in a crystal.

The distance from a "depleted" line to the corresponding "enhanced" line of a Kikuchi pattern corresponds to an angle of scattering of twice the Bragg angle. The positions of the various lines of a Kikuchi-diffraction pattern allow one to infer not only some of the interplanar spacings of the crystal, but also the precise orientation of the crystal with respect to the electron beam. Where a "depleted" line runs through the central area of irradiation, some of the rays of the incident radiation must make an angle equal to the Bragg angle with this particular plane, and the entire cone of illumination makes an angle quite close to the Bragg angle. There will then be a weak diffracted image of the defining aperture containing the strongly dif-

(d)

Fig. 9. (a) and (b) show the Kikuchi-line pattern from an MgO micro-crystal. The deduced orientation is exhibited in (c) and (d). In this case, the unit vectors perpendicular to the faces, rather than the reciprocal vectors, are used in the transformation equations. The specimen was prepared by dispersing MgO smoke in collodion; this procedure promoted the isolation of single MgO crystals.

Note the difference in the (420) striation patterns of (a) and (b), two different exposures, indicating a very slight change in orientation between exposures. The calculated and observed Kikuchi patterns are in agreement except that the reflections with odd indices are absent except for the case of ($\bar{5}$ 3 $\bar{1}$), where the plane is at its Bragg angle with respect to the incident beam.

phenomenon was observed for mica by Kossel and Möllenstedt, and interpreted by MacGillavry[18] in terms of the dynamical theory of electron diffraction. The spacings of these striations permit a determination of the thickness of the crystal (assuming that it is of uniform thickness in the direction of the electron beam), and

---

[18] C. H. MacGillavry, Physica 7, 329 (1940).

in favorable cases, of the structure factor for the particular reflection.

Figures 8, 9 and 5c are examples of the Kikuchi lines produced when the electron probe is concentrated on a micro-crystal. Calculated patterns and the inferred orientation of the crystal are also illustrated for Figs. 8 and 9. The orientations were deduced by requiring that two of the planes whose negative Kikuchi lines run through the central cone of illumination make an angle equal to their respective Bragg angles with the $z$-axis (the direction of the electron beam in Figs. 8b and 9c). The predicted patterns are calculated by finding by inspection all the linear combinations (with integer coefficients) of the unit reciprocal vectors that have small negative components along the $z$-axis. In all cases, the measured spacings and angles between Kikuchi lines were correct within experimental errors (±0.2–5 percent for the spacings, depending on the sharpness of line; ±*ca.* 1°–2° for the angles, depending on the length and sharpness of the lines).

In the early stages of the present work, when the electron probe was focused on a specimen or a membrane, a contamination "spot" formed rapidly on the irradiated area. Figure 6 (c) is a conventional electron micrograph of a pair of $Al_2O_3 \cdot H_2O$ crystals that had been exposed to an electron beam of rather large area for several minutes in the diffraction unit; the contamination spot, defining the area of irradiation, approximately 2.5 microns in diameter, is clearly visible. In practice, the area irradiated with a concentrated probe would become completely opaque to electrons after 30–60 seconds of bombardment. It was not possible, therefore, to study systematically the production of Kikuchi lines by micro-crystals until a method of preventing contamination was developed.

This difficulty in "probe" analysis was previously encountered in the electron microanalyzer.[19] The carbonaceous nature of the deposit is demonstrated in this instrument; the inelastic scattering spectra of thin films of silver or silica[20] showed no peak caused by the $K$-level of carbon when first exposed to a probe of *ca.* 2000A diameter. In later exposures the carbon $K$-line developed, and by the time the specimen was opaque only the carbon line was observed.

It has been discovered that, in the diffraction unit or in the electron microanalyzer, contamination can be avoided if the specimen chamber of the unit is exposed to an electron spray (60ma at 800v) for a few minutes before concentrating the probe on the specimen. Contamination will be entirely negligible for 10 minutes or so, and not serious for several days after this treatment. It should be mentioned that this technique is not effective in preventing contamination of electron microscope specimens. Here contamination appears to be a somewhat more complicated phenomenon.

In early stages of the work, before the method of avoiding contamination was discovered, patterns of a few spots were frequently obtained when the probe was focused behind or in front of the specimen. If the diffracted spot does not form a complete image of the crystal, and if a complete two-dimensional array is not obtained, it is difficult to interpret the pattern. One reason for this is that the particular portion of the crystal that is diffracting the beam is unknown, so that a precise measurement of the angle of scattering is not feasible. It is believed, however, that most of such crystals would give useful Kikuchi patterns which provide precise information about the inter-planar spacings and angles.

In concluding the description of the experimental work, it should be pointed out that the work to date has been confined to the study of the patterns produced by crystals of known structure. It is evident in the Kikuchi patterns of Figs. 8 and 9 that even a highly symmetrical and simple crystal can give rise to a quite complicated electron diffraction pattern. The application of the method to the identification of unknown crystals or the determination of their lattice constants, would be greatly facilitated by the development of a stage which allows precise adjustment of the orientation of the crystal with respect to the electron beam without moving it from the field of view.

## IV. THEORETICAL INTERPRETATION

The spacings of the striations in the 420 reflection of MgO in Fig. 9(a) were compared with the predictions based on the dynamical

---

[19] J. Hillier and R. F. Baker, J. App. Phys. 15, 671 (1944).

[20] Silica experiment by R. F. Baker.

TABLE I. Observed and calculated displacements between maxima of striations of Fig. 9a.

| Maxima involved | $\bar{1}$–0 | 0–1 | 1–2 | 2–3 | 3–4 | 4–5 |
|---|---|---|---|---|---|---|
| Observed displacement ($\times 10^4$) | 13.0 | $13.4_5$ | 7.3 | 7.8 | 6.9 | 5.9 |
| Calculated displacement | 13.1 | 13.1 | 7.9 | 7.4 | 7.0 | 7.0 |

theory of electron diffraction. The formula given by MacGillavry[18] for the angular variation of diffracted intensity is:

$$\frac{I(\Delta)}{I_0}=\frac{\sin^2\left\{\frac{1}{2}\frac{Dv_{hkl}}{K}\left(1+\frac{4\pi^2\Delta^2K^2}{d_{hkl}{}^2v_{hkl}{}^2}\right)^{\frac{1}{2}}\right\}}{1+\frac{4\pi^2\Delta^2K^2}{d_{hkl}{}^2v_{hkl}{}^2}},\tag{1}$$

where $\Delta$ = deviation of angle of incidence from Bragg angle, in radians

$K=2\pi/\lambda$ = wave vector of electron beam,

$D$ = thickness of crystal,

$d_{hkl}$ = inter-planar spacing,

$$v_{hkl}=\frac{8\pi^2me}{h^2}\frac{d^2e}{\pi R}\sum\nolimits_j(z_j-f_j)\exp\{2\pi i(\bar{b}_{hkl}\cdot\bar{r}_j)\}.$$

In this last relation, $R$ is the volume of the unit cell, and $\sum_j$ the electronic structure factor for the *hkl* reflection. The total deviation of the rays in this treatment is always $2\theta_B$.

The formula (1) is applicable to a crystal slab of uniform thickness in the direction of the electron beam. It is assumed that only one strong reflection occurs. There are clearly two strong reflections in Fig. 9. In Fig. 9(a), the striations are sensibly parallel and perpendicular to the direction of scattering so that this pattern was chosen for analysis. It is interesting that in the next exposure (a minute or so later) (Fig. 9(b)) the 420 pattern was highly perturbed by interaction with the $\bar{2}62$ reflection; evidently a very slight change in the orientation of the crystal took place. The next exposure showed parallel striations again. If in formula (1) we set $\Delta_l=d/D$,

$$\frac{I(\Delta)}{I_0}=\frac{\sin^2\left\{\pi\left(\frac{\Delta^2}{\Delta_l{}^2}+\frac{d_{hkl}{}^2v_{hkl}{}^2}{4\pi^2\Delta_l{}^2K^2}\right)^{\frac{1}{2}}\right\}}{1+\frac{4\pi^2\Delta^2K^2}{d_{hkl}{}^2v_{hkl}{}^2}}.\tag{2}$$

The quantity $\Delta_l$ is evidently the limiting value of the angular displacement in radians between the intensity maxima of the striations as $\Delta$ increases. Table I lists the measured values of the displacements (in radians) between maxima. Taking $\Delta_l=6.7\pm0.5\times10^{-4}$, and $\Delta_0-\Delta_1=13.2\pm0.2\times10^{-4}$, one calculates that $D=1400\pm100$A and $v_{420}=7.7\pm2.0\times10^{15}$ cm$^{-2}$. The value calculated from the definition of $v_{hkl}$ is $7.85\times10^{15}$ cm$^{-2}$. Using this value and the value 1400A for the thickness of the crystal, the calculated displacements between maxima of Table I are obtained. Evidently the greatest distance is between the central maximum and the next one; all the other distances are rather close to the limiting value. For a strong reflection the method provides a reasonably accurate determination of the structure factor for a reflection; for a weak reflection the percentage accuracy would be very low.

In the particular example cited here, no electron micrograph was obtained to substantiate the assumption of uniform thickness of the crystal. The agreement of the results with theory, however, supports this assumption.

We may now consider why in some cases cross-grating patterns, in which the Bragg law of incidence is apparently not obeyed, were observed and in other cases, Kikuchi-line patterns, which depend on those electrons incident at or very close to the Bragg angle being much more strongly diffracted than those incident at other angles. We first note that there is no logical contradiction between the occurrence of a strong reflection of rays incident at the Bragg angle, and weak reflections of rays incident at other angles for a particular crystal. Figure 5 is an example of a two-dimensional grating pattern and a Kikuchi-line pattern obtained from the same böhmite crystal; from the pattern of Fig. 8 for BeO we see that there is a 110 reflection of the entire aperture of illumination and displaced from that a broad Kikuchi line because of electrons inelastically scattered onto a direction making the Bragg angle with the 110 plane.

It is beyond the scope of the present paper to attempt to assess exactly the effect of disorder in a crystal on its diffraction pattern. In general the effect of such disorder will be to increase the intensity of diffraction of rays not incident at the Bragg angle.

TABLE II. "Rocking crystal" curve for MgO, 200 reflection.

| | 0 | $10^{-3}$ | $5 \times 10^{-3}$ | $10^{-2}$ | $1.285 \times 10^{-2}$ | $5 \times 10^{-2}$ |
|---|---|---|---|---|---|---|
| $I/I_0$ | 1/2 | 0.485 | 0.29 | 0.127 | 0.085 | 0.068 |
| $D_0$ (period of $\sin^2$ term, $A$) | 360 | 354 | 274 | 254 | 181 | 149 |

The dynamic theory of electron diffraction, however, does indicate that even for perfect crystals the kinds of diffraction pattern reported in this paper are to be expected. MacGillavry's formula (1) for the intensity of a reflection gives for the half-width of incidence of a reflection (neglecting the $\sin^2$ term)

$$\Delta_{\frac{1}{2}} \sim v_{hkl} d_{hkl},$$

$$\Delta_{\frac{1}{2}} \sim (\textstyle\sum_j)_{hkl} d_{hkl}^3,$$

so that wide angle reflections give the best Kikuchi lines, whereas the inner reflections give broad Kikuchi lines and readily contribute to cross-grating patterns. This relation is evident in the 110 and 220 Kikuchi lines of BeO in Fig. 8.

As an example of the intensity of diffraction for angles of incidence that are considerably different from the Bragg angle, it is of interest to apply MacGillavry's formula to calculate a "rocking curve" for the 200 reflection of MgO, using $\lambda = 5.4 \times 10^{-10}$ cm. In this calculation (Table II), the average value of the $\sin^2$ term is taken as ½.

Even at normal incidence ($\Delta = \theta_B$) the diffracted intensity is great enough to give noticeable reflection. One similarly computes for the intensities of the 220 and 400 reflections at $\Delta = \theta_{220}$ and $\Delta = \theta_{400}$ the values 0.011 and 0.0013, respectively.

Miss MacGillavry's formula (1) considers only the interaction between one diffracted ray and the incident ray, the treatment of the general case of the interaction of all the diffracted rays being very complicated. It is of interest, however, to present calculations for the symmetrical case of normal incidence on a cube face of MgO considering the interaction of all four of the 200 reflections and all four of the 220 reflections. This is a simple computation and serves to indicate if formula (1) is seriously wrong or if it gives results of the same order of magnitude as those obtained by more elaborate calculations. Only an outline of the methods of calculation and the results need be presented.[21]

Bethe's dynamical equations for this case are:

$$(K^2 - k_{000}^2)\psi_{000} + 4v_{200}\psi_{200} + 4v_{220}\psi_{220} = 0,$$

$$v_{200}\psi_{000} + \left(K^2 - k_{000}^2 - \frac{4\pi^2}{d_{200}^2} + v_{400} + 2v_{220}\right)\psi_{200} + (2v_{200} + 2v_{420})\psi_{220} = 0,$$

$$v_{220}\psi_{000} + (2v_{200} + 2v_{420})\psi_{200} + \left(K^2 - k_{000}^2 - \frac{4\pi}{d_{220}^2} + 2v_{400} + v_{440}\right)\psi_{220} = 0.$$

In these relations, $k_{000}$ is the magnitude of the wave vector of the undiffracted wave in the crystal; its three possible values are determined by equating the determinant of the linear equations to zero. The $\psi$'s are the amplitudes of the various waves in the crystal. With numerical coefficients inserted, the cubic characteristic equation is solved, and the relative amplitudes of the internal waves determined for each solution. The customary boundary conditions for the Laue case lead to the intensity formulae: ($D$ in Angstrom units)

$$I_{000} = 1 - 0.904 \sin^2(\pi D/146) - 0.032 \sin^2(\pi D/125) - 0.060 \sin^2(\pi D/67.4),$$

$$I_{200} = 0.192 \sin^2(\pi D/146) + 0.0088 \sin^2(\pi D/125) - 0.0083 \sin^2(\pi D/67.4),$$

$$I_{220} = 0.037 \sin^2(\pi D/146) - 0.0077 \sin^2(\pi D/125) + 0.0098 \sin^2(\pi D/67.4).$$

The average value for the intensity of the diffracted waves is $\bar{I}_{200} \cong 0.10$, $\bar{I}_{220} \cong 0.02$.

The precise numerical values obtained are of no great significance because of the very special case treated; what is important is that these values are of the same order of magnitude as those obtained from formula (1) so that this formula may be used to indicate reliably the extent of a cross-grating pattern for a perfect crystal.

An outstanding deficiency of the dynamic theory as presented is that it neglects the effect of incoherent scattering on the propagation of a

---

[21] See references 15 and 18 for a complete discussion.

wave system in a crystal. The energy of the electron beam in the crystal is pictured as oscillating back and forth between the incident and the diffracted beams without damping. The effect of incoherent scattering will be to increase the general background, to tend to destroy the diffracted rays—particularly for rays not incident at the Bragg angle,—and to cause the development of Kikuchi lines.

## V. CONCLUSIONS

One can conclude then that two-dimensional grating patterns are to be expected for crystals oriented with an important lattice vector approximately parallel to the electron beam, provided the crystals are not too thick and independent of whether or not the crystals are slightly disordered or warped. Kikuchi-line patterns are to be expected for most other crystals that are not excessively thick or disordered; the wide angle reflections will give the sharpest and best Kikuchi lines. Because of the shape of the "rocking crystal" reflection curves, crystals which give rise to two-dimensional grating patterns may also give rise to Kikuchi-line patterns.

# Microsecond Measurement of the Phosphorescence of X-Ray Fluorescent Screens*

FITZ-HUGH MARSHALL
*Westinghouse Research Laboratory, East Pittsburgh, Pennsylvania*

(Received February 4, 1947)

Microsecond square-wave x-ray pulses, repeated a thousand times a second, were obtained by operating an x-ray tube directly from a radar pulser. The phosphorescent build-up and decay of light emitted by fluorescent materials when irradiated by the x-ray pulses was observed with a multiplier phototube connected to an oscilloscope. Oscillograms of $CaWO_4$ (radiographic intensifying screen) and $BaSO_4$ indicate simple exponential response, with decay to $1/e$th intensity in 6 and 0.8 microseconds, respectively. $MgWO_4$ and Patterson B (fluoroscopic) and D (photofluorographic) screens were found to complete their main response to microsecond excitation in 10 to 100 microseconds, but their decay is not exponential.

A SUSTAINED interest in the subject of phosphorescence during the last decade has led to extensive experimental work, though rarely with x-ray excitation, and to various theoretical proposals to account for the many cases in which the observed decay does not follow a simple exponential law as would be expected for a simple monomolecular process.[1–4] Attempts have been made to interpret these more complicated cases as composites of superimposed exponential curves, as hyperbolic decay associated with a bimolecular mechanism, or as due to emission delays by electron traps. The present experiment is not sufficiently comprehensive to test the validity of these theories, for it had as its immediate purpose only the determination of the speed of response of standard types of commercial fluorescent x-ray screens. But the experimental method employed has proved so simple and effective that others may wish to develop it for a more detailed treatment, either for the study of x-ray screens as such or for a more fundamental investigation of phosphorescence. The microsecond timing technique used, instead of the more common millisecond timing, is clearly necessary to resolve rapid phosphorescence effects, which should not be disregarded in a general study. The use of x-rays, instead of the more usual ultraviolet or cathode-ray excitation, not only provides new test conditions but also simplifies absorption corrections when they are necessary, as in hyperbolic decay: in general the x-ray correction is less, can be determined accurately and easily, and does not involve taking into account a large change of intensity within individual crystals.

The equipment used in this study of the short persistence phosphorescence of x-ray fluorescent screens is illustrated in the block diagram of Fig. 1. An x-ray tube was operated directly from a radar pulser. The pulser provided microsecond square-wave potential pulses at 10 to 30 kv, repeated a thousand times a second. The x-ray tube current during the pulse was as high as 500 ma, but the corresponding average current was well within the rating of the air-cooled fluoroscopic tube used. With a water- or oil-

cooled tube, much larger currents could have been obtained if needed, though probably with some reduction in the filament life because of operation at abnormally high temperatures. The x-rays irradiated the fluorescent sample, which for simplicity was taped directly against the R.C.A. multiplier phototube used to measure the light emitted, the phototube then being wrapped in black paper to exclude room light. The distance from the x-ray target to the fluorescent sample was about 15 cm. Stray high-frequency pickup from the pulser was practically eliminated by (1) covering the phototube with a grounded hood of aluminum foil to complete the system of standard grounded circuit shields, (2) introducing a cathode-follower stage mounted in pre-amplifier position directly under the phototube, and (3) grounding various extra points of the equipment for optimum results as determined by trial and error. The phototube and cathode-follower stage were mounted on top of the pulser along with the x-ray tube and its filament isolation transformer. The multiplier phototube was operated at about 90 v per stage from a d.c. supply, which was well filtered and well regulated.

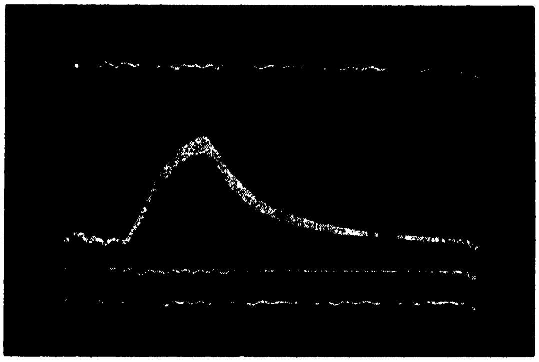

FIG. 2. Oscillogram of the growth and decay of the phosphorescent response of barium sulphate. The total time of the trace is 5 microseconds.

The cathode-follower stage was connected directly to the amplifier input of a DuMont 248 oscilloscope, no additional amplification being required. This oscilloscope, which has a number of special auxiliary circuit features, was used as a synchroscope to trigger the pulser a microsecond after the beginning of the rapid sweep of the cathode-ray beam. The sweep time could be varied and accurate time-marker intervals superimposed on the trace. From the phototube through the oscilloscope the response of the circuit was checked to be nearly flat to about 5 megacycles per second. The response of the phototube itself is good to about 100 megacycles per second.

The phosphorescent response of the fluorescent sample during and after the microsecond of irradiation by x-rays thus registered on the oscilloscope screen and was photographed. Additional exposures on the same film were used to introduce reference traces. Figure 2 is an oscillogram obtained in this way for barium sulphate, the fastest fluorescent material studied. The time represented by the complete curve is 5 microseconds. Trace *a* is the main response curve, trace *b* is a base line recorded with x-rays off and displaced downward to prevent confusion from overlapping of the small initial irregularities caused by stray pick-up, and traces *c* are similar lines above and below upon which microsecond time markers have been introduced for accurate time measurement.

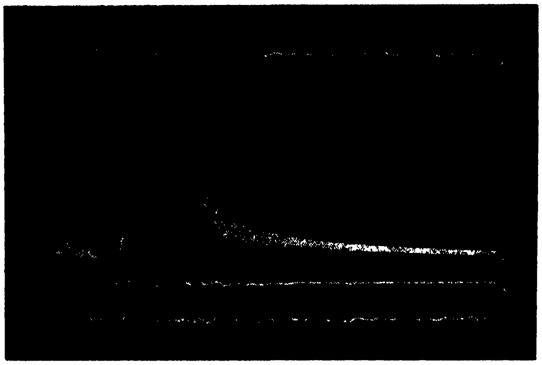

FIG. 3. Response to direct x-rays.

As will be shown, the response for barium sulphate is exponential. Following through the succession of events recorded in Fig. 2, we see that during the first microsecond there are no x-rays. Then the x-ray pulse starts, and the phosphorescent response begins to rise as the material is irradiated at constant intensity for a microsecond. During excitation active phosphorescent centers are created at a constant rate. But as the number of active centers increases,

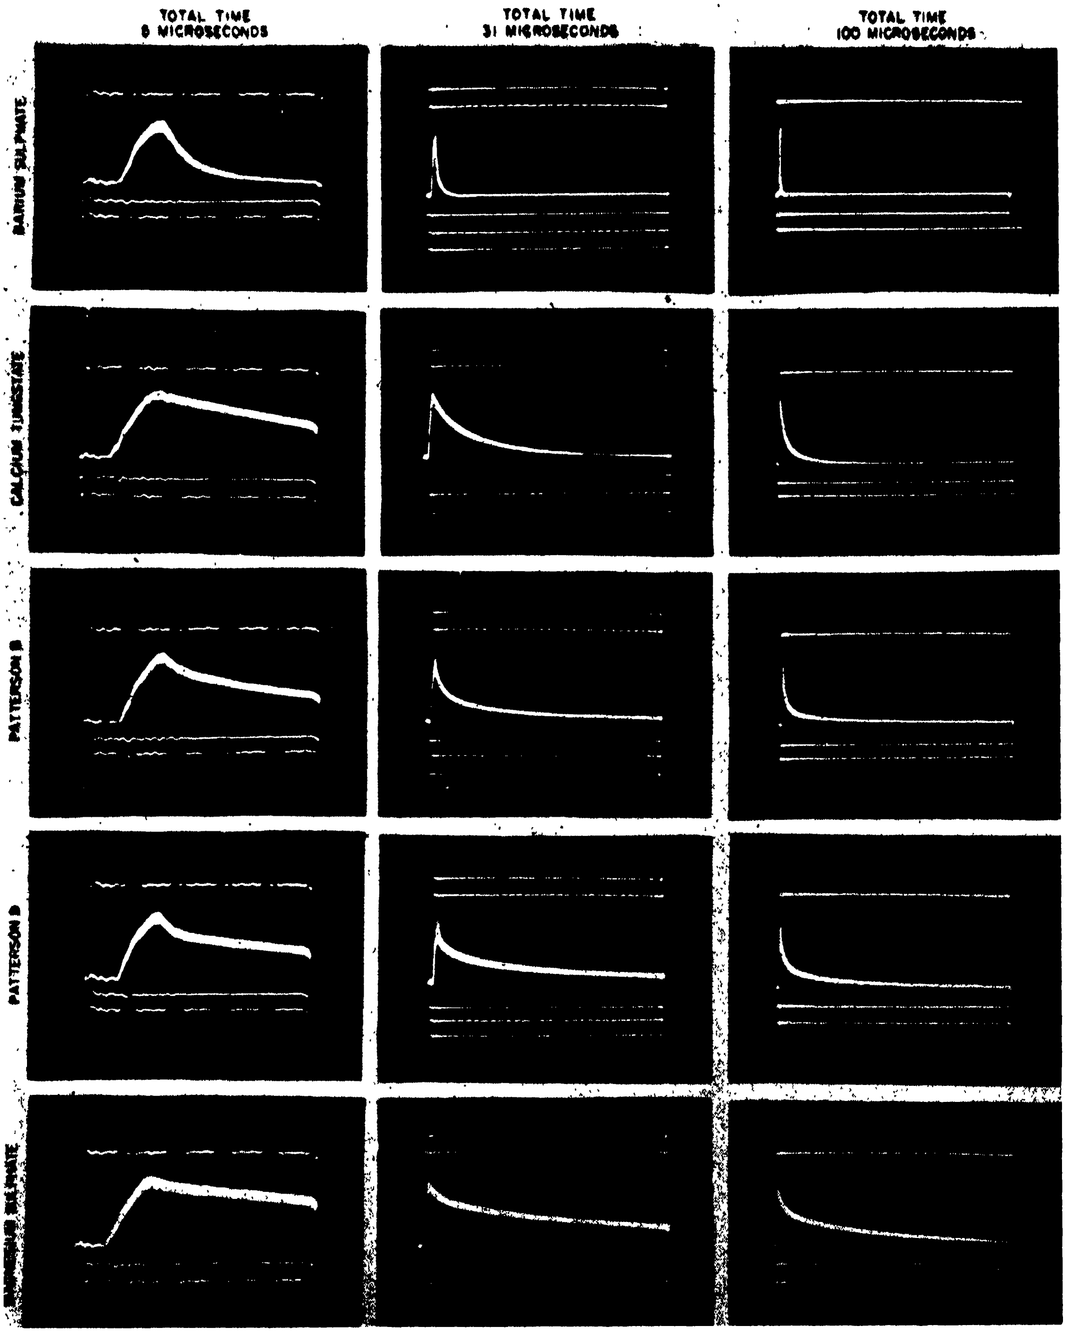

FIG. 4. Comparative oscillograms of the phosphorescent response of various fluorescent materials to a microsecond x-ray pulse.

so does the rate at which they disappear with the emission of light, this rate being always proportional to the number remaining. If the excitation were to continue indefinitely, the response would exponentially approach that equilibrium level *d* at which the active centers disappear as fast as they are created. But in this case the x-rays are turned off after a microsecond of irradiation, and the light intensity decays exponentially toward zero as the active centers disappear. For barium sulphate the phosphorescent period (time for decay to 1/*e*th intensity) is only 0.8 microsecond.

A direct test of the resolution and general effectiveness of the equipment is provided by Fig. 3. It so happens that the phototube responds weakly to direct x-rays with no intervening fluorescent screen. The oscillogram of Fig. 3 is for direct x-rays of extremely high intensity. The curve differs from a square wave because of the presence within the phototube of a weakly fluorescent material which phosphoresces exponentially with a period of 1.2 microseconds. When this superimposed response, similar to the one in Fig. 2, is subtracted, a reasonably square wave remains, resolved to about 0.2 microsecond.

The broadening of the main trace in all oscillograms recorded has been studied carefully and found to be due to noise of the statistical fluctuations in the number of x-ray quanta that are effective in producing phototube response.[5] The noise is exceptionally high in Fig. 3 for the following reason: although very few x-ray quanta are absorbed at the photosurface, each quantum which is absorbed produces a shower of photo-electrons.

In Fig. 4 is presented a complete set of oscillograms for the various fluorescent materials studied. The first, at the upper left, is a repetition of the 5-microsecond curve for barium sulphate shown in Fig. 2. On the 31-microsecond oscillograms, 10-microsecond time markers have been introduced in addition to the 1-microsecond markers. On the 100-microsecond oscillograms only 10-microsecond markers are included. This set of oscillograms covers the fastest and slowest materials studied and the three most commonly used types of x-ray screens. The x-ray intensity has been adjusted to bring the maximum response to approximately the same value for all curves.

The barium sulphate (which included 5 percent of lead sulphate) and the magnesium tungstate were selected from an assortment of available experimental powders which had been prepared for an unrelated purpose in another laboratory; the fluorescent intensity of each of these powders was very low in comparison with that of commercial x-ray screens. The calcium tungstate, which fluoresces blue, was a standard commercial radiographic intensifying screen; the shape of the response curve appeared to be the same for the several brands, grades, and thicknesses of screens tested, though this has not been checked by careful measurement. The Patterson B screen fluoresces with the familiar yellow-green of fluoroscopic screens, of which it is a standard example; it may be classed as a zinc-cadmium sulphide screen. The Patterson D screen, which fluoresces blue, is one which has been developed recently for photofluorography; it may be broadly classed as a zinc sulphide screen.

The simplest kind of phosphorescent response is an exponential one, the equations for the intensity, $I_g$ during excitation or growth and $I_d$

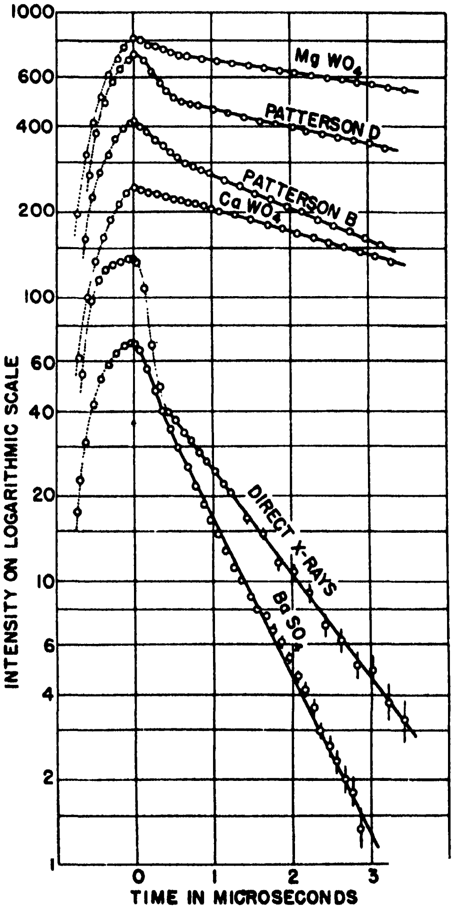

FIG. 5. Response curves plotted from measurement of 5-microsecond oscillograms.

---

[5] Fitz-Hugh Marshall, J. W. Coltman, and L. P. Hunter, Rev. Sci. Inst. tentatively scheduled for publication in July, 1947 issue.

during decay, being of the form

$$I_g = A(1-e^{-t/T}) \quad \text{and} \quad I_d = Be^{-t/T},$$

where $t$ is time, $T$ is the phosphorescent period, and $A$ and $B$ are constants. While there is no particular reason for expecting exponential response, it is a simple matter to check whether a response is exponential from either the growth or the decay portions of the curve. In this experiment the decay portion yielded much greater accuracy than the steep, poorly resolved growth portion.

In Figs. 5 and 6 the decay curves for the various materials studied are plotted on semi-logarithmic paper, on which a simple exponential decay would appear as a straight line. The data are taken from careful measurement of the oscillograms. Intensities have been multiplied by arbitrary factors to separate the curves conveniently. An attempt has been made to adjust the time scale so that the decay is shown starting at zero time. In Fig. 5 portions of the earlier growth curves are included as dotted lines for reference; the initial drop-off of the curve for direct x-rays is also dotted, for it represents the poorly resolved response of the circuit to the cut-off of the square wave rather than a phosphorescent decay. The spread shown for lower points on some of the curves indicates error due to uncertainty in measurement of small ordinates on the oscillograms; the deviation shown is about a thirtieth of the width of the recorded trace. Somewhat larger errors may very well be present from non-linearity in registration of the cathode ray tube.

Within the limits of experimental error, the response appears to be exponential for calcium tungstate, barium sulphate, and the fluorescence of the phototube under direct x-rays, the phosphorescent periods being 6, 0.8, and 1.2 microseconds, respectively. The several small but clearly discernible deviations from linearity in the curves for those materials can be explained qualitatively in the following way. A slight bend for barium sulphate during the first microsecond of decay is attributable to a small component of direct x-ray action on the phototube. A bend in the calcium tungstate curve at 5 microseconds must be ascribed to an overswing in the amplifying circuit, for at the corresponding time a dip through a minimum is clearly observed on the 31- and 100-microsecond oscillograms for barium sulphate and also on the oscillograms in Fig. 7. As for the deviation of the points from a straight line at the lower end of the calcium tungstate curve, other experiments[1, 4] indicate that calcium tungstate is so rapid in its decay that it would be uncalled for to suspect a progressive upswing in the curve on the basis of these few points of large experimental error; however, Strange has reported two approximately exponential cathodoluminescent periods for calcium tungstate.[2]

A detailed analysis has not been attempted for the magnesium tungstate and sulphide screens. Their decays are obviously not exponential. The comparatively sharp bends near the start of these curves are evidently real, and they suggest the presence of superimposed decay curves. The later portions of these curves fit simple hyperbolic decay a little better than exponential decay, but the difference is not considered significant in the absence of additional supporting evidence and a more complete knowledge of the composition of the commercial screens involved. No change in the shape of the curves was noticed on the oscilloscope with variation of x-ray potential or intensity, as might be expected for hyperbolic decay. If a more detailed experiment is undertaken by others, this point should be checked more carefully, along with temperature dependence. Other studies which might be of interest include the response as a function of wave-length

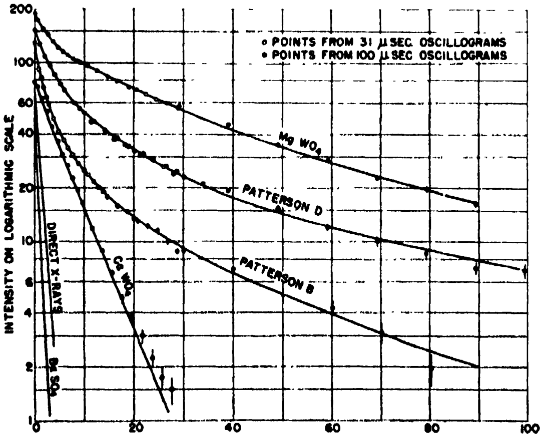

FIG. 6. Response curves extended through 100-microseconds of decay.

of light emitted by the screen and the effect of infra-red stimulation of the screen.[3]

In interpreting the oscillograms and curves in this paper, it is important to note that the unusual technique of microsecond excitation has altered the shape of all curves which are not simple exponential responses in such a way as to accentuate rapid phosphorescence effects and to suppress slow persistence effects. Thus the results may not immediately appear to be consistent with observations made under more conventional conditions. This was forcibly brought out during the experiment by an attempt to observe the phosphorescence of willemite, a screen with a persistence comparable to the flicker time of the eye. Although the willemite could be seen to glow brightly when irradiated with x-rays, an oscillogram obtained according to the normal procedure of this experiment (i.e., one made with x-ray intensity adjusted to bring the peak response to the usual amplitude) revealed only the response of the phototube to direct x-rays and was indistinguishable from an oscillogram for direct x-rays without the intervening willemite. A difference was finally obtained, as illustrated in Fig. 7, by greatly increasing the x-ray intensity (and the amplification), past the point of overloading the amplifier at the peak. In the second part of Fig. 7, the main evidence of the luminescence of the willemite is the broadening of the curve by the high noise level of the light, which is intense but which does not decrease appreciably during the short interval between pulses.

Let us assume for simplicity that the reciprocity law holds perfectly for each of the components involved in the oscillogram at the right in Fig. 7, that is, that the total area under the curve (extended to infinite time) associated with each component is independent of the time of x-ray excitation so long as the total quantity of x-rays remains unchanged. It is evident that if the same quantity of x-rays had been introduced during a pulse time of 10 microseconds, instead of one microsecond, the willemite portion of the response would not have been appreciably altered, but the direct x-ray portion of the response would have been spread over approximately ten times as much time and would therefore have risen only a tenth as high above the willemite response. With a pulse time of a thousandth of a second, such as might ordinarily be used for studying willemite, it is doubtful that any direct x-ray component could be detected, even with the x-ray intensity increased further to bring the peak response to the usual level.

FIG. 7. Comparative 100-microsecond oscillograms for direct x-rays and willemite. The amplifier gain and the x-ray intensity have been so greatly increased as to cause overloading at the peaks.

This dependence of the shape of the response curve upon the length of time of excitation might provide the basis of a method for isolating component decays in composite curves. A pulser with variable pulse time would permit observation of the change of shape of the response curve with pulse time. A further useful innovation might be that of Strange of balancing out the main part of the response with counter exponential condenser discharge curves and measuring only the difference.[2] It should be noted that hyperbolic decay curves would behave differently from composite exponential curves, there being an actual energy shift from long-persistence effects to short-persistence effects as the pulse length is shortened.

It should be mentioned that in the present experiment all persistence after a thousandth of a second is rendered completely indistinguishable by the beginning of the next sweep cycle and the advent of a new x-ray pulse; the zero ordinate point seen at the beginning of each oscillogram trace is merely the response level at the end of the previous millisecond cycle.

Let us finally consider the practical importance of the results of this experiment with respect to the speed of response of commercial x-ray screens. It is necessary to introduce supplementary information from other sources, inasmuch as long-persistence effects of relatively high energy might be present without detection by the present experiment.

Under ordinary conditions calcium tungstate does not show any detectible persistence. When a calcium tungstate screen is whirled as a disk before a narrow beam of x-rays, there is no noticeable blurring of the edge of the primary spot on the screen covered by the x-ray beam. We may therefore conclude that the curves for calcium tungstate recorded in this experiment include all of the response which is of practical importance and that the response is almost complete in $10^{-5}$ second.

In contrast, the sulphide screens, especially Patterson D, are commonly known to have long-persistence effects which are visible for some seconds or minutes after exposure to intense x-rays. Since these are not detected in the present experiment, it is necessary to consider whether a large fraction of the total light emitted by the screen is associated with the long-persistence effects. The case for Patterson D is of greatest practical importance, for it is usually found to be the brightest screen as measured photographically or photoelectrically. A rotating-disk test shows the primary spot on the screen to be bright and sharply delineated from the phosphorescent trail. On the basis of this and other tests, it appears safe to say that the main useful part of the response (perhaps three-fourths for Patterson D, more for Patterson B) is included in the oscillograms of this experiment and is complete in 20 microseconds or so. Thus the amount of long-persistence light is too small to be especially important from the standpoint of efficiency; on the other hand, it is large enough to be a disturbing factor in fast response applications for which it is essential that there be no detectible residual from earlier x-ray events.

As a practical case in point, we may consider x-ray motion pictures. These are now generally obtained by photographing the fluorescent screen. When Patterson D is used with conventional x-ray and camera equipment, noticeable blurring or multiple-image effects occur, especially at the leading edge of a dark area moving into a bright area. This blurring does not occur when calcium tungstate screen is used, but the effective intensity is less.

These conclusions also apply to the photomultiplier x-ray detector.[5] This detector consists of a fluorescent screen wrapped around a multiplier phototube and is therefore equivalent to the x-ray detector used in this experiment. Speed of response is important in the analysis of fast x-ray phenomena. Here again the rapid response and high intensity of Patterson D make it very suitable for many applications. However, the long-persistence effects of this screen cannot always be disregarded. For example, when the detector is used as an integrating exposure meter to terminate a radiographic exposure after the incidence of a given quantity of x-rays, the long-persistence effects result in an objectionable dependency upon exposure time and upon recent exposure history.

# X-Ray Diffraction Studies of Chrome-Steel Slags[1]

G. P. Chatterjee and S. S. Sidhu
*University of Pittsburgh, Pittsburgh, Pennsylvania*

(Received March 21, 1947)

X-ray diffraction studies of the crystalline constituents in the acid open hearth chrome-steel samples showed that chromium exists in these samples as a chrome-iron spinel of the form, $FeO \cdot Cr_2O_3$. Its density was 5.109 g/cc and its melting 2160°C. It crystallized in the face-centered cubic structure with $a_0 = 8 \cdot 348$A and $Z=8$.

## I. INTRODUCTION

THE essential major elements in most of the common alloy steels are chromium (Cr), nickel (Ni), and manganese (Mn). Nickel is not oxidized during steel making. Of the other two elements, Cr is more costly, and its loss in slag through oxidation or any other combination increases the cost of steel to a greater extent than an equivalent loss of Mn. The nature of control methods, which may lead to decreased losses of Cr, depends on the knowledge of the different phases in which Cr is present in the slag. The object of this investigation was to study by x-ray diffraction methods if Cr exists in the acid open hearth chrome-steel slag as (a) free $Cr_2O_3$ or CrO, (b) solute in FeO solvent, (c) silicates of chromium, and/or (d) spinels of the type $FeO \cdot Cr_2O_3$ or $CrO \cdot Fe_2O_3$.

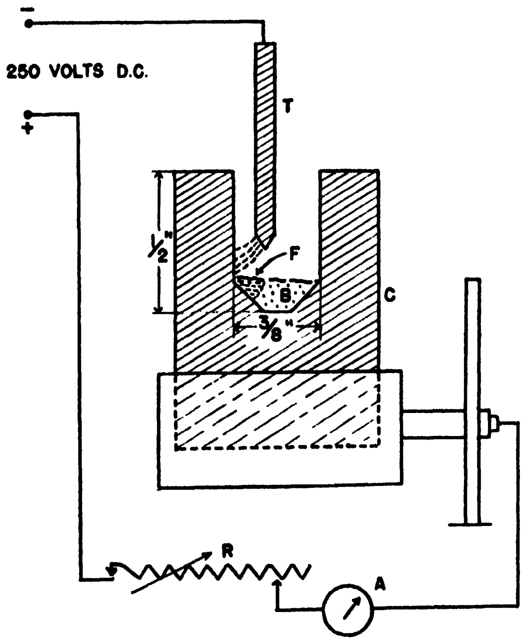

Fig. 1. The schemetic diagram of the small indirect arc furnace for preparing synthetic spinel. $T$ = top electrode; $C$ = rotating crucible; $F$ = fused charge; $B$ = unfused charge; $R$ = variable resistance; and $A$ = ammeter.

## II. EXPERIMENTAL PROCEDURE

Acid open hearth chrome-steel slag samples were obtained from regular heats of steel and poured into Fluidimeter.[2] The slag solidified and cooled rapidly inside the mould to preserve nearly the original conditions in which the different constituents existed in the molten slag. From the chemical analyses of these samples, samples of synthetic slag were prepared. A mixture of pure FeO and $Cr_2O_3$ (mole proportion by weight) was put in graphite crucible $C$ of a small 250-volt d.c. arc furnace as shown in Fig. 1. A small amount of borax was added to facilitate rapid melting. The top electrode $T$ was placed slightly eccentric with respect to the bore of the crucible. An indirect arc was struck on the side of the crucible while the crucible was rotated. In one complete rotation of the crucible, the entire mixture was melted beneath the arc. The time of rotation was 20 seconds and the current through the electrodes was 10 amperes. During the arcing the electrode $T$ was kept negative and the crucible positive. It was found by optical pyrometer that the positive electrode was always at higher temperature than the negative electrode.

---

[1] The paper was presented, in part, at the joint meeting of the American Society for X-Ray and Electron Diffraction and the Electron Microscope Society of America, Pittsburgh, Pennsylvania (Dec. 1946).

[2] Fluidimeter designed by the Acid Open Hearth Research Association under the direction of Dr. G. R. Fitterer, University of Pittsburgh, Pittsburgh, Pennsylvania.

To remove borates and other contaminants formed during melting, the synthetic samples were powdered and boiled in 1:2 HCl solution for a few minutes in a test tube. The solution with the residue was filtered and washed several times with hot water until the filtrate was free from iron salts and chlorides. The residue was dried in a muffle furnace at 120°C for one hour.

X-ray diffraction patterns of both the natural and synthetic slag samples were made by the usual powder method with filtered Mo$K\alpha$ radiation and a cylindrical camera of 171.9 mm effective diameter.

### III. DISCUSSION OF RESULTS

The x-ray diffraction data obtained from the powder patterns are given in Table I. It is apparent from the data that the chrome-steel slag contains the same compound or compounds that are present in the synthetic slag and also small amounts of faylite, $(FeO)_2SiO_2$. The analysis of the diffraction data of the synthetic slag sample shows that it contains no free FeO, $Cr_2O_3$, nor a solid solution of FeO and $Cr_2O_3$, but a compound formed from the two oxides. That this compound is a spinel similar to chromite ($FeO\cdot Cr_2O_3$), one of the natural spinels reported by Dana[3] may be shown from its crystal structure as determined below:

For cubic crystal system

$$d_{hkl}=a_0/(h^2+k^2+l^2)^{\frac{1}{2}},$$

or

$$(h^2+k^2+l^2)=a_0^2\times\frac{1}{d_{hkl}^2}, \tag{1}$$

where $d_{hkl}$ = interplanar spacing corresponding to plane $hkl$ and $a_0$ = side of the unit cubic cell. For face-centered cubic crystal, the Miller indices of the planes that given reflections and the sum of the squares of the Miller indices are given in Table II. By plotting $(h^2+k^2+l^2)$ as function of $1/d^2$, one gets a straight line as shown in Fig. 2. The slope of this line as given in Eq. (1) is $a_0^2$. An accurate value of $a_0$ thus determined is 8.348A.

The density of the synthetic slag sample determined by the usual picnometer method was 5.109 g/cc. The molecular weight of the compound $FeO\cdot Cr_2O_3$ is 223.87 g/mole. Therefore the number of molecules per unit cell of the compound is

TABLE II. Interplanar spacings and the corresponding Miller indices of the first eight lines of the synthetic spinel.

| $I/I_0$ | $d$ in A | $1/d^2$ in $A^{-2}$ | Miller indices $hkl$ | $(h^2+k^2+l^2)$ |
|---|---|---|---|---|
| M | 4.83 | .043 | 111 | 3 |

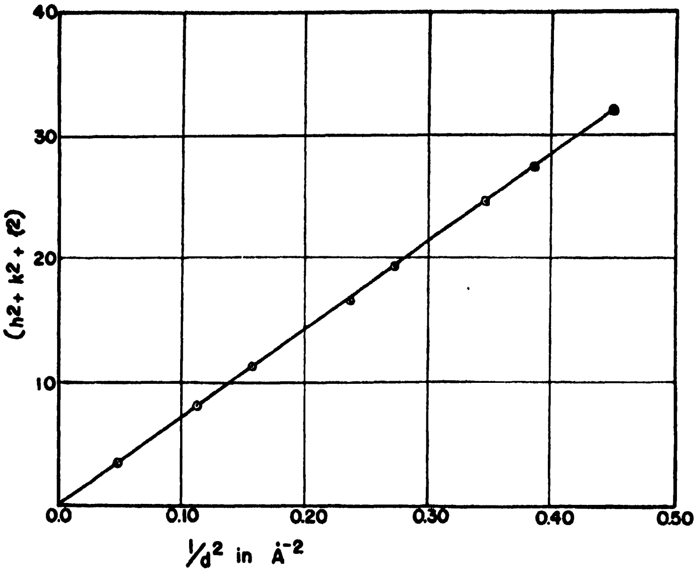

FIG. 2. $(h^2+k^2+l^2)$ as a function of $1/d^2$ for $FeO \cdot Cr_2O_3$.

If, on the other hand, it is assumed that the compound formed is $CrO \cdot Fe_2O_3$ whose molecular weight is 227.71 g/mole the number of molecules per unit cell is

$$Z=\frac{5.109\text{ g/cc}\times(8.348)^3\times10^{-24}\text{ cc}\times6.023\times10^{23}\text{/mole}}{227.71\text{ g/mole}}=7.86.$$

Since for a compound the number of molecules per unit cell must necessarily be whole number, it is evident that the chemical formula of the compound formed is $FeO \cdot Cr_2O_3$ with $Fe^{++}$ as the divalent element and $Cr^{+++}$ as the trivalent element.

## IV. CONCLUSIONS

1. The crystalline constituents in the acid open hearth chrome-steel slag samples are (a) chrome-iron spinel of the type $FeO \cdot Cr_2O_3$[4] and (b) small amounts of $(FeO)_2SiO_2$.

2. The density of the spinel as determined by the picnometer method is 5.109 g/cc and its melting point about 2160°C.

3. The spinel crystallizes in the face-centered cubic system with lattice constant $a_0$ as 8.348A and the number of molecules per unit cell is 8.

## ACKNOWLEDGMENT

The authors express their thanks to G. R. Fitterer for his very valuable suggestions and his assistance in supplying some of the necessary materials for this investigation.

---

[4] More exactly $(FeO, MnO) \cdot Cr_2O_3$, since the acid open hearth slag sample contains some amount of MnO which is usually present as $(MnO)_2SiO_2$ dissolved in $(FeO)_2SiO_2$. It is not unlikely, however, that some MnO may replace FeO in the spinel $FeO \cdot Cr_2O_3$. The atomic weight of Mn differs only by 0.92 from that of Fe and the atomic scattering factor of Mn does not differ much from that of Fe, the effects of replacing FeO to a small extent by MnO is therefore hardly detectable.

# Spherical Aberration of Compound Magnetic Lenses

L. MARTON* AND K. BOL
*Stanford University, Stanford University, California*

(Received January 15, 1947)

A reduction of the spherical aberration of strong electron lenses can be achieved by a strong lens as a virtual image former and by a transformation of the image in a real one by means of one or more weak lenses. Calculations are carried out for bell-shaped magnetic fields of the axial field distribution

$$H(z)=\frac{H_0}{1+(z/a)^2},$$

and numerical values of the achieved reduction of the aberration are given for different lens strength, magnification, and image distance of the compound system.

EARLY in the development of electron optics, it was recognized that spherical aberration is one of the most serious limiting factors in the performance of electron lenses. From the beginning, efforts have been directed toward a reduction of this defect. One of the earliest attempts was that of Scherzer[1] who demonstrated that for a thin and weak electrostatic lens an axial field distribution of the form $\phi(z)=\phi_0 e^{-Bz^2}$ gives the minimum spherical aberration. The first similar calculation for a magnetic lens was carried out by Glaser.[2] Later Recknagel[3] and Plass[4] contributed to the same subject. All these calculations deal with very weak lenses; the only practical lenses with somewhat reduced aberration were designed by Gray[5] and Law.[6]

Scherzer demonstrated in another paper[7] that the spherical aberration of electron lenses can never be reduced to zero. Rebsch and Schneider[8] showed furthermore that no combination of electric and/or magnetic lenses can have less aberration than any of the components alone would have. Already at that time, however, Rebsch[9] demonstrated that, theoretically, the aperture defect may be reduced below any prescribed limit if in a compound lens the physical size of the component lenses is reduced proportionately. For obvious reasons this method is not very practical.

A somewhat different approach to the problem of reduction of the spherical aberration of short focus, thick electron lenses was briefly reported eight years ago by one of us.[10] It consists of combining a strong lens, forming a virtual image, with one or more weak lenses which convert the virtual image into a real image. This procedure is universally adopted for the construction of light microscope objectives and other light optical systems, and a more thorough investigation of its application to electron optical systems seems desirable. In what follows, a quantitative evaluation of the reduction of the spherical aberration of strong magnetic lenses is given. For this purpose the theory of strong magnetic lenses, developed by Glaser,[11] must be somewhat extended. Since this discussion is limited to the reduction of spherical aberration, the reduction of other aberrations by the use of compound lenses, which was recently reported,[12] will be completely omitted.

Glaser has shown[11] that for practical fields both the spherical and chromatic aberrations have minima when the object is near the center of the lens, for which position the image is virtual for practically all lenses.

---

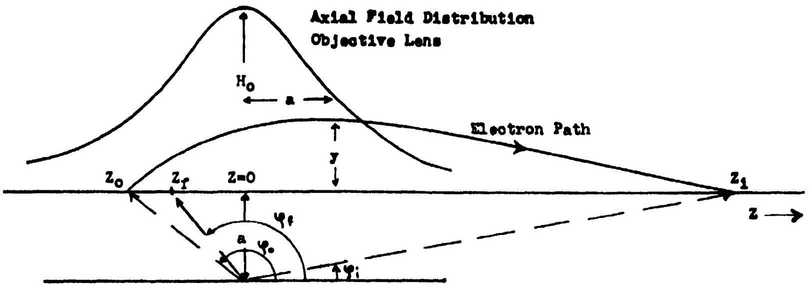

FIG. 1. Representation of symbols and coordinates used in Case I, a single objective lens.

Our problem, then, is to determine how small is the additional aberration introduced by the weak lenses. If it is sufficiently less than the decrease achieved by the formation of a virtual image by the first lens, our purpose is accomplished.

### BASIC THEORY FOR FIELDS OF FORM $H_0/[1+(z/a)^2]$

It was first shown by Glaser[1] that the spherical aberration produced by a magnetic lens with field distribution $H$ along the $z$-axis is given by:

$$\frac{\Delta r}{M}=\alpha^3\frac{e}{96mV}\int_{z_0}^{z_i}\left(\frac{2e}{mV}H^4+5H'^2-HH''\right)y_1^4dz. \tag{1}$$

Here $y_1$ represents the path equation of an electron satisfying the initial condition:

$$y_1(z_0)=0,\quad y_1'(z_0)=1. \tag{2}$$

As for the other symbols: $\Delta r$ is the divergence in the image plane, $z_i$, of a beam of aperture $\alpha$ at $z_0$, $M$ is the magnification, $V$ the electron energy in terms of the accelerating voltage, and $e/m$ the ratio of charge to mass of the electron. If $H$ is given by

$$H=H_0/[1+(z/a)^2], \tag{3}$$

then the path equation is

$$y=a(1+(z/a)^2)^{\frac{1}{2}}\{D_1\sin[(1+k^2)^{\frac{1}{2}}\operatorname{arccot}z/a]+D_2\cos[(1+k^2)^{\frac{1}{2}}\operatorname{arccot}z/a]\}, \tag{4}$$

$D_1$ and $D_2$ being arbitrary, while $k^2=eH_0^2a^2/8mV$. $a$ is the so-called half-width of the magnetic field. $k^2$ is a measure of the refracting power. The equation is put in a more palatable form if one sets $z/a=\cot\varphi$ (see Fig. 1) and $(1+k^2)^{\frac{1}{2}}=\omega$. One then obtains

$$y=aC_1\frac{\sin\omega(\varphi-\varphi_0)}{\sin\varphi}, \tag{5}$$

one constant having been chosen so that $y(z_0)=0$. For convenience we quote a few more formulas from Glaser:

$$z_{F_0}=a\cot(n\pi/\omega),\quad z_{F_i}=-a\cot(n\pi/\omega), \tag{6a}$$

$$f_0=\frac{a}{\sin(n\pi/\omega)},\quad f_i=\frac{-a}{\sin(n\pi/\omega)}, \tag{6b}$$

$$N<\omega<N+1, \tag{6c}$$

$N$ being the number of focal positions. Here $f$ is the focal length and $z_F$ is the location of the focal point.

The aberration for a single lens of this type has been thoroughly studied, whence we give just a resumé of some of Glaser's work.

Our problem, to be sure, is to study the aberration produced by a compound objective. This, however, we can immediately do by extending Eq. (1) over the whole system, as long as we obey the restriction that the radial distance of a paraxial ray be zero at the endpoints of the path of integration.

*Case I. Single lens.* The equation for the spherical aberration is obtained by integrating Eq. (1). From it follows that:

$$\frac{\Delta r}{M}=\alpha^3\frac{a_1k_1^2}{6\omega_1^4}\frac{1}{\sin^4\varphi_0}K_1, \tag{7}$$

where $K_1$ is given by

$$K_1=\int_{\varphi_0}^{\varphi_i}[2(4k_1^2-3)\sin^2\varphi+7]\sin^4\omega_1(\varphi-\varphi_0)d\varphi. \tag{8}$$

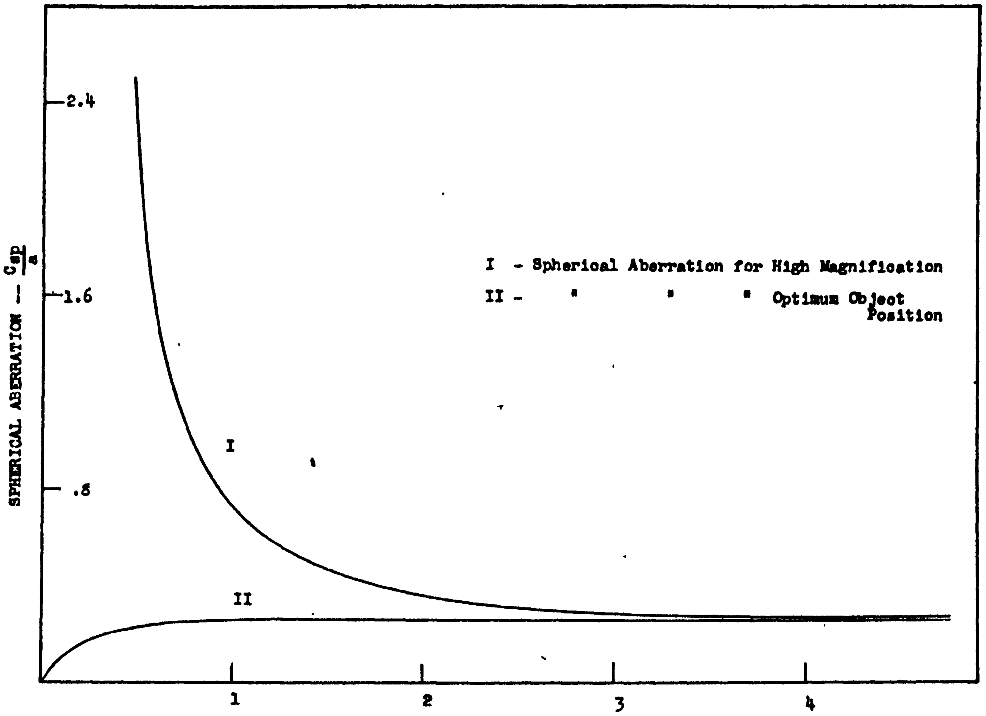

FIG. 2. Spherical aberration *vs.* lens strength for high magnification and optimum object position. (From Glaser.)

Since we need other upper limits later on, we leave it variable and obtain for the complete expression:

$$K_1(\varphi_0,\varphi)=\tfrac{3}{2}\omega_1^2(\varphi-\varphi_0)-\omega_1\sin 2\omega_1(\varphi-\varphi_0)+\tfrac{1}{8}\omega_1\sin 4\omega_1(\varphi-\varphi_0)-\frac{3(4k_1^2-3)}{16}\sin 2\varphi$$

$$+\frac{3}{4}\frac{\omega_1^4}{k_1^2}\frac{4k_1^2-3}{4k_1^2+3}\sin 2\varphi_0+\frac{4k_1^2-3}{4k_1^2}\omega_1\sin 2\omega_1(\varphi-\varphi_0)\cos 2\varphi-\frac{4k_1^2-3}{4k_1^2}\cos 2\omega_1(\varphi-\varphi_0)\sin 2\varphi$$

$$-\frac{1}{8}\frac{4k_1^2-3}{4k_1^2+3}\omega_1\sin 2\omega_1(\varphi-\varphi_0)\cos 2\varphi+\frac{1}{16}\frac{4k_1^2-3}{4k_1^2+3}\cos 4\omega_1(\varphi-\varphi_0)\sin 2\varphi. \quad (9)$$

For high magnification, however, $\varphi_0 \cong \varphi_F$ while $\varphi_i \sim 0$, and from the lens equation (6) $\omega\varphi_F=\pi$, so that the expression is much simplified. The aberration for $\varphi_0=\varphi_F$ as a function of $k^2$ is given by Fig. 2.

The aberration is, to be sure, not a minimum for $\varphi_0=\varphi_F$. The presence of the factor $\sin^{-4}\varphi_0$ suggests immediately that the object should be close to the center, or $\varphi_0 \sim \pi/2$, as was mentioned in the introduction. Indeed, Glaser also plots the aberration for the optimum object position, which we give in Fig. 2.

For high $k^2$ the aberration is not appreciably altered by picking the optimum position; for the lower $k^2$ that are actually used in practice $(1<k^2<2)$, however, improvement is possible.

There are two objections to having the object right at the optimum position: the magnification is almost unity for practical values of $k$, and the image is virtual.

In order to accomplish anything we must therefore sacrifice some improvement in the aberration to gain magnification, and we must put in at least a second lens to attain a real image. We must, therefore, invesigate next the aberration introduced by the second lens.

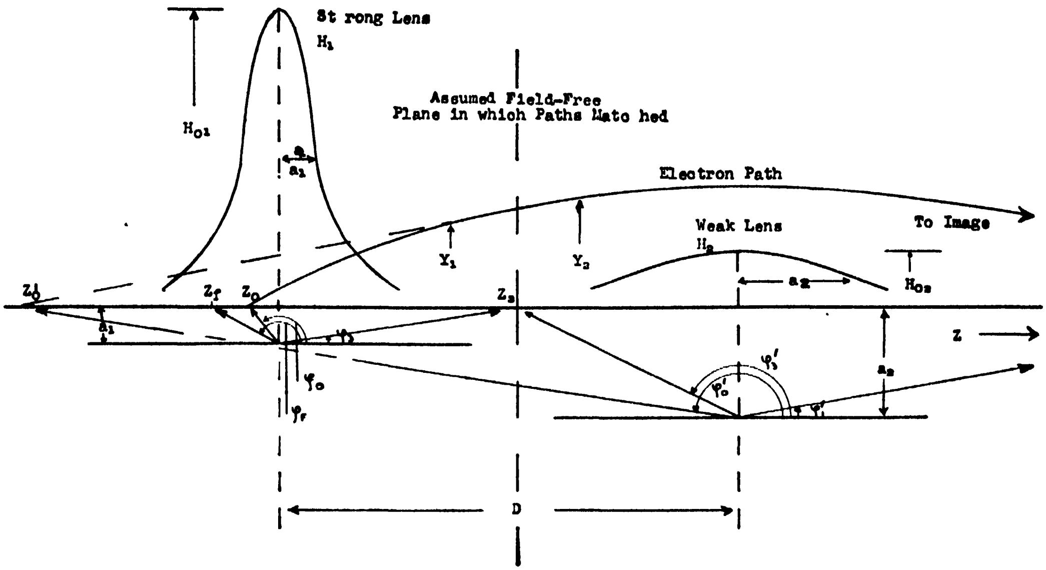

FIG 3. Representation of symbols and coordinates used in Case II, for a doubly compound objective lens.

*Case II. Two lenses.* We first define our axial field $H$ as follows:

$$H=\begin{cases} H_1=H_{01}/[1+(z/a_1)^2] \text{ for } -\infty<z<z_3, \\ H_2=H_{02}/\{1+[(z-D)/a_2]^2\} \text{ for } z_3<z<\infty. \end{cases} \quad (10)$$

$D$ is the distance between lens centers.

Quite arbitrarily we choose $z_3$ so that

$$H_1(z_3)\cong H_2(z_3).$$

We also assume that the two fields do not interact to an appreciable extent. This is done so that we can use the path equations of the previous section for each field, the constants of the second being adjusted to match the first at $z_3$. Only in the absence of such interaction are the calculations strictly valid.[11, 12]

Equation (1) then becomes

$$\frac{\Delta r}{M}=\alpha^3\frac{e}{96mV}\left[\int_{z_0}^{z_3} f(H_1)y_1^4dz+\int_{z_3}^{z_i} f(H_2)y_2^4dz\right]. \quad (11)$$

The integrals can be transformed into that of Eq. (8) by adopting a new coordinate system for the second lens. We take $z'=z-D$ and $z'/a_2=\cot\varphi'$ (Fig. 3). Applying furthermore the initial condition (2) to Eq. (5), we obtain for $y_1$ and $y_2$

$$y_1=\frac{a_1}{\omega_1 \sin\varphi_0}\,\frac{\sin\omega_1(\varphi_0-\varphi)}{\sin\varphi},$$

and

$$y_2=a_2C_2\frac{\sin\omega_2(\varphi'-\varphi_i')}{\sin\varphi'} \quad (12)$$

where $\varphi_i'$ is chosen in accordance with Newton's image equations, which hold for this type lens, and where $C_2$ is to satisfy the matching condition.

Slightly modifying Glaser's results we then obtain

$$\frac{\Delta r}{M}=\alpha^3\left[\frac{a_1k_1^2}{6\omega_1^4}\,\frac{1}{\sin^4\varphi_0}K_1+\frac{a_2k_2^2}{6}C_2^4K_2\right]$$
$$=\alpha^3C_{sp}. \quad (13)$$

For $K_1$ and $K_2$ we write (see Eq. (8))

$$K_1=\int_{\varphi_0}^{\varphi_3} f(k_1,\varphi,\varphi_0)d\varphi,$$
$$K_2=-\int_{\varphi_i'}^{\varphi_3'} f(k_2,\varphi',\varphi_i')d\varphi'. \quad (14)$$

As we have already seen, (Eq. (9)), the exact expressions for $K_1$ and $K_2$ are exceedingly cumbersome; but fortunately they may be approximated—for the values we use—to within a few percent by the following equations:

$$K_1=\tfrac{3}{2}\omega_1^2(\varphi_3-\varphi_0)+\frac{3\,\omega_1^4}{4\,k_1^2}\,\frac{4k_1^2-3}{4k_1^2+3}\sin 2\varphi_0,$$

$$K_2=-\left[\tfrac{3}{2}\omega_2^2(\varphi_3'-\varphi_i')+\frac{4k_2^2-3}{4k_2^2}\omega_2\sin 2\omega_2(\varphi_3'-\varphi_i')\cos 2\varphi_3'-\frac{4k_2^2-3}{4k_2^2}\cos 2\omega_2(\varphi_3'-\varphi_i')\sin 2\varphi_3'\right]. \tag{15}$$

Now we but need an evaluation of $C_2$ to have an analytic expression for the aberration constant, $C_{sp}$. To do this it is convenient to write $y_2$ as

$$y_2=a_2C_2\frac{\sin\omega_2(\varphi'-\varphi_0')}{\sin\varphi'}, \tag{16}$$

$\varphi_0'$ being the position of the virtual image formed by the first lens as seen by the second, and again being determined by the Newtonian image relations.

Although we must match both $y_1$ and $y_2$ and their slopes, it is obvious, $\varphi_0'$ having been determined, that if $C_2$ satisfies either condition it will automatically satisfy the other. We thus pick as most convenient the condition that the path distances (see Eq. (12)) be equal. We have then:

$$a_2C_2\frac{\sin\omega_2(\varphi_3'-\varphi_0')}{\sin\varphi_3'}=\frac{a_1}{\omega_1\sin\varphi_0}\,\frac{\sin\omega_1(\varphi_0-\varphi_3)}{\sin\varphi_3}. \tag{17}$$

Fortunately, the arguments are such that we can approximate as follows:

$$a_2C_2\frac{\omega_2(\varphi_3'-\varphi_0')}{\pi-\varphi_3'}=\frac{a_1}{\omega_1\sin\varphi_0}\,\frac{\pi-\omega_1(\varphi_0-\varphi_3)}{\varphi_3}. \tag{18}$$

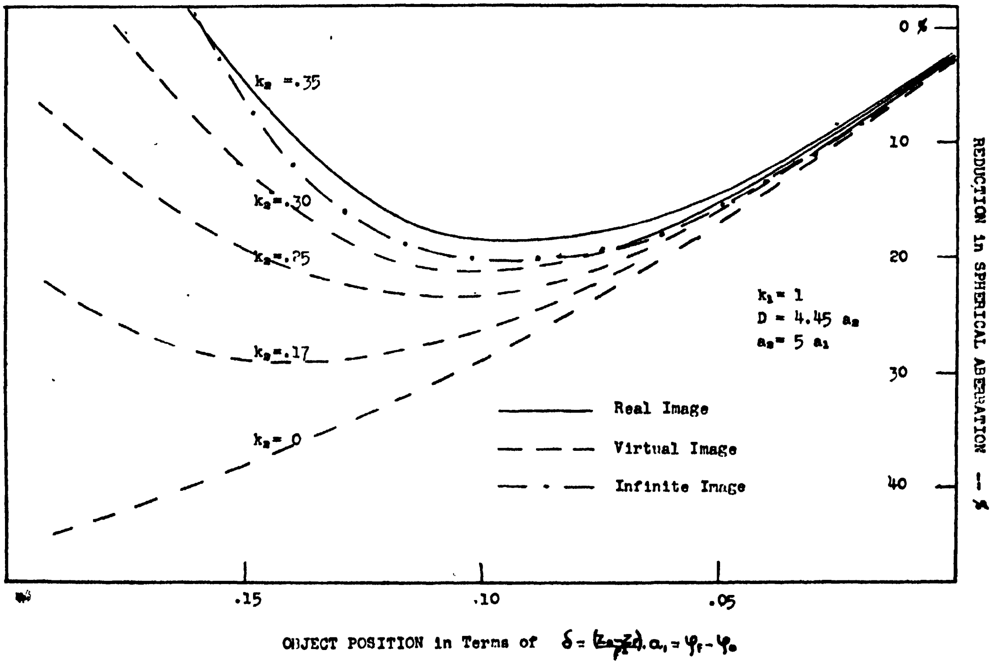

FIG. 4. Spherical aberration *vs.* objective position in first lens, for a second lens of varying strength, but fixed half-width. An infinite image is formed when the first lens forms a virtual image on the focal position of the second lens. Above this boundary, the system forms a real final image, below, a virtual one.

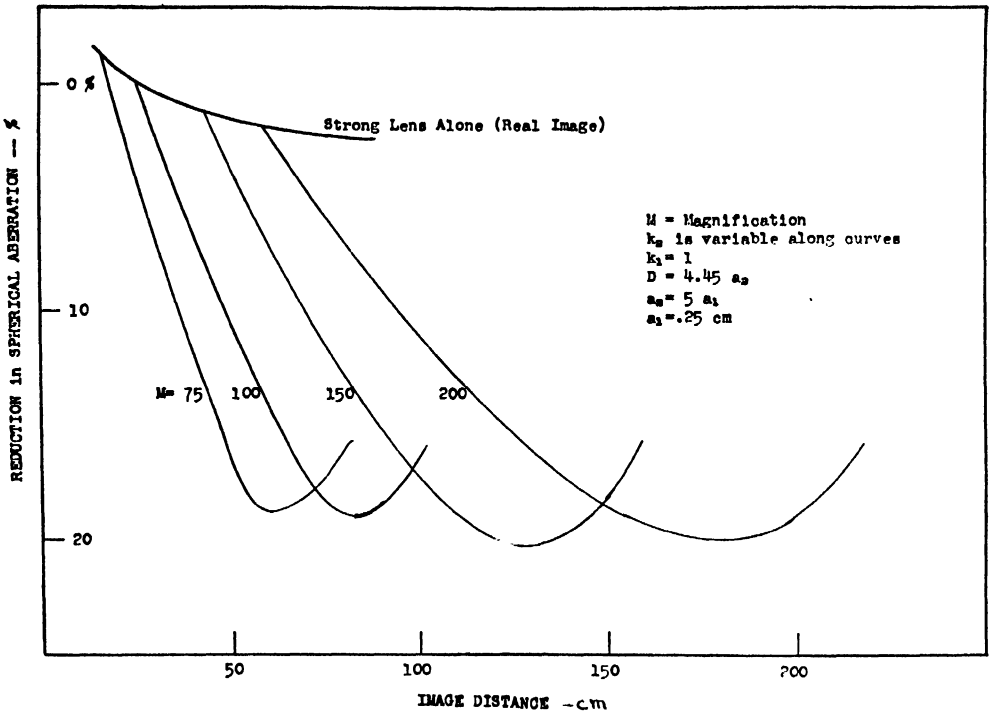

FIG. 5. Spherical aberration *vs.* the final image distance for a typical set of conditions.

Now setting $\varphi_0=\varphi_F-\delta$, and applying the fact that $\omega\varphi_F=\pi$ (Eq. (6)), $\varphi_F$ being the focal position, we obtain:

$$C_2=\frac{a_1}{a_2}\frac{1}{\sin\varphi_0}\frac{1+\delta/\varphi_3}{\omega_2}\frac{\pi-\varphi_3'}{\varphi_3'-\varphi_0'}. \tag{19}$$

Thus we have obtained for the aberration constant of a two-component compound lens:

$$\frac{C_{sp}}{a_1}=\frac{1}{6\sin^4\varphi_0}\left[\frac{k_1^2}{\omega_1^4}K_1+\left(\frac{a_1}{a_2}\right)^3K_2\frac{k_2^2}{\omega_2^4}(1+\delta/\varphi_3)^4\left(\frac{\pi-\varphi_3'}{\varphi_0'-\varphi_3'}\right)^4\right]. \tag{20}$$

## DISCUSSION

We have already seen that $\varphi_0$ should be close to $\pi/2$. The question remains how the second term varies with $\varphi_0$. As the beam leaving the first lens is converged less, or $\varphi_0\rightarrow\pi/2$, one can expect it to increase rapidly, since the aberration increases with the cube of the aperture. The behavior with $\varphi_0$ for different $k_2$ is shown in Fig. 4.

For the same reason the two lenses should be close together. It is unfortunate that we have not succeeded so far in treating the case of interacting fields, so that we could find the exact behavior when $D$ becomes small. It is certain, however, that practical compound lenses will need to be close enough together to make field interaction inevitable.

One reason for the need is the final image distance involved. Figure 5 gives an idea of the increase in image distance for only a 20 percent reduction in the aberration. Decreasing $D$ is the only way of decreasing the aberration and keeping a reasonable image distance.

Another way of decreasing $C_{sp}$ is by increasing the ratio of the half-width of the second lens to that of the first. (See Fig. 6.) But here again we increase the final image distance, as is also indicated on the graph, in a manner approximately proportional to $a_2/a_1$.

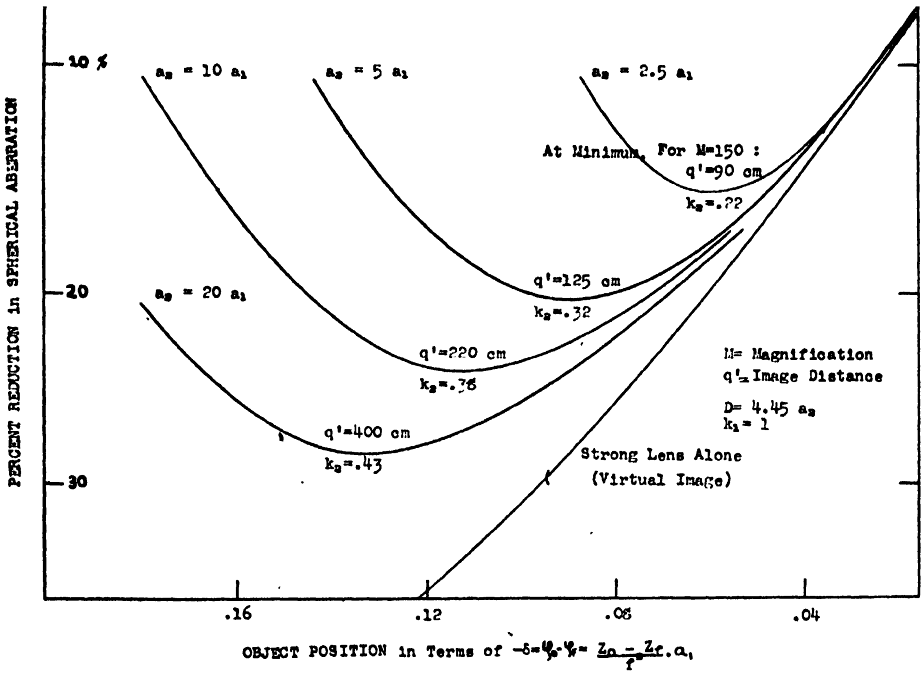

FIG. 6. Spherical aberration *vs.* object position, for a second lens of varying half-width. The total magnification along the curves is infinite, but to gain an idea as to how the image distance $q'$ varied, we took the lens strength indicated by the aberration minimum and calculated $q'$ for a magnification of 150.

Thirdly, the contribution of the second lens is almost proportional to $k_2^2 (k_2^2 \ll 1)$, shown in Fig. 4. There again, however, another consideration enters. The focal length of the second lens is inversely proportional to $k_2^2$. The greater this focal length, the higher must be the magnification by the first lens in order to produce a virtual image outside the second focal point and thus secure a real final image.

But for high magnification by the first lens one achieves almost no reduction in the aberration. The result is that there is an optimum value for $k_2$, as is shown in Fig. 7 (which is merely Fig. 4 plotted against total magnification).

This optimum value, we note, is not necessarily the best from the point of view of image distance. Referring once more to Fig. 5, it is seen that especially for high magnification the aberration minimum is very flat. One can thus gain a considerably shortened image distance, without appreciably increasing the aberration, by taking a value of $k_2^2$ somewhat less than the optimum value.

We saw from Fig. 4 that some decrease in the aberration is possible using only two lenses, but that even greater decreases come with the formation of a virtual image by a very weak second lens. The question then arises whether one cannot use three lenses to good advantage.

Our next problem is to decide therefore whether the contribution of the third lens can be made sufficiently small to make its addition worth while.

*Case III. Three lenses.* Again proceeding as in the previous section we easily obtain for the aberration:

$$\genfrac{}{}{0pt}{}{C_{sp}}{a_1} \quad \frac{\Upsilon}{6\sin^4\varphi_0}\left\{\frac{k_1^2}{\omega_1^4}K_1+\left[\left(\frac{a_1}{a_2}\right)^3\left(1+\frac{\delta}{\varphi_3}\right)^4 K_2\frac{k_2^2}{\omega_2^4}\left(\frac{\pi-\varphi_3'}{\varphi_3'-\varphi_0'}\right)^4\right]\right.$$

$$\left.\times\left[1+\left(\frac{a_2}{a_3}\right)^3\frac{K_3}{K_2}\cdot\frac{k_3^2}{k_2^2}\frac{\sin^4\omega_2(\varphi_4'-\varphi_0')}{\sin^4\omega_3(\varphi_4''-\varphi_i'')}\frac{\sin^4\varphi_4''}{\sin^4\varphi_4'}\right]\right\}. \quad (21)$$

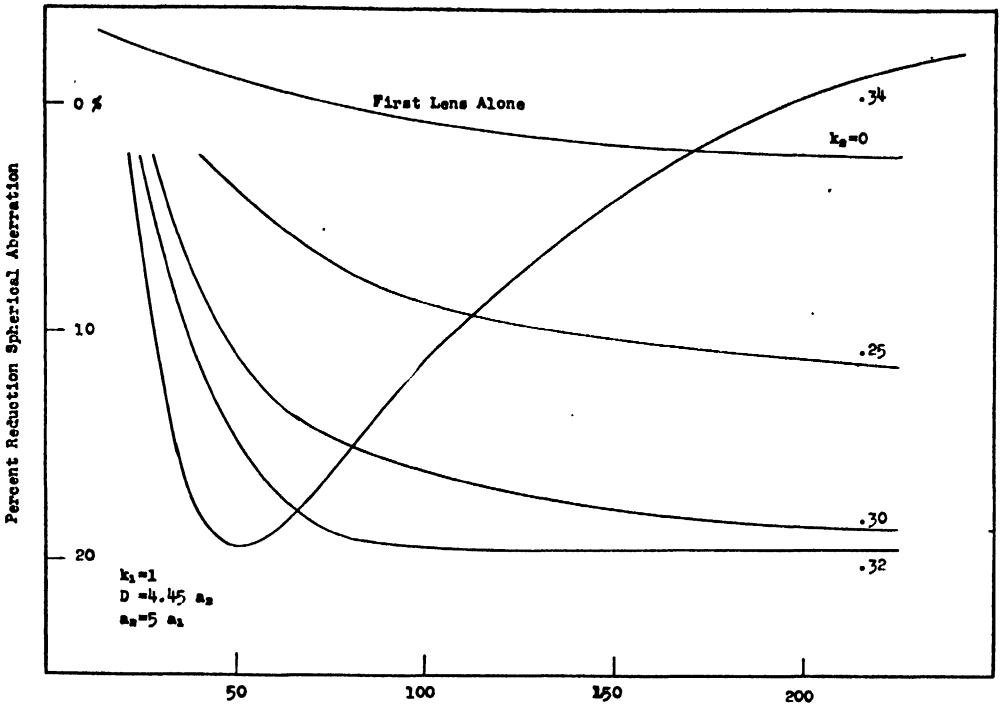

FIG. 7. Aberration *vs.* total magnification. This is a plot of graph II *vs.* magnification instead of object position.

The symbolism is exactly analogous to that for Case II except that the subscript 4 refers to the field-free plane between the second and third lenses. All double primes refer to the coordinate system of the third lens.

Equation (21) leads us to the following qualitative conclusions:

(1) By making $a_2/a_3$ small enough (say $\frac{1}{5}$) we can obtain $C_{sp_{3\text{ lenses real image}}} = C_{sp_{2\text{ lenses virtual image}}}$. In other words, the last term in Eq. (21) must be $\ll 1$.

(2) The image distance, $q$, depends almost entirely on the spacing between the last two lenses. If we wish to satisfy the condition of no interaction between the lenses, $q$ will be greater than for the two lens combination.

Both aberration and image distance, for the combination of two or three lenses, show a considerable improvement only for conditions exceeding the limits imposed by our method of derivation. It is hoped that a more rigorous derivation and/or experiments will enable us in the near future to substantiate and to extend the results of this preliminary calculation.

## CONCLUSION

By combining two lenses one can approach the lower limit to the aberration set by the first lens, used as a virtual image former. For such lens separation for which the interaction of the lens fields is negligible, the image distance is considerably greater than that of the first lens used as a real image former.

How closely one can approach this lower limit cannot be answered without a study of the aberration for very close, interacting fields.

Certainly it seems desirable to have the lenses close together.

In addition it has been found that there is an optimum value for the strength of the second lens in a two-lens system, and that the half-width of the second field should be several times greater than that of the first.

Three lenses may be used to improve the aberration, but only at a cost of a great image distance.

# Physical Properties of Calcium Tungstate X-Ray Screens

J. W. COLTMAN, E. G. EBBIGHAUSEN,* AND W. ALTAR
*Westinghouse Research Laboratories, Pittsburgh, Pennsylvania*

(Received January 6, 1947)

The absolute energy of the light from a fluorescent calcium tungstate x-ray screen, its spectral distribution, and the efficiency of conversion from x-rays to light have been determined. The absolute energy and its spectral distribution were obtained spectrographically by comparison with a standard tungsten filament lamp. Equations are given for determining the distribution of light in the diffusing screen material, and calculation of the light losses are made for varying screen thickness and x-ray absorption. The data for energy distribution of the ingoing x-rays were taken from measurements obtained in this laboratory by a new method to be published elsewhere. Allowance for scattering and secondary *x*-radiation was made and a conversion efficiency of 5.0 percent was obtained for this calcium tungstate phosphor.

## INTRODUCTION

THE primary purpose of this research was to obtain experimentally the absolute efficiency of the transformation of x-ray energy into light energy by calcium tungstate. Of the various fluorescent materials which might have been examined, calcium tungstate appeared to be the one whose investigation would be most fruitful, first, because of its wide utilization in radiography, and second, because the fluorescence of this phosphor is not due to the presence of a foreign material serving as an activator. Thus calcium tungstate phosphors produced by different manufacturers should have the same spectral distribution, and probably will not vary greatly in their efficiency. As a basis for theoretical studies of fluorescence, knowledge of the behavior of calcium tungstate is probably of more value than that for the sulphide phosphors which are very sensitive to minute quantities of impurities.

The problem of determining the conversion efficiency divides itself into three main parts. First, the absolute energy and spectral distribution of the light emitted from the screen must be determined. Second, the light losses in the screen must be determined in order that the total light generated may be calculated. Third, the energy of x-rays absorbed in the screen must be measured. The resultant efficiency will be a characteristic of the calcium tungstate itself and of the wave-length of the exciting x-rays. With this information and a knowledge of the functional dependence of the light losses on the structure of the screen as presented herein, the behavior of any calcium tungstate screen may be predicted. The method of analysis developed to obtain the light losses are applicable to the transmission of light in diffuse media in general and, in particular, to phosphors other than calcium tungstate.

## Ia. LIGHT ENERGY AND ITS SPECTRAL DISTRIBUTION

The spectrographic part of the problem consisted of the determination of the spectral energy distribution of the $CaWO_4$ screen when excited by 80 kv x-rays, filtered by one half millimeter of Cu and one millimeter of Al, and with a tube current of 20 milliamperes. The procedure involved a photographic comparison between the known spectral energy distribution of a temperature-calibrated tungsten ribbon filament lamp and that of the $CaWO_4$ screen.

### The Experimental Apparatus

The standard source was a lamp with a tungsten ribbon filament and quartz window loaned by the National Bureau of Standards. The ribbon filament is about $1\frac{1}{2}$ inches long and $\frac{1}{8}$ inch wide and is supported in the bulb by heavy nickel leads.

The temperature calibration of the lamp was made by Mr. M. S. Van Dusen, Acting Chief of the Pyrometry Section, who gave the value of the brightness temperature outside of the quartz

---

* Now at University of Oregon, Eugene, Oregon.

window as 2614°K at a current of 39.20 amperes and for a point about midway along the filament. The position is marked by a small nick on one edge of the filament itself. Values of the spectral transmission of the quartz window were also supplied by Mr. Van Dusen.

In order to compute the spectral distribution of the radiation from the filament, it was necessary to obtain the true temperature of the filament inside the bulb and to have a knowledge of the spectral emissivity of tungsten over the intended working range of wave-length (3000A–7000A). A compilation of spectral emissivities was furnished by Dr. W. W. Coblentz, retired head of the Radiation Laboratory of the National Bureau of Standards. The conversion from the brightness temperature to the true temperature is accomplished by the following formula, derived from Planck's radiation formula:

$$\frac{1}{T_t}=\frac{1}{T_{BO}}+\frac{\lambda}{.4343C_2}\log_{10}(t_\lambda\cdot\epsilon_\lambda), \qquad (1.1)$$

where

$T_t$ = true temperature of the filament

$T_{BO}$ = brightness temperature of the filament outside the window as determined by the N.B.S. optical pyrometer

$\lambda$ = mean effective wave-length in cm of the filter used in the N.B.S. optical pyrometer

$C_2$ = the second constant in Planck's radiation formula

$t_\lambda$ = transmission of the quartz window at the above-mentioned wave-length

$\epsilon_\lambda$ = the spectral emissivity of tungsten at $\lambda$.

With $T_{BO}=2614°\text{K}$, $\lambda=6650\times10^{-8}$ cm, $C_2=1.435$, $t_\lambda=0.927$, $\epsilon_\lambda=0.426$, the true temperature of the filament is 2947°K.

The spectral energy distribution outside the lamp was obtained by substitution of the above value of the true temperature in Planck's radiation formula, and correction of the result for the spectral emissivities of tungsten and for the spectral transmission of the quartz window.

When the image of the central portion of the filament was focussed on the slit of the spectrograph, the resulting spectrum was a continuous band with a narrower and darker band running down its length. This latter band was caused by the region of the filament at the nick where the filament was narrower, and its resistance and hence its temperature higher, than regions of the filament above and below the nick. This narrow band was not wide enough to measure in the microphotometer, so it was necessary to use some other portion of the filament where the temperature variation with length was small. Measurements of temperature with an optical pyrometer were made covering the $\frac{1}{2}''$ range from a point $\frac{1}{8}$ inch above the nick to within $\frac{1}{8}$ inch of the top of the filament. The true temperature fell only about seven degrees over this range, and at its center was 41° lower than that at the nick. The portion of this region used for projection onto the length of the slit (2 mm) of the spectrograph was about $\frac{3}{8}$ inch. Hence the true temperature variation over this range was of the order of about 4°. From Planck's radiation law one derives the percentage change in energy at a given wave-length for a change in true temperature to be

$$(dE_\lambda/E_\lambda)\ \text{percent}=100(C_2/\lambda T^2)dT. \qquad (1.2)$$

For a true temperature of 2906°K the percentage change of $E_\lambda$ per degree is about 0.57 percent at 3000A and 0.28 percent at 6000A. One may take 0.4 percent as a mean. Hence, a change of 4° (true) corresponds to less than a 2 percent change in $E_\lambda$. Furthermore, since the quartz lens used to focus the filament on the slit of the spectrograph does not give a perfectly sharp image, the effect is to smooth out variations in $E_\lambda$ and produce a spectrum of uniform density across its width. Instead of recomputing the energy distribution for the adopted temperature of 2906°K, the one for 2947°K was used with the correction factor

$$\begin{aligned}C&=\exp(C_2/\lambda)(T_1-T_2/T_1T_2)\\&=\exp(C_2/\lambda)(\Delta T/T^2), \qquad (1.3)\end{aligned}$$

where $\Delta T=41°$ and $T$ is the mean of 2947°K and 2906°K. It appears that the combined error from all sources in the computed energy varies from about 6 percent at 3000A to about 3.0 percent at 6500A with an average for the middle of the spectrum of about 4.5 percent.

One of the most difficult problems was the reduction of the filament brightness to a value closely approximating that of the fluorescent screen. This was necessary because of reciprocity failure of the photographic emulsion which demands that the exposure times on the standard lamp and the fluorescent screen be of quite the

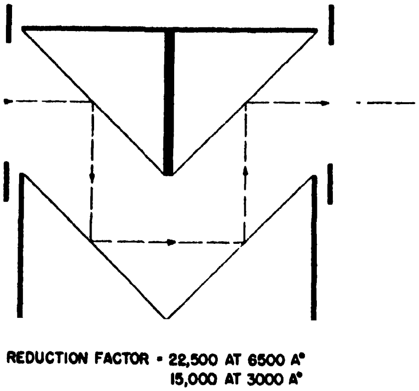

FIG. 1. Schematic arrangement of reflection-type attenuator.

same order of magnitude. A rough computation on the basis of available data indicated that the lamp might be brighter by a factor of the order of one million. Only by the combined use of three methods could the filament brightness be reduced to the point where the exposure times became nearly equal. Reduction by transmission filters had to be rejected as impractical, because transmission coefficients were not known with sufficient accuracy at the various wave-lengths. Of the following three methods used, one will be discussed in detail now and the second and third in later sections:

1. The method of successive reflections.
2. Rotating sectors.
3. Stops in the collimator of the spectrograph.

In the first method the brightness was reduced by successive reflections from four air-glass surfaces. The apparatus designed and constructed for this purpose was called the "attenuator." The attenuator consisted of four borosilicate crown glass prisms arranged as in Fig. 1. The arrows indicate the path of the light through the system. The system was enclosed in a brass box, and the prisms were carefully aligned so that parallelism and perpendicularity of the faces was assured. The angle of incidence of the central ray of the beam closely approximated 45° at all of the four surfaces of reflection. At each surface a small fraction of the light was reflected, and the remainder was transmitted into the prism. In order that as little as possible of this light should be returned to the beam by internal reflections, all prism surfaces except the ones used for reflection were coated with a solution of propyl methacrylate mixed with lampblack, and the prisms were baked in an oven at 120°F for two hours. The result was a non-reflecting and absorbing coating which served to remove to a very high degree all light transmitted into the prism.

According to Fresnel's formulas the amplitude ratios of the reflected light are:

$$\frac{\sin(I-I')}{\sin(I+I')} \quad \text{and} \quad \frac{\tan(I-I')}{\tan(I+I')}$$

for light polarized in, and, respectively, at right angles to, the plane of incidence. The intensity of the parallel component after four successive reflections becomes:

$$R(I_{\parallel})=\left[.707\left(\frac{\sin(I-I')}{\sin(I+I')}\right)^4\right]^2 =\frac{1}{2}\left(\frac{\sin(I-I')}{\sin(I+I')}\right)^8, \qquad (1.4)$$

and similarly for the perpendicular component:

$$R(I_{\perp})=\frac{1}{2}\left(\frac{\tan(I-I')}{\tan(I+I')}\right)^8. \qquad (1.5)$$

Computation shows that for the range of spectrum to be studied, $I_{\perp}$ is about 9000 times fainter than $I_{\parallel}$ and hence the light may be said to be completely polarized.

With $I$ fixed at 45°, $I'$ depends upon $n$ (Snell's Law) and since $n$ varies with the wave-length, $R$ itself is a function of the wave-length.

In order to determine the variation of $n$ with wave-length, one of the prisms was mounted on a spectrometer and $n$ was determined for each of the three mercury lines of wave-length 5460.7A, 4358.3A, and 4046.6A. The resulting indices were, respectively, 1.5260, 1.5349, and 1.5389. Each determination had a standard deviation of unity in the fourth place of $n-1$. With these three values of the wave-length and their respective indices, the constants of the Hartmann formula were obtained:

$$n=1.5041+\frac{83.416}{\lambda-1648.0}. \qquad (1.6)$$

For several wave-lengths between 3000A and 6500A, $n$ was determined from (1.6), then $I'$ from Snell's Law and finally the reduction factors from (1.4). The curve of reduction factor *vs.* wave-length is given in Fig. 2. These factors were applied to the spectral energy distribution curve of the filament outside the lamp and result in the distribution curve of the light as it leaves the attenuator.

Attention must be given to the fact that the light from the attenuator is practically completely polarized, while the light from the fluorescent screen is unpolarized. Thus the loss in the spectrograph may not be the same for both sources. In order to test this, two spectrograms of equal exposure times were taken of the lamp through the attenuator. For the first exposure, the plane of the normals to the reflecting surfaces was held perpendicular to the length of the slit and parallel for the second exposure. From the resulting densities of the spectra it appeared that the effective exposure was only about half as great in the first case as in the second. In order to avoid the difficulty the attenuator was mounted so that the plane of the normals made an angle of 45° with the slit and, therefore, as far as the spectrograph was concerned, it was receiving isotropic light.

The errors in the computed reduction factors are evaluated as follows:

1. As already stated $n$ has been determined with a standard deviation of one part in the fourth place of $n-1$. For the middle of the spectral range, this value results in an error of about 0.1 percent in the value of $R$— a negligible quantity.
2. Since $n$ was determined for only three wave-lengths, interpolation had to be used for shorter and longer wave-lengths using formula (1.6). The error in $R$ to be expected, particularly in the short wave-length region where $n$ is changing rapidly, is estimated to be of the order of 0.3 percent in the neighborhood of 3200A and of 0.1 percent for wave-lengths longer than 4000A.
3. The beam through the attenuator, as defined by the lens which focusses the filament on the slit and by the angular size of the collimator, has an angular diameter of about two degrees, of which only the central ray will strike the reflecting surfaces at an angle of incidence of 45°. The limiting values at the first surface will be 44° and 46°. However, it will be seen that (by design) if $I$ is 46° at the first surface, it will have the same value at the second, 44° at the third, and 44° at the last surface. Calculation shows that the error made in $R$ by assuming $I=45°$ for the whole beam is about 0.2 percent and thus is negligible.

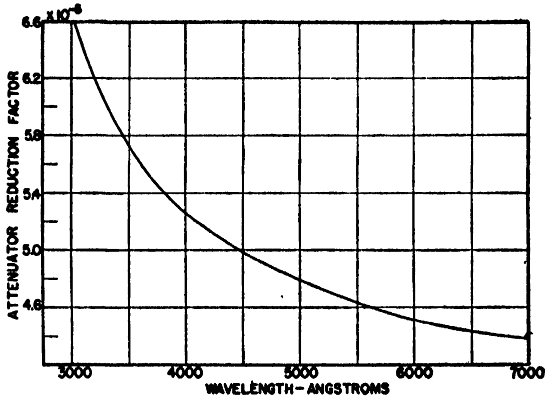

FIG. 2. Reduction factor of attenuator as a function of wave-length.

4. Particular care was used in the alignment of the attenuator so that the resulting error in $R$ is probably less than 0.4 percent.

The total error is probably not in excess of 1 percent.

The spectrograph was an all quartz optics, low dispersion instrument. The arrangement was such that the plate holder could be moved at right angles to the spectrum, and thus several spectra could be obtained on one plate. The length of spectrum from 3000A to 6500A was about $\frac{3}{4}$ inch. The spectrograph was mounted on a turntable which permitted the slit to be turned to either the standard lamp, the mercury lamp (for a comparison spectrum), or the fluorescent screen. By means of lead sheets, the whole instrument was very well shielded from the direct or scattered radiation of the x-ray tube. On the turntable was mounted a motor to turn cardboard sectors, used to reduce the lamp brightness by a given amount, and also a mount for the quartz lens to focus the lamp filament on the slit. Inside the prism case was an arrangement to hold stops for the further control of the lamp brightness. The length of the slit was 2 mm and the width 0.2 mm.

The fluorescent material, a sample of Eastman Ultra Speed back screen, consisted of a layer of $CaWO_4$ covered by a film of lacquer and mounted on a sheet of white cardboard four inches square. It was centered over a two inch square hole in a sheet of $\frac{1}{8}$ inch lead and the whole unit was mounted over the open end of the protective cone of the x-ray tube.

## The Experimental Procedure

Generally speaking, our procedure was a comparison, at a number of wave-lengths, between the brightness of the screen and the standard lamp filament as seen through the attenuator. Given the magnitude of the latter and its spectral distribution, it was possible to compute the light output of the screen on an absolute scale.

One of the most difficult problems, the reduction of the brightness of the standard lamp to a level comparable to that of the fluorescent screen, was accomplished by the use of the attenuator (already described), rotating sectors, and collimator stops. This permitted the use of equal exposure times for the lamp and the fluorescent screen and thereby avoided the danger of reciprocity failure. In order to provide a calibration on each plate, five exposures were made using five cardboard sector disks, eight inches in diameter; the first, *A*, providing a reduction factor 12.5 and the others, *B*, *C*, *D*, and *E* approximately 25, 50, 100, and 200. When using these disks, one must avoid the intermittency effect because of which the photographic density is a measure of the total light impinging only under certain conditions. A continuous exposure and an intermittent one of the same total energy will produce the same density on the photographic plate, provided the total time of exposure is the same in both cases, and the frequency of interruption is above a certain critical rate. The Eastman Kodak Company's publication, "Photographic Plates for use in Spectroscopy and Astronomy," states that this critical rate varies from about 100 flashes per second for a one-second exposure to a few flashes per second for a one hour exposure. The motor used to drive the sectors operated at 2850 r.p.m. and since no exposure was less than twenty minutes, no error caused by the intermittency effect was incurred.

The ~~final ad[illegible]ment of~~ lamp brightness was obtained by placing one of several stops between the prism and the collimator lens at a position close to the latter. The first stop defined the beam leaving the collimator lens to the extent that all of the beam entered the prism and passed through the camera lens to the photographic plate. This stop was used when photographing the spectrum of the fluorescent screen, and its reduction factor was designated as unity. Six more stops were made with reduction factors varying from 2 to 37. With this last stop, the total reduction of the lamp brightness, including the average of that of the attenuator and that of sector *A*, reached a factor of nine million. This much was needed when working in the region around 6000A where the screen fluorescence is weak, and the lamp output high.

All photographic plates used were coated with Eastman 103-F emulsion. On each plate eight exposures were made; one from the fluorescent screen, five from the standard lamp using sector disks *A* to *E*, and two exposures from a mercury lamp to obtain wave-length scales at the top and bottom of a plate.

The densities of the spectra were compared in an Arl Dietert microphotometer. At each position the density was determined for the fluorescent spectrum and for each of the five comparison spectra.

Since different portions of the spectrum required widely varying exposure times to give densities on the linear portion of the emulsions, it was necessary to use several plates to cover the complete spectrum. For each wave-length the transparencies of the five comparison spectra were plotted on semi-logarithmic paper against the reduction factors of the sectors, taking that for sector *A* as unity. From this curve was determined the factor by which the fluorescent spectrum was fainter than the spectrum belonging to sector *A*.

This factor was combined with reduction factors for the collimator stop, the factor 12.5 for the sector disk *A* and the factor for the attenuator, to give a total reduction ratio between intensities at corresponding wave-lengths from the standard lamp and from the $CaWO_4$ screen. A total of seven plates were measured.

## Experimental Results

Near the end of the investigation it was found that the portion of the $CaWO_4$ screen which had been exposed to x-rays was somewhat fainter, showing that it had suffered a certain degree of "fatigue." Measurements indicated that the exposed portion of the screen was about 8 percent fainter than the outer portion that had been protected from x-radiation by the lead.

In order to deduce from the measurements on a fatigued screen the spectrum of a fresh screen, measurements on each plate were corrected by an amount proportional to the total x-ray exposure time of the screen up to the time when the plate in question was taken.

The total time of exposure of the screen to x-rays was about six and one-half hours. This includes exposure times for test plates and several others that for one reason or another were not used. The results from the individual plates are given collectively in Fig. 3. The ordinates are $10^{-5}$ ergs/cm$^2$ sec. *A* unit. The assumption is made that both the lamp filament and fluorescent screen radiate according to Lambert's cosine law, and a correction for departures will be added later.

The curve given in Fig. 3 is not final, but must be corrected for slit broadening. The effect is to pull in both ends of the curve to a certain extent without changing the total area. Integration of this curve yields the result that the total energy output of the screen was 2.54 ergs/cm$^2$/sec.

A correction factor of 0.92 must be applied to this value to correct for the departure from Lambert's law in the angular distribution of the light from the screen. The experimental determination of this factor is described in Section Ib. The total energy thus reduces to 2.34 ergs/square centimeter per second, for a measured x-ray intensity of 0.149 *r*-units per second incident on the screen. The final corrected spectral curve, Fig. 4, is given in terms of light energy generated in the screen per *r*-unit absorbed. The method for measuring the light losses is given in Section 2.

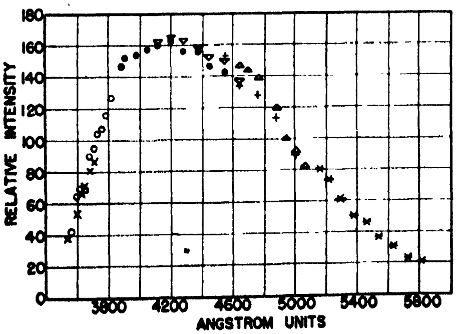

FIG. 3. Spectrum of CaWO$_4$ as obtained from seven plates (uncorrected).

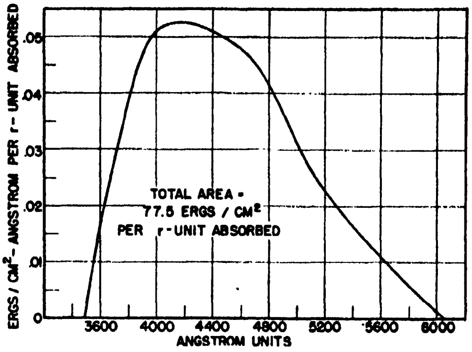

FIG. 4. Fluorescent spectrum of CaWO$_4$ excited by 80 Kv constant potential x-rays. Filter used was ½ mm copper+1 mm aluminum. Screen contained .109 gm/cm$^2$ of CaWO$_4$.

An estimate of the accuracy of this determination involves a consideration of such sources of error as the temperature of the lamp, the spectral emissivities of tungsten, the brightness reduction factors, and errors of the photographic emulsion. It appears that the final total energy has been determined to within an accuracy of about 12 percent.

### Ib. ANGULAR DISTRIBUTION OF THE LIGHT

In order to calculate the total light emitted from the screen from the measured brightness in a specific direction, it is necessary to know the angular distribution of the emission from the screen. In the case of the filament, this factor was taken care of by using the normal emissivity of tungsten for calculation. For the screen, measurement of the angular distribution was made by means of a photo-multiplier cell illuminated through a collimator consisting of a simple lens and a small diaphragm stop at its focal point. The whole assembly was capable of rotation about an axis lying in the plane of the fluorescent screen.

If the emission of light followed a Lambertian (cosine) distribution, the light received by the photocell would be independent of angle. Actually a falling-off at large angles was observed as shown in Fig. 5. Integration of this curve combined with suitable angular variables yields a constant which relates the total light emitted from the screen to that which would have been emitted from a Lambertian source with the same normal intensity. This factor varies slightly with

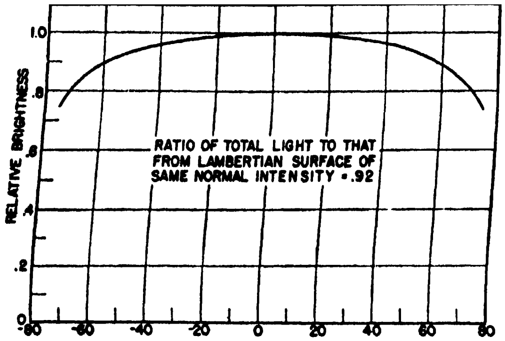

FIG. 5. Angular distribution of light from $CaWO_4$ screen relative to a Lambertian surface.

the wave-length of the exciting x-rays, since the latter affects the distribution of light-generating centers within the screen. Under the conditions of the spectroscopic experiment the $CaWO_4$ screen had a factor of 0.920.

## II. TRANSMISSION OF LIGHT IN DIFFUSE SCREENS

The light produced by the x-rays in the interior of the fluorescent layer is eventually transmitted out of the screen by means of a series of reflections and refractions from individual crystals. Part of the light is lost by absorption in the crystals and in the binder, and part finds its way out of the back surface of the layer. Some of the latter may be recovered by means of a reflecting backing, a white mounting card being commonly used.

Since the particles involved are small compared to the area of interest, and the lateral dimensions of the screen are large compared to the thickness, the problem can be treated as if the material were homogeneous and as if the light were traveling in one dimension only, i.e., perpendicular to the screen.

In the following discussion the words "light forward" and "light backward" refer to directions in the same sense as that of the x-rays. Thus with the screen located between the x-ray tube and the observer, the light forward is that seen by the observer and comes from what will be termed the front of the screen; the light backward from the back of the screen is directed toward the x-ray tube.

The first step in the analysis is to derive the reflection and transmission coefficients of a diffuse layer as a function of its thickness. A layer of thickness $x$ (Fig. 6) has by definition a reflection coefficient $R(x)$. If a layer of thickness $dx$ is added to this, a new reflection coefficient will result. The reflection coefficient of the elementary layer itself will to the first order be proportional to its thickness. Let this reflection coefficient be $kdx$. Similarly, the amount *not* transmitted will be proportional to the thickness to the first order; let this coefficient be $\alpha dx$. It will be evident that $\alpha \geq k$, being equal to $k$ if there is no true absorption of light in the layer. (In Fig. 6 the layer $dx$ is shown separated from the layer $x$ for convenience in tracing the course of the light. It is to be understood that in this and later derivations the layers are actually continuous.). Light is incident on the combination from the left. A fraction $kdx$ will be reflected from the first layer, a portion $1-\alpha dx$ will be transmitted to the second layer. The amount reflected from the second layer is $(1-\alpha dx)R$, of which a quantity $(1-\alpha dx)^2R$ is transmitted out to the right and adds to the initially reflected light. The portion $kdx(1-\alpha dx)R$ which is returned undergoes an exactly similar set of steps. Summing up the infinite series of rapidly diminishing contributions:

$$kdx+R(1-\alpha dx)^2(1+Rkdx+R^2(kdx)^2+\cdots)$$

$$=kdx+\frac{R(1-\alpha dx)^2}{1-Rkdx}=R(x+dx), \quad (2.1)$$

the new reflection coefficient $R(x+dx)$ is obtained. Subtracting $R$ from both sides, and

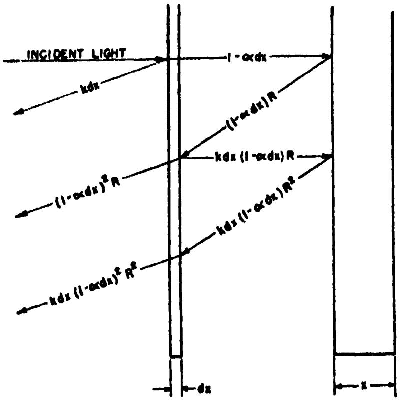

FIG. 6. Schematic representation of light flow for derivation of reflection coefficient formula.

neglecting differentials of higher order than one, we obtain

$$R(x+dx)-R(x)=k(1-2(\alpha/k)R+R^2)dx$$

or

$$\frac{dR}{dx}=k(1-2(\alpha/k)R+R^2).$$

Thus:

$$kx=\int\frac{dR}{[1-2(\alpha/k)R+R^2]},$$

$$kx=-\frac{1}{[(\alpha/k)^2-1]^{1/2}}\tanh^{-1}\frac{R-\alpha/k}{[(\alpha/k)^2-1]^{1/2}}+\text{const.},\tag{2.2}$$

$$R=\frac{\alpha}{k}+[(\alpha/k)^2-1]^{1/2}\tanh((\alpha^2-k^2)^{1/2}x+\text{const.}).$$

The constant is determined by setting $R=0$ when $x=0$, and by further reduction we obtain

$$R=\frac{(k/p)\sinh px}{\cosh px+(\alpha/p)\sinh px},\tag{2.3}$$

where

$$p\equiv(\alpha^2-k^2)^{1/2}.$$

By similar consideration of the multiple reflections in the transmission case, and by use of formula 2.3, the expression for the transmission coefficient is found to be

$$T=\frac{1}{\cosh px+(\alpha/p)\sinh px}\tag{2.4}$$

where $p$ has the same meaning as before.

The constant $p$ is an important characteristic of the material and represents the degree of absorption. For very large $x$, 2.4 reduces to

$$T=\text{constant }e^{-px}$$

the usual exponential function, and $p$ plays the role of a linear absorption coefficient. At large $x$, $R$ approaches a constant, and only after this condition is reached will $T$ be exponential. The physical reason for this is clear; if a thin layer is placed behind another layer, the *incident* light on the new layer is enhanced by the multiple reflections between the two, and only if the original layer is so thick as to have attained the limiting reflection coefficient will the transmission be exponential. The form of these functions is shown in Fig. 7 for values of $k$ and $\alpha$ typical of $CaWO_4$. The values of $k$ and $p$ (or $k$ and $\alpha$) suffice to describe completely the light yield from the front and back of the screen, as well as the light absorbed, if the thickness and distribution of light sources within the screen are given. These coefficients may be experimentally determined by measuring $R$ and $T$.

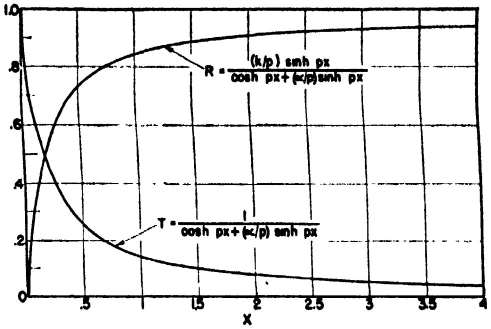

FIG. 7. Reflection and transmission coefficients as a function of thickness ($x$) of diffusing material.

### Determination of the Optical Constants

Values for $p$, $k$ and $\alpha$ could be obtained in principle by measuring $T$ or $R$ as a function of thickness, by virtue of Eqs. (2.3) and (2.4). In carrying out such an experiment one must make sure, however, that the amount of light from the source and the action of the detector for the light are not affected by introduction of the sample. For example, a ground-glass diffuser is not a suitable source because it is itself reflecting; introduction of the sample will enhance the incident light intensity to a value higher than that measured without the sample. For the same reason the detector must be non-reflecting; a photographic plate, for instance, is not sufficiently absorbing to avoid errors due to multiple reflections.

Since the procurement of such ideal light sources and detectors constitutes a serious experimental difficulty, it seemed preferable to eliminate the error altogether by means of a method which does not require measurement of light intensity in the absence of the sample. A tungsten bulb, suitably housed, was used to illuminate one side of the layer; the brightnesses of the two sides were measured by means of a Macbeth Illuminometer and the ratio of the brightnesses was taken to be $R/T$. This was repeated with samples of varying thickness.

By definition, $R$ and $T$ are the results of a scattering process which does not alter the angular distribution of the light. Therefore, Eqs. (2.3) and (2.4) must not be applied indiscriminately to the present case where a nearly parallel light beam is incident on the front of the sample and, upon entering, is gradually scattered in all directions, approaching an equilibrium distribution in direction only as a limiting case. The angular distribution of the light thus varies with depth of penetration, whereas Eqs. (2.3) and (2.4) were derived from an assumed stationary equilibrium for the angular distribution; so the latter is presumed to remain unaffected by further scattering and not to vary with depth.

While this poses a very serious difficulty, generally speaking, for the measurement of arbitrary samples, the calcium tungstate screen has the fortunate quality that its scattering power outweighs its absorbing power by an order of magnitude; consequently determination is possible by examining sufficiently thick samples. If the conversion from parallel light to light with completely random orientation takes place in a relatively thin front layer, further re-distribution will proceed in accordance with the underlying assumptions of Eqs. (2.3) and (2.4).

An empirical criterion of this condition is afforded by inspection of the spatial distribution of the light emerging from the front and back of the screen. For a very thin layer it is clear that while the reflected light has a nearly random distribution, the transmitted light will contain large portions of unscattered light; thus a difference in the angular distribution of the light from the front and the back indicates that equilibrium has not yet been reached. In the thinnest sample used a rough check of the angular distributions showed they were alike and nearly Lambertian. Furthermore, the reflectivity of the thinnest sample was calculated to be 85 percent. Thus addition of further layers can change the reflected light by 10 percent at most and the brightness of the front side is always a good measure of the incident light quantity. For this reason, even though the values of $k$ and $\alpha$ may be somewhat in error due to our use of a parallel beam, this does not apply to the value for $p$, which can be computed from the logarithmic derivative $d\log T/dx$ for large thicknesses $x$.

Samples were prepared by soaking an Eastman Ultra-Speed front screen in alcohol and thus removing its fluorescent layer. This layer contained 0.0445 gm/cm$^2$ of $CaWO_4$ per cm$^2$. It is self-supporting because the internal binder is not soluble in alcohol, whereas the cement used to mount it on the card is soluble. One-inch squares were cut from the layer while still wet, and were superimposed to make up samples of 1, 2, and 4 layers. These were cemented over holes in metal sheets and allowed to dry.

It might be supposed that the protective coating on the layers (a film of cellulose plastic) would violate the assumption of homogeneity of the material. However, consideration of the multiple reflections between the crystalline material boundary and film-air interface show that for the index of refraction of this film the effect is completely negligible for the thicknesses used.

Four points on the $R/T$ curve were determined, at zero, 1, 2, and 4 layers. Values of $R/T$ are shown in Table I. From Eqs. (2.3) and (2.4) we see $R/T$ should be of the form $k/p\,\sinh px$. Values of $k$ and $p$ were chosen to fit the experimental points, namely, $k=5.55$/layer and $p=0.30$/layer. The third column gives the calculated points for comparison. Since $\alpha^2=k^2+p^2$, $\alpha$ is also 5.55/layer within the experimental error, with the understanding of course that

$$(\alpha^2-k^2)^{\frac{1}{2}}=0.30/\text{layer}.$$

From the fit obtained, the values of $k$, $\alpha$, and $p$ are estimated to have probable errors of less than 3 percent. In the following treatment these values have been used, and the thickness $x$ is always measured in terms of one layer as the dimensional unit.

TABLE I.

| $x$ (layers) | $R/T$ (exp.) | 18.5 sinh.30$x$ |
|---|---|---|
| 0 | 0 | 0 |
| 1 | 5.43±.05 | 5.63 |
| 2 | 11.8 ±.13 | 11.8 |
| 4 | 27.6 ±.4 | 27.9 |

After these measurements had been evaluated and the results had been used to compute the conversion efficiency and the curves of light yields, it was decided to repeat the measurements of the optical constants of the screen using a diffuse source for the incident light. The sample was mounted over an aperture in an Ulbricht photometric sphere arranged so that the brightness of both sides of the sample could be observed with a Macbeth Illuminometer. These measurements gave a good fit for the ratio $R/T=k/p\,\sinh px$, using $k=6.0$ and $p=0.33$. Adoption of these new values would change the curves of light yields which are presented below. Since these are meant to be illustrative, and quantitative only pending measurement of the optical constants of an individual sample, it did not seem worth while to recompute them. However, the new constants were used for computation of conversion efficiency.

### The Light Distribution in the Screen

Having derived expressions for transmission and reflection of a diffuse layer, one is in a position to compute, for a given distribution of light generation throughout the screen, the fractional amounts emerging from the screen in both the forward and backward directions.

Since the x-ray intensity decreases exponentially with depth of penetration, light production also follows an exponential law, being highest at the back where the x-rays are incident. Consider the element of thickness $dx$ located at a distance $x$ from the back of the screen whose thickness is $\epsilon$ (Fig. 8). This element is between two layers, of finite thickness $x$ (layer 1) and $\epsilon-x$ (layer 2), respectively. Of the light $dL$ generated in the element, $\frac{1}{2}$ starts out toward layer 2, while $\frac{1}{2}$ starts toward layer 1. These are subject to multiple reflections as shown in Fig. 8, the lower half being concerned with the light starting toward 2 and the upper with that starting toward 1. The fraction $f$ out the front due to $dL$ is given by the sum of the contributions as before, and

$$f=\frac{1}{2}\,\frac{T_2(1+R_1)}{1-R_1R_2}. \tag{2.5}$$

The coefficients $R_1$, $R_2$ and $T_2$ are, of course, functions of $x$ and $\epsilon-x$ as in formulas (2.3) and (2.4). It is now necessary to multiply $f$ by the light produced in the element $dx$ and integrate over $x$ from 0 to $\epsilon$ to obtain the total light out.

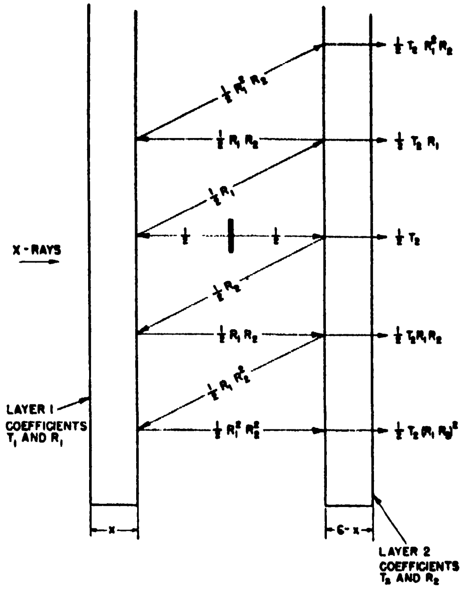

FIG. 8. Schematic representation of light flow from a luminous element within the screen.

If the absorption coefficient of the x-rays is $\mu$, we have by definition that the x-rays absorbed in a layer $dx=I\mu dx$ where $I$ is the intensity of x-rays at the point $x$. Let $\rho$ = conversion efficiency of x-rays into light; the light produced in $dx$ is then $\rho I\mu dx$. But $I=I_0e^{-\mu x}$, where $I_0$ is the incident x-ray intensity, and $dL=\rho\mu I_0e^{-\mu x}dx$ (2.6)

The forward light yield is then:

$$L=\frac{\rho\mu I_0}{2}\int_0^{\epsilon}e^{-\mu x}\frac{T_{(\epsilon-x)}(1+R_{(x)})}{(1-R_{(x)}R_{(\epsilon-x)})}dx. \tag{2.7}$$

Before performing this integration we shall find it very convenient to derive a relation between the transmission coefficient of the screen as a whole ($T_\epsilon$) and the coefficients of its parts. In Fig. 9 is shown the schematic diagram from which we find:

$$\begin{aligned}T_\epsilon&=T_1T_2(1+R_1R_2+(R_1R_2)^2+\cdots),\\ T_\epsilon&=T_1T_2/(1-R_1R_2).\end{aligned} \tag{2.8}$$

Substituting in formula (2.5) we get

$$f\doteq\frac{T_\epsilon}{2}\left(\frac{1}{T_1}+\frac{R_1}{T_1}\right). \tag{2.9}$$

$T_\epsilon$ is a constant independent of $x$, and from 2.3 and 2.4 we have $1/T_1 = \cosh px + (\alpha/p)\sinh px$, $R_1/T_1 = (k/p)\sinh px$. Formula 2.7 then becomes:

$$L = \frac{p\mu I_0 T_\epsilon}{2}\int_0^\epsilon e^{-\mu x} \times\left(\cosh px + \frac{\alpha+k}{p}\sinh px\right)dx. \quad (2.10)$$

In preference to an expression for light out itself, we shall divide $L$ by the total light generated to obtain the fraction $F_F$ which is transmitted out the front of the screen. The total light produced is:

$$pI_0(1-e^{-\mu\epsilon})$$

and

$$F_F = \frac{\mu}{(1-e^{-\mu\epsilon})[\cosh p\epsilon + (\alpha/p)\sinh p\epsilon]} \times\int_0^\epsilon e^{-\mu x}\left(\cosh px + \frac{\alpha+k}{p}\sinh px\right)dx. \quad (2.11)$$

Carrying out the integration we obtain the final expression:

$$F_F = \frac{\mu\{(\mu+\alpha+k) - e^{-\mu\epsilon}[(\mu+\alpha+k)\cosh p\epsilon + ([\mu(\alpha+k)/p]+p)\sinh p\epsilon]\}}{2(1-e^{-\mu\epsilon})(\mu^2-p^2)(\cosh p\epsilon + (\alpha/p)\sinh p\epsilon)}. \quad (2.12)$$

In an exactly similar manner the formula for the fraction out the back of the screen is found;

$$F_B = \frac{\mu\{(\mu-\alpha-k)(\cosh p\epsilon - e^{-\mu\epsilon}) + ([\mu(\alpha+k)/p]-p)\sinh p\epsilon\}}{2(1-e^{-\mu\epsilon})(\mu^2-p^2)(\cosh p\epsilon + (\alpha/p)\sinh p\epsilon)}. \quad (2.13)$$

Graphs of these functions are given in Figs. 10 and 11 for various values of $\mu$ and $\epsilon$, using $k = 5.55$/layer and $p = 0.30$/layer. Values of the thickness $\epsilon$ are in terms of one-layer units, and $\mu$, the x-ray absorption coefficient is per layer. It is apparent that for zero thickness of screen half of the light is transmitted in each direction regardless of $\mu$. At the limit $\mu \rightarrow 0$ light is produced uniformly throughout the screen, and for thicker screens equal amounts of somewhat less than 50 percent are emitted in each direction, the remainder being absorbed in the screen. For thick screens and high $\mu$, the fraction emitted toward the back is much more than 50 percent, while the light forward is much less. For $\mu = \infty$, all of the light is produced in a layer of zero thickness at the back. Half of the light is immediately emitted backwards and a fraction $R(\epsilon)$ of the remaining half is reflected in addition. The fraction out the front is the transmission coefficient times the half originally directed toward the screen. Thus all the curves of Figs. 10 and 11 approach different limits as $\mu \rightarrow \infty$.

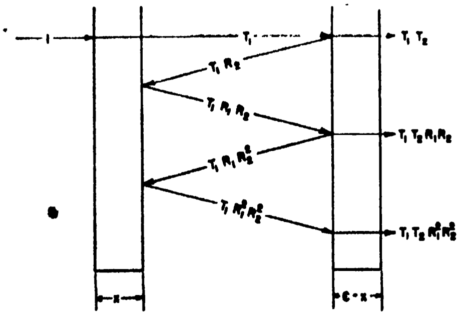

FIG. 9. Light flow diagram for derivation of formula relating partial and total transmission coefficients.

While these curves show wide variations in yields, actually the ranges of $\mu$ and $\epsilon$ usually encountered in practice are such that the fractions forward and back are fairly close to 50 percent. At 80 kv constant potential, $\mu$ is approximately 0.25 per layer; for a screen of $\epsilon = 1$ (Eastman Ultra-Speed front) the fraction forward is 47.6 percent, the fraction back 51.2 percent. At higher voltages little error is introduced by assuming 50 percent each way unless the screen is abnormally thick. At the lower voltages, $\mu$ rises rapidly, attaining a value of 2.2 at 20 kv and 3 at 17.4 kv. Here the fractions out the front and back are markedly affected by the operating voltage.

### Effect of Mounting Card

In practice a screen is never used without a backing of some sort. Usually this is made white, with the intent of recovering the light emitted

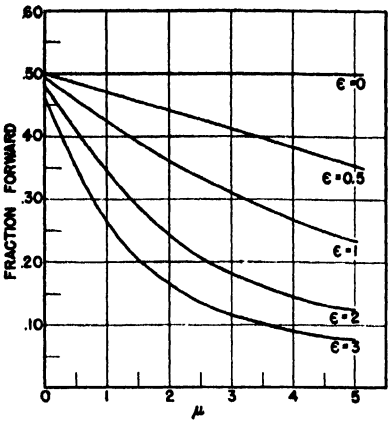

FIG. 10. Fraction of light generated which escapes from the front of the screen as a function of screen thickness ($\epsilon$) and x-ray absorption coefficient ($\mu$).

in the backward direction. The efficacy of this procedure will now be examined. Figure 12 shows schematically a layer of fluorescent material backed by a card of reflection coefficient $R_0$.

The ratio of the light returned to the light emitted backward from the screen is defined as $E$.

$$E = R_0T(1 + RR_0 + (RR_0)^2 + \cdots, \qquad (2.14)$$

$$E = \frac{R_0T}{1 - RR_0}.$$

By way of example, if a screen of thickness $\epsilon = 1$, $R = 0.844$ and $T = 0.15$, is backed by a card of reflection coefficient $R_0 = 0.80$, one finds $E = 0.37$, so of all light which was previously lost out the back of the screen, only 37 percent is recovered by using a backing card of 80 percent reflectivity. This is the result of the "whiteness" of the calcium tungstate; if the card is not of superior reflecting power, it is of small value. Some of this loss is in the layer itself, but the major portion goes into the card. The card upon which the Eastman screen was mounted had a diffuse reflection coefficient of 0.84. Table II illustrates the role played by this mounting card in the light losses. These data were computed for 80 kv, using the constants $k = 6.0$ and $p = 0.33$. At higher voltages very little change takes place in the light distribution, and the tabulated values will remain essentially constant. At lower voltages the losses will increase considerably, reaching a limit at $\mu = 0$ of 52 percent for the thin screen and 74 percent for the thick screen.

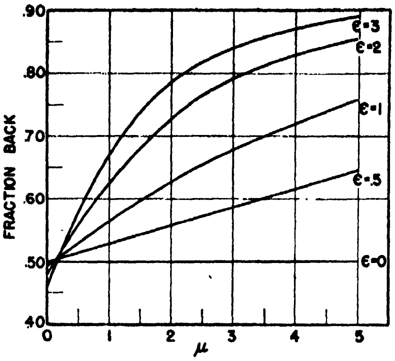

FIG. 11. Fraction of light generated which escapes from the back of the screen as a function of screen thickness ($\epsilon$) and x-ray absorption coefficient ($\mu$).

The increase in light to be expected from the use of a card has been plotted in Fig. 13. At first glance these numbers may seem quite high; however, it must be remembered that in the vast majority of cases $\mu$ is 0.5 or smaller, so that the increase will seldom exceed 40 percent.

Two experimental checks of the above formulas were made. In the first the light from a fluorescent screen was measured with and without a backing card. In the second, two screens of different thickness were measured and the expected relative light output calculated on the basis of the above formulas. Both tests checked calculated values within 3 percent.

So far we have not discussed the variation with thickness of the amount of x-rays absorbed. This, of course, is the most important factor in determining light output for thin screens. With increasing screen thickness the x-rays are more and more nearly completely absorbed; in addi-

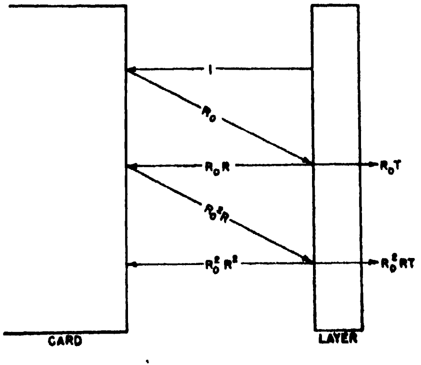

FIG. 12. Light flow diagram for derivation of effect of reflecting card.

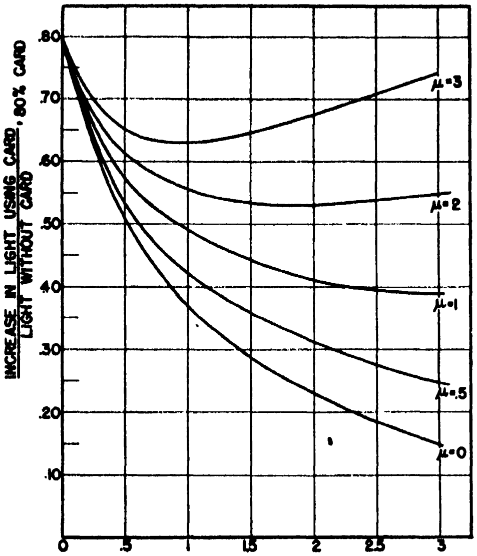

FIG. 13. Increase in light to be gained by using a backing card with 80 percent reflectance, as a function of screen thickness ($\epsilon$) and x-ray absorption coefficient ($\mu$).

tion, the effectiveness of the card backing decreases and losses in the phosphor and binder begin to gain importance. Thus the light output reaches a maximum at a thickness which will depend upon the absorption coefficient (or voltage) of the x-rays. In Figs. 14 and 15 is shown the utilization factor $U$, defined as the ratio of the light obtained from the front of the screen to the total light which would have been generated had all the x-rays been absorbed. The curves of Fig. 14 were calculated for a screen without mounting card, those of Fig. 15 with a mounting card having 100 percent reflection. It will be seen that in practical cases the utilization is seldom over 30 percent.

In the case of a "back" screen one is interested in the light out the back, i.e., toward the x-ray tube. This quantity increases with the screen thickness, but the gain is very slight beyond a certain point. A thick layer of $CaWO_4$ is much whiter than any available cardboard; for a simple example we can just set the thickness of the back screen at infinity and inquire how the utilization factor varies with $\mu$. If $\epsilon$ is infinite, $F_B$ in formula 2.13 is the utilization factor, since all the x-rays are absorbed. The formula reduces to:

$$U_B = [(p+\alpha+k)/2(p+\alpha)](\mu/\mu+p). \quad (2.14)$$

The factor is plotted in Fig. 16 using values of $p$ and $\alpha$ for $CaWO_4$ as before. It is seen that even with an infinitely thick screen the utilization is not very high for $\mu$ less than 0.3, i.e., for x-ray voltages above 80 kv.

In the design of screens for radiographic purposes an all-important consideration is the resolving power of the screen-film combination. In general, the thickness of the screen is largely determined by the stringency of this requirement. No treatment of resolving power is attempted here, because the primary purpose of the investigation is to measure the true efficiency of the $CaWO_4$ screen. The curves in the preceding portion show accurately the light produced as the screen thickness and x-ray absorption coefficient vary, but they form a basis for selection of screen thickness only on the assumption that resolving power is to be ignored. For this reason it is of little value to extend the treatment to

TABLE II. Light losses in two typical x-ray intensifying screens.

| | Thin screen (1 layer) .045 gm/cm² $CaWO_4$ | Thick screen 2.45 layer .109 gm/cm² $CaWO_4$ |
|---|---|---|
| Light lost in phosphor and binder | 2.2% | 9.6% |
| Light lost in mounting card | 28.7% | 36.0% |
| Light yield (total) | 69.1% | 54.4% |

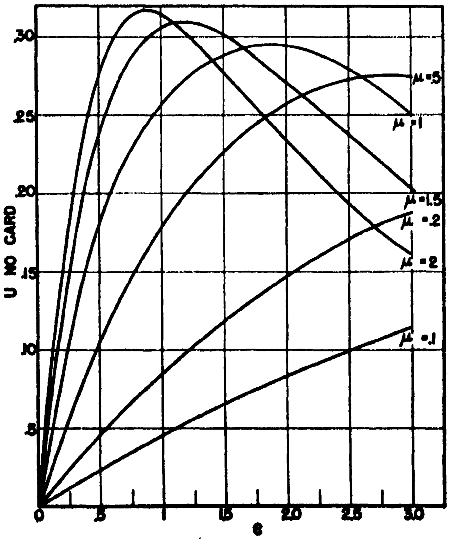

FIG. 14. X-ray utilization factors for a screen with a non-reflecting backing.

other cases, such as a front and back screen combination. The information presented here is sufficient to calculate the light yield of any such combination, given the absorption coefficient, thicknesses, and mounting card reflectances of the screens used.

It should be pointed out here that if the film used with a screen is itself reflecting, all of the light will not be absorbed in the film. Measured white-light reflectances of x-ray screen film are high enough to cause errors of 8 percent with an Ultra-Speed front screen; however, it is quite possible that the reflectance is different for the blue and ultraviolet light of the screens.

## III. EFFICIENCY OF FLUORESCENCE

To obtain the x-ray energy absorbed in the screen, it is necessary to have a knowledge of the energy spectrum of the incident radiation and of the absorption of energy from this spectrum by the screen.

Information as to the exact continuous spectrum of x-ray radiation from a thick target is not available in the literature. Curves originally published by Ulrey[1] have been reprinted in all the texts for 25 years in spite of the fact that they were known to be in serious error at the time of publication. Our use of these curves in combination with the known absorption coefficients of $CaWO_4$ led to obvious and large discrepancies with the measured absorption of the screen, and an independent determination of the x-ray spectrum seemed desirable. Figure 17 shows the energy distribution from the x-ray tube used by us, as determined by Mr. R. L. Longini with a method to be published by him at a later date. This spectrum applies to the tube run at 80 kvc with $\frac{1}{2}$ mm copper and 1 mm aluminum filter. On the same figure is given the curve of energy absorbed by the screen, calculated from the known total absorption coefficients. The integrated areas under these curves, when converted to ionizing power, agreed with our measured absorption value.

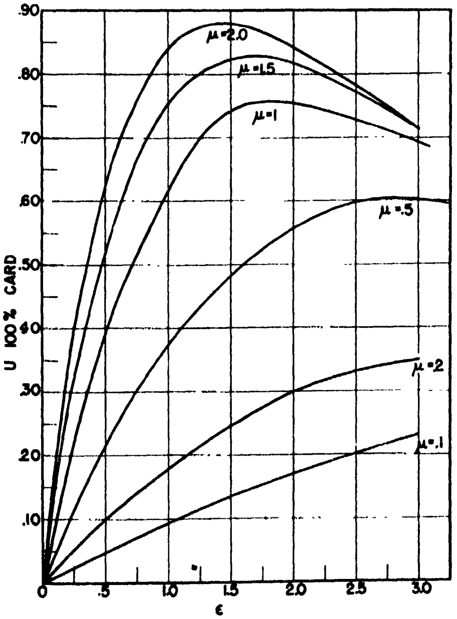

FIG. 15. X-ray utilization factors for a screen with a perfectly reflecting back.

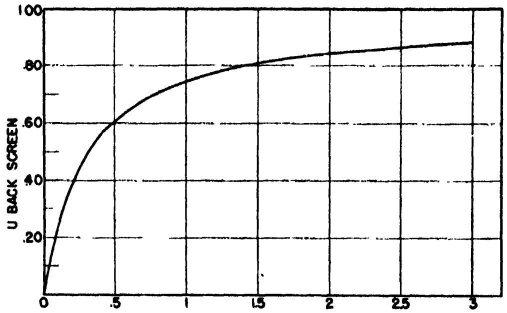

FIG. 16. X-ray utilization factor for a very thick screen used as a back screen, plotted against μ.

All x-radiation which leaves the screen is considered not to be part of the input for the purpose of our computation of conversion efficiency. Our measurement of the undeflected x-ray beam leaving the screen fails to include the scattered and fluorescent x-radiation which leaves under large angles. The former can be shown to be negligible at the voltages used; the latter is important only for energies above the *K*-absorption edge of tungsten. Of the 299 ergs absorbed in the region to the left of the *K*-edge in Fig. 17, absorption by *K*-electron ejection includes 190 ergs which will be re-emitted as *K*-radiation. Of this, about 5 percent is converted into Auger electrons and 26.5 percent of the remainder is reabsorbed in our particular thickness of screen, so that 133 ergs escaped as x-rays. Thus the total x-ray input must be reduced from 714 ergs to 581 ergs.

---

[1] C. T. Ulrey, Phys. Rev. 11, 401 (1918).

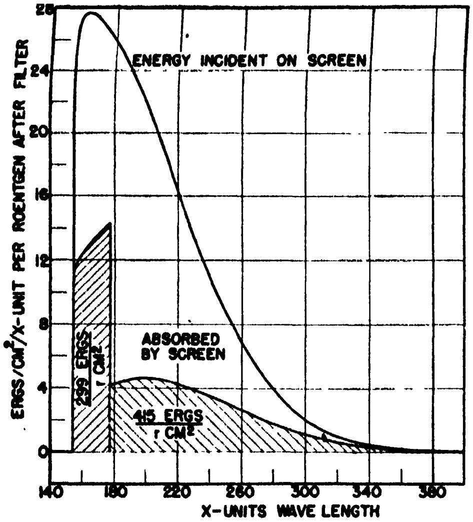

FIG. 17. Spectral energy distributions of x-rays incident on the screen and x-rays absorbed by the screen.

We are now in a position to calculate the efficiency of calcium tungstate. From Part I we have the light out of one side as 2.34 ergs/cm$^2$/sec with an incident radiation of 8.92 r/min. At 581 ergs/cm$^2$ r we have then 86.2 ergs/cm$^2$/sec absorbed in the screen. Thus the "gross" efficiency is 2.72 percent. From Part II, however, we find that the screen emits only 54.5 percent of the light generated, and the intrinsic efficiency of the calcium tungstate is finally found to be 5.0 percent.

This efficiency may be expected to vary only slightly with the wave-length of the x-radiation involved, since one electron ejected by an x-photon excites many fluorescent centers and dissipates its energy gradually.

It is of interest to compute the number of fluorescent centers activated by a single absorbed x-photon. Taking the average wave-length of the absorbed x-rays as 0.22 angstroms, and the average wave-length of the light produced as 4400 angstroms, we see that energetically it would be possible to get 20,000 light quanta from one x-photon. Since the material is only 5 percent efficient, however, on the average each x-photon absorbed produces 1000 light quanta.

# Pressure and Oil Flow in Oil-filled Cables at Load Variations

HANS LOTTRUP KNUDSEN
*Holstebro, Denmark*

(Received September 23, 1946)

This paper presents a method for calculating pressure and oil flow in a section of an oil-filled cable at load variations with due regard to both the hydraulic resistance of the oil canals and the elasticity of the sheath and the pressure armor, if any, and the compressibility of the oil. The present article restricts itself to cable sections terminated with oil reservoirs in which the pressure is constant; in a forthcoming paper this restriction will be dropped. Formulas are given for pressure, oil current, and amount of oil which flows through a cross section of the cable for an arbitrarily prescribed oil expansion per unit length. These formulas are applied to the following oil expansion functions: $S_0\cdot 1$, $d/dt(N_0\cdot 1)$, $e^{-t/T}\cdot 1$, and $1/\sqrt{t}\cdot 1$, which represent the oil expansion or terms occurring in the series giving the oil expansion in some important cases. Generalized functions are plotted for the pressure at the midpoint, the oil current at the endpoints, and the amount of oil which passes the endpoints for the above mentioned oil expansion functions. Using these generalized functions, the calculation of pressure and oil flow, with the simplifying assumptions made here, is reduced to elementary operations. Numerical examples illustrate the use of the given formulas and curves.

---

## LIST OF SYMBOLS

| | | |
|---|---|---|
| $a$ | cm$^2$ | Area of oil canal. |
| $A$ | cm$^2$ | Oil volume per unit length. |
| $c$ | kg$^{-1}$ cm$^4$ | Capacitance per unit length. |
| $c_1$ | kg$^{-1}$ cm$^4$ | Capacitance per unit length corresponding to the elasticity of sheath and pressure armor. |
| $c_2$ | kg$^{-1}$ cm$^4$ | Capacitance per unit length corresponding to the compressibility of oil. |
| $C$ | kg$^{-1}$ cm$^5$ | Capacitance of the entire cable. |
| $d$ | cm | Diameter of oil canal in single-core cable. |
| $D$ | cm | Diameter of cable under sheath. |
| $E$ | kg cm$^{-2}$ | Modulus of elasticity for the sheath material. |
| $f$ | cm | Perimeter of the conductors in which short-circuit current flows. |
| $F(x)$ | 1 | Function defined in (54). |
| $I(x, t)$ | cm$^3$ sec.$^{-1}$ | Current of oil. |
| $k$ | kg$^{-1}$ cm$^2$ | Specific compressibility of oil. |
| $K_0$ | cm$^2$ sec.$^{-\frac{1}{2}}$ | Constant factor in an expression for the oil expansion. |
| $l$ | cm | Arbitrarily defined length in cable cross section. |
| $L$ | cm | Length of cable. |
| $M(x, t)$ | cm$^3$ | Amount of oil which flows through a cross section of the cable. |
| $N_0$ | cm$^2$ | Instantaneous oil expansion per unit length. |
| $p$ | °C cm $W^{-1}$ | Specific thermal resistance for insulation. |
| $P(t)$ | cm$^{-1}$ $W$ | Effect transferred from conductors to insulation per unit length. |
| $q$ | °C$^{-1}$ cm$^{-3}$ $W$ sec. | Specific heat of insulation. |
| $r$ | kg cm$^{-6}$ sec. | Hydraulic resistance in cable per unit length. |
| $R$ | kg cm$^{-5}$ sec. | Hydraulic resistance of entire cable. |
| $S(t)$ | cm$^2$ sec.$^{-1}$ | Oil expansion per unit time per unit length. |
| $S_0$ | cm$^2$ sec.$^{-1}$ | Constant factor in expression for oil expansion. |
| $t$ | sec. | Time. |
| $T$ | sec. | Time constant occurring in the expression for oil expansion. |
| $V(x, t)$ | kg cm$^{-2}$ | Pressure. |
| $\beta$ | °C$^{-1}$ | Volumetric expansion coefficient of oil. |
| $\beta'$ | °C$^{-1}$ | Volumetric expansion coefficient of insulation. |
| $\gamma$ | g cm$^{-3}$ | Density of oil. |
| $\delta$ | cm | Sheath thickness. |
| $\vartheta(x, t)$ | °C | Temperature in insulation. |
| $\vartheta_0$ | °C | Temperature of conductors after short circuit. |
| $\nu$ | centistokes | Viscosity of oil. |

## PRESSURE AND FLOW QUALITATIVELY REGARDED

IN the calculation of oil-filled cable systems it is important to have a method for computing the variations of the pressure for a certain system under the most severe load variations to which it can be subjected in service. These commonly consist of (1) switching off the load and (2) short circuiting. In the first case the oil in the cable is cooled and consequently the pressure decreases below the normal value until an amount of oil equaling the contraction of the oil has flowed into the cable. In consequence of the diminished pressure the electrical strength of the cable may decrease so much that breakdown occurs. On the other hand, in the case of a short circuit the oil expands rapidly because of the rise in temperature, and the pressure in the cable will for some time increase and later decrease as the surplus of the oil flows towards the oil reservoirs of the system. In the case of a short circuit the pressure in the cable may increase so much that there is a risk of the sheath and the pressure armor being destroyed.

All calculations of the pressure must be based upon the variations of the temperature in the cable with the given load variations. Several methods of computing the variations of the temperature and the oil expansion at load variations in cables placed under different circumstances have been described in the literature. Some of these methods will be mentioned later.

When the oil expansion has been calculated, the variations of the pressure and the oil flow will be investigated. The dependence of the temperature on load variations has been treated thoroughly in the literature. That is not the case with the pressure and the oil flow.

In many cases the increase or decrease in pressure for the greatest expansion of oil per unit time at load variations has been calculated under the assumption of stationary oil flow in the cable. For oil cable systems with different types of oil reservoirs, Emanueli[1] has developed a theory for the calculation of pressure and oil flow, in which the pressure drop along the cable is calculated as if the oil flow were stationary. Shanklin and Buller[2] make the same assumption in their calculations of the pressure drop.

H. Spanne, chief engineer at Sieverts Kabelverk, Sundbyberg, Sweden, however, demonstrated about ten years ago in a factory bulletin, that the elasticity of the sheath and of the pressure armor, if any, and the compressibility of the oil in an oil-filled cable greatly limit the pressure variations occurring at load changes. Spanne has also made an estimate of the pressure variations.

In the present article a method has been developed for calculating the variations of pressure and the oil flow in an oil-filled cable with reservoirs at both ends, for an oil expansion given as a function of the time, with due regard to the flow resistance in the cable as well as to the elasticity of the sheath and the presssure armor, if any, and to the compressibility of the oil. Only those cases in which the expansion of oil per unit time and per unit length is the same at every point of the cable have been treated here.

## SIMPLIFYING ASSUMPTIONS

The following assumptions are the most important of those made in this paper:

1. All deformations in the cable are purely elastic.
2. No force is needed to accelerate the oil in the canals.
3. The viscosity of the oil in the oil canals is constant.
4. The pressure in the oil reservoirs is constant.

Assumptions 1 and 2 are approximately satisfied in most practical oil-filled cables. As the viscosity of the oil varies much with the temperature, 3, however, is not well satisfied. The difficulties involved in solving the problem are, however, greatly increased if assumption 3 is not made. Assumption 4 is well satisfied for cable systems with oil reservoirs consisting of oil tanks with atmospheric pressure at the surface of the oil. However, assumption 4 is often rather well satisfied in other types of oil reservoirs, too, as the oil expansion in the cable for a load variation often is small compared with the oil expansion corresponding to the total temperature variation for which the system has been constructed. (The total temperature includes, for instance; the seasonal change of temperature.) This statement applies especially in the case of a short circuit in which the temperature of the conductors may certainly be rather high, but in which the total developed heat energy, and consequently also the oil expansion, often are small.

An article is being prepared, in which assumption 4 is not made, due regard on the contrary being given to the characteristics of different oil reservoirs.

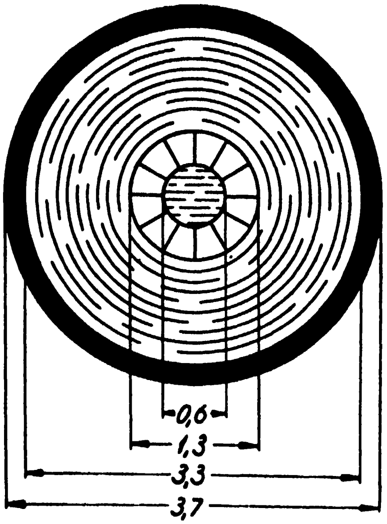

FIG. 1. Single core oil-filled cable, $77/\sqrt{3}kV$, 1×95 mm.[2]

## MATHEMATICAL FORMULATION

The mathematical expressions for the flow in an oil-filled cable depend on how the flowing medium is defined. This, for example, can be defined as the mass of the oil, or as the volume of the oil. Here we shall base the calculations on a third and more convenient definition, defining the flowing medium as the volume of the oil reduced to constant pressure.

The amount of medium per unit length at a certain point of the cable will then increase proportionally to the pressure because of the elasticity of the sheath and of the pressure armor, if any, as well as of the compressibility of the oil. We define the capacitance per unit length, $c$, as the ratio of the increase in amount of medium per unit length to the increase of pressure. The capacitance $c$ is then composed of two parts, one part $c_1$, arising from the elasticity of the sheath and the pressure armor, and another part $c_2$, arising from the compressibility of the oil.

When no pressure armor is present, the capacitance $c_1$ for a cable with a sheath of thickness $\delta$, diameter $D$, and modulus of elasticity $E$ is

$$c_1=\frac{\pi D^3}{4\delta E}. \tag{1}$$

It is a trivial matter to develop the corresponding formula for cables with a pressure armor.

$c_2$ is calculated from the compressibility of the oil, $k$, and the amount of oil per unit length, $A$.

$$c_2=kA. \tag{2}$$

$c$ is thus

$$c=c_1+c_2. \tag{3}$$

The current of the medium is defined as the amount of oil which passes a section of the cable per unit time. The resistance per unit length is defined as the ratio of the pressure drop per unit length to the current.

The flow at the moderate currents in question will be laminar, and $r$ can consequently be expressed as follows,[3]

$$r=B\frac{\gamma\nu}{l^4}, \tag{4}$$

where $\gamma$ is the density, $\nu$ the kinematic viscosity of the oil, $l$ a length which increases proportional to the linear dimensions of the section of the oil canal, and $B$ a constant which merely depends on the shape of the oil canal and the way in which $l$ has been defined. If $l$ stands for the inner diameter of oil canals with a circular section one gets

$$B=\frac{128}{9.81\cdot\pi}\cdot 10^{-7}=4.15\cdot 10^{-7}.$$

For a cable with a length $L$ the total capacitance is $C=Lc$ and the total resistance $R=Lr$. The time constant $RC$ for the oil flow in the cable is a measure of the rate at which disturbances in the state of equilibrium of the cable are smoothed. In order to give an idea of the order of magnitude of the time constant it has been computed below in a practical case for two different temperatures.

### Example 1

The time constant at the temperatures 20°C and 40°C shall be calculated for an oil-filled cable $77\sqrt{3}kV$, 1×95 mm², without pressure armor and with the principal dimensions as shown in Fig. 1.

$D=3.3$ cm,

$d=0.6$ cm,

---

[3] *Handbuch der Physik* (1927), Vol. 7, p. 103.

$$\delta = 0.2\ \text{cm},$$

$$A = 3.3\ \text{cm}^2,$$

$$L = 10^5\ \text{cm},$$

$$E = 1.7\cdot 10^5\ \text{kg cm}^{-2},$$

$$k = 8\cdot 10^{-5}\ \text{kg cm}^2,$$

$$\gamma\nu = \begin{cases} 44.8\ \text{centipoise for } 20^\circ\text{C} \\ 16.4\ \text{centipoise for } 40^\circ\text{C}, \end{cases}$$

$$c_1 = \frac{\pi\cdot 3.3^3}{4\cdot 0.2\cdot 1.7\cdot 10^5} = 8.3\cdot 10^{-4}\ \text{kg}^{-1}\ \text{cm}^4,$$

$$c_2 = 8\cdot 10^{-5}\cdot 3.3 = 2.6\cdot 10^{-4}\ \text{kg}^{-1}\ \text{cm}^4,$$

$$c = 1.09\cdot 10^{-3}\ \text{kg}^{-1}\ \text{cm}^4,$$

$$r = \frac{128}{9.81\cdot\pi}\cdot 10^{-7}\cdot\frac{\gamma\nu}{0.6^4} = 3.2\cdot 10^{-6}\cdot\gamma\nu$$

$$= \begin{cases} 1.43\cdot 10^{-4}\ \text{kg cm}^{-6}\ \text{sec. for } 20^\circ\text{C} \\ 5.3\cdot 10^{-5}\ \text{kg cm}^{-6}\ \text{sec. for } 40^\circ\text{C}, \end{cases}$$

$$RC = rcL^2 = \begin{cases} (1.43\cdot 10^{-4})\cdot(1.09\cdot 10^{-3})\cdot 10^{10} \\ \qquad = 1560\ \text{sec. for } 20^\circ\text{C}, \\ (5.3\cdot 10^{-5})\cdot(1.09\cdot 10^{-3})\cdot 10^{10} \\ \qquad = 580\ \text{sec. for } 40^\circ\text{C}. \end{cases}$$

This example shows that the time constant for the oil flow is not negligible compared to the intervals of time commonly necessary for smoothing the temperature in a cable under load variations. This means that the elasticity of the sheath and the compressibility of the oil will limit the pressure variations in the cable with changes in load.

The differential equations and the boundary conditions for the oil flow will now be given. Because we have assumed that the cable has constant parameters, without making the treatment of the problem less general we can suppose that the static pressure in the cable and consequently also the pressure at the endpoints of the cable are zero at any moment. Over the dynamic pressure distribution, calculated according to this assumption, we can thus superimpose the static pressure distribution in the cable. In this paper only the dynamic pressure distribution is considered. For a given oil expansion per unit length of the cable per unit time, $S(t)$, we shall calculate as functions of time and position the pressure $V$, the current $I$, and the amount of oil which flows through a cross section of the cable, $M$.

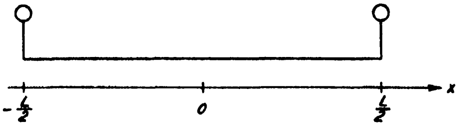

FIG. 2. Coordinate system along a cable section terminated with oil reservoirs.

A coordinate axis is placed along the cable with the origin at the midpoint (see Fig. 2). $V$ and $I$ then satisfy the following partial differential equations.

$$c\frac{\partial V}{\partial t} = \frac{1}{r}\frac{\partial^2 V}{\partial x^2} + S, \tag{5}$$

$$I = -\frac{1}{r}\frac{\partial V}{\partial x}, \tag{6}$$

$$V = 0 \text{ for } x = \begin{cases} -L/2 \\ L/2 \end{cases} \quad 0 < t < \infty, \tag{7}$$

$$V = 0 \text{ for } t < 0, \quad -L/2 < x < L/2. \tag{8}$$

Equations formally identical with the equations given above are obtained for several problems within other domains of physics. Suppose we have a metallic wire, isolated against heat, the length being $L$, with the heat conduction resistance per unit length $r$, the heat capacitance per unit length $c$, and with the endpoints at the temperature zero. If an electrical current producing the effect per unit length $S(t)$ is flowing in the wire, the temperature $V$ and the heat current $I$ satisfy Eqs. (5)–(8).

There also exists an electrical analogy to the problem in question. If current sources of the strength per unit length $S(t)$ are supposed homogeneously distributed along a telegraph cable of length $L$, without inductance and leakage but with resistance per unit length $r$, capacitance per unit length $c$ (Thomson cable), and with the ends short-circuited, the potential $V$ and the current $I$ will satisfy Eqs. (5)–(8).

In the oil-flow problem the mass of the oil corresponds to the inductance of the cable in the electrical analogy. The mass of the oil has no corresponding meaning in the problem of heat conduction.

It is convenient to solve first the problem given by Eqs. (5)–(8) for $S(t)=S_0\cdot 1$, where $S_0$ is a constant.

### PRESSURE AND FLOW WITH CONSTANT OIL EXPANSION $S_0\cdot 1$

The thermal analogy to this problem has been treated by Straneo,[4] Schaufelberger,[5] and Weinreich[6] for use in measuring the electrical and thermal constants of metallic wires. The authors mentioned above solve the problem by use of eigenfunctions following classical methods.

The problem, however, is very conveniently solved by Heaviside's operational calculus. The appropriate method has been described e.g., by Dahr[7] in his treatment of the telegraphist's equation for transmission lines in which electromotive forces are induced. (See also Jeffrey's treatment of related problems.[8]) For convenient reference the application of the method on the present problem is briefly outlined below.

Introducing the operators

$$\mathfrak{L}V(x,t)=v(x,p),\tag{9}$$

$$\mathfrak{L}I(x,t)=i(x,p),\tag{10}$$

Eqs. (5)–(8) are transformed into the following equations:

$$cpv=-\frac{1}{r}\frac{d^2v}{dx^2}+S_0,\tag{11}$$

$$i=-\frac{1}{r}\frac{dv}{dx},\tag{12}$$

$$v=0\ \text{for}\ x=\begin{cases}-L/2\\ L/2.\end{cases}\tag{13}$$

First the more simple problem of a point source 1 acting at the point $x=\xi$ is solved. For the pressure and the current in this problem the differential equations that are obtained from (11) and (12) by setting $S_0=0$ are valid, while to the boundary condition (13) are added the conditions

$$v(\xi-0)=v(\xi+0),\tag{14}$$

$$i(\xi-0)+1=i(\xi+0).\tag{15}$$

As the solution of this problem one gets the following expression for the pressure, which in this special case will be called $w(x,\xi)$,

$$w(x,\xi)=\begin{cases}-rL\dfrac{\sinh\left(-\frac{1}{2}+\frac{\xi}{L}\right)(pRC)^{\frac{1}{2}}\sinh\left(\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}}}{(pRC)^{\frac{1}{2}}\sinh(pRC)^{\frac{1}{2}}}=w_1(x,\xi)\ \text{for}\ -\dfrac{L}{2}<x<\xi\\[2ex] -rL\dfrac{\sinh\left(\frac{1}{2}+\frac{\xi}{L}\right)(pRC)^{\frac{1}{2}}\sinh\left(-\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}}}{(pRC)^{\frac{1}{2}}\sinh(pRC)^{\frac{1}{2}}}=w_2(x,\xi)\ \text{for}\ \xi<x<\dfrac{L}{2}.\end{cases}\tag{16}$$

The expression for $v$, in the case of a constant, homogenously distributed source, is now obtained by integration of $S_0w$ over the entire length of the cable

$$v(x,p)=S_0\int_{-L/2}^{L/2}w(x,\xi)d\xi=S_0\left[\int_{-L/2}^{x}w_2(x,\xi)d\xi+\int_{x}^{L/2}w_1(x,\xi)d\xi\right]$$

$$=S_0rL^2\left[\frac{1}{pRC}-\frac{\sinh\left(\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}}-\sinh\left(-\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}}}{pRC\sinh(pRC)^{\frac{1}{2}}}\right].\tag{17}$$

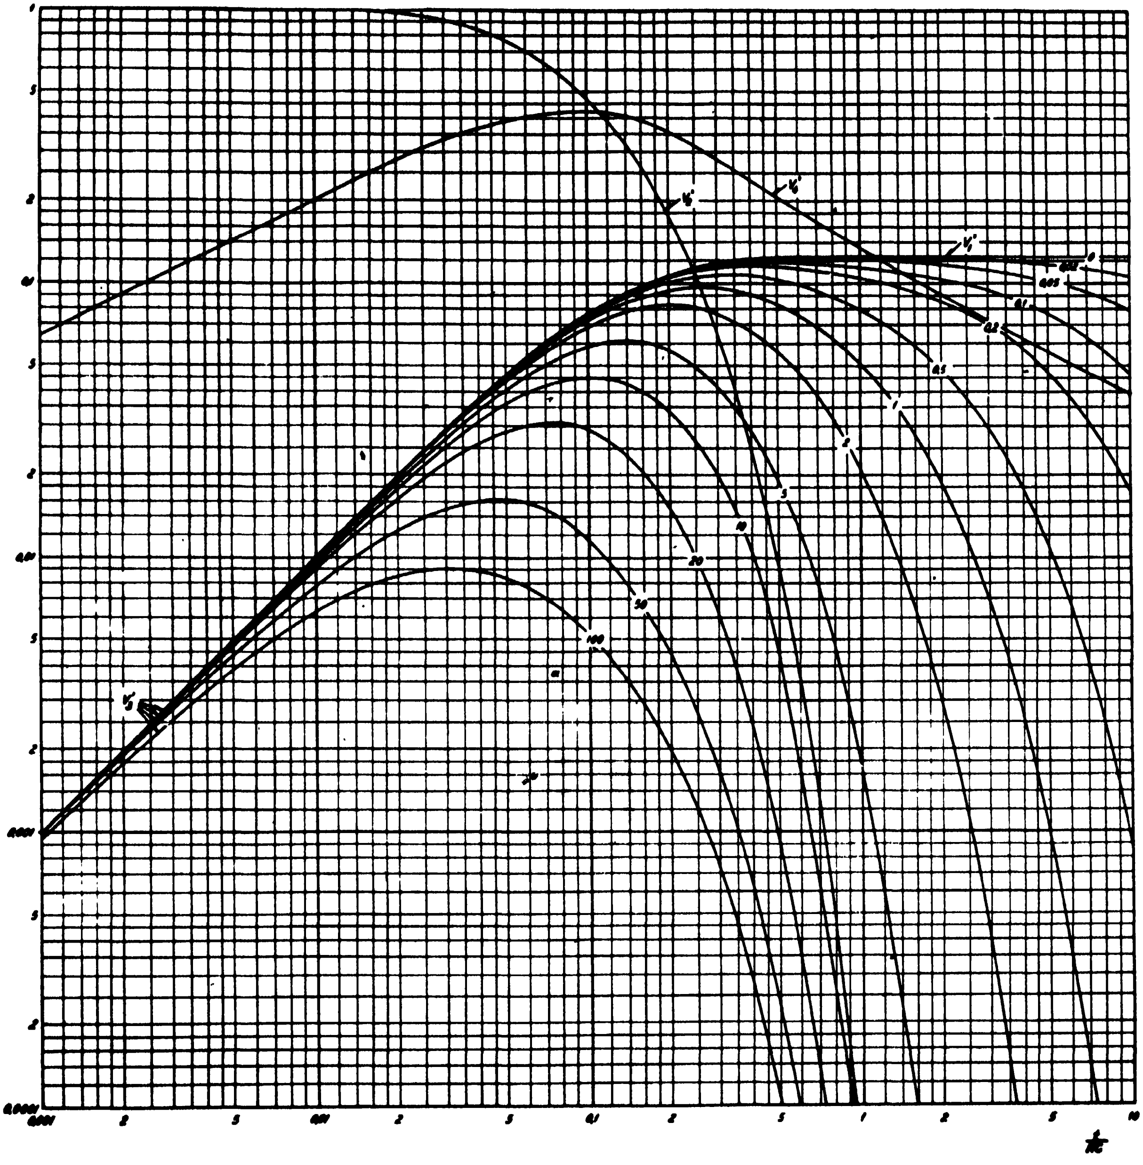

FIG. 3. Generalized functions used in the calculation of the pressure at the midpoint of a cable section with a time constant for the oil flow *RC*.

$V_1'(t/RC)$ applies in the case of an oil expansion $S(t)=1\cdot 1$.
$V_2'(t/RC)$ applies in the case of an oil expansion $S(t)=(d/dt)(1\cdot 1)$.
$V_3'(t/RC)$ applies in the case of an oil expansion $S(t)=e^{-\alpha t/RC}\cdot 1$.
$V_4'(t/RC)$ applies in the case of an oil expansion $S(t)=1/(t)^{\frac{1}{2}}\cdot 1$.

The time function for operators of this type can be obtained either by expanding the operator in an infinite series of terms containing exponential functions and transforming this series, term by term, or by applying Heaviside's expansion theorem. The first method corresponds to expressing the solution in reflected waves as demonstrated e.g., by Wagner,[9] whereas by the last method the solution is expressed in eigenfunctions. Here we shall use the last method.

According to Heaviside's expansion theorem the time function $H(t)$ that corresponds to an

---

[9] K. W. Wagner, Operatorenrechnung (Johann Ambrosius Barth Verlag, Leipzig, 1940), p. 196.

operator $f(p)/g(p)$, where $f(p)$ and $g(p)$ are functions of $p$, which satisfy certain conditions, and where $g(p)=0$ has the simple roots $p_n$, $n=1, 2, 3, \cdots$, is

$$H(t)=\mathfrak{L}^{-1}\frac{f(p)}{g(p)}=\frac{f(0)}{g(0)}+\sum\frac{f(p_n)e^{p_nt}}{p_ng'(p_n)}. \tag{18}$$

If we write the operator $v$ (17) as follows

$$v=\frac{f(p)}{g(p)}, \tag{19}$$

where

$$f(p)=S_0rL^2\frac{1}{(pRC)^{\frac{1}{2}}}\bigg[\sinh(pRC)^{\frac{1}{2}} -\sinh\left(\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}} +\sinh\left(-\frac{1}{2}+\frac{x}{L}\right)(pRC)^{\frac{1}{2}}\bigg], \tag{20}$$

$$g(p)=(pRC)^{\frac{1}{2}}\sinh(pRC)^{\frac{1}{2}}, \tag{21}$$

$v=f(p)/g(p)$ satisfies the conditions for the use of the formula (18). The roots of the equation

$$g(p)=(pRC)^{\frac{1}{2}}\sinh(pRC)^{\frac{1}{2}}=0, \tag{22}$$

different from zero are

$$(p_nRC)^{\frac{1}{2}}=\pm jn\pi, \quad n=1, 2, 3, \cdots, \tag{23}$$

or

$$p_n=-\frac{n^2\pi^2}{RC}, \quad n=1, 2, 3, \cdots. \tag{24}$$

The time function $V=\mathfrak{L}^{-1}v$ is then

$$V(x, t)=S_0rL^2\Bigg\{\frac{1}{8}-\frac{1}{2}\left(\frac{x}{L}\right)^2 -\frac{4}{\pi^3}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3}\cos\frac{x}{L}(2n+1)\pi \times\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\Bigg\}. \tag{25}$$

For $t=0$ the term containing the sign of summation expresses the Fourier series of $\frac{1}{8}-\frac{1}{2}(x/L)^2$ in the interval $-L/2<x<L/2$. $V$ can thus be expressed in the following way

$$V(x, t)=S_0rL^2\frac{4}{\pi^3}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3}\cos\frac{x}{L}(2n+1)\pi \times\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \tag{26}$$

For $x=0$ this leads to

$$V(0, t)=S_0rL^2\frac{4}{\pi^3}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3} \times\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \tag{27}$$

$[V(0, t)/S_0rL^2]=V_1'$ has been plotted as a function of $t/RC$ in Fig. 3.

$I$ is calculated from (6) and (26)

$$I(x, t)=S_0L\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}\sin\frac{x}{L}(2n+1)\pi \times\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \tag{28}$$

For $x=\pm L/2$ this leads to

$$I\left(\pm\frac{L}{2}, t\right)=\pm S_0L\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2} \times\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \tag{29}$$

$[I(\pm(L/2), t)/\pm S_0L]=I_1'$ has been plotted as a function of $t/RC$ in Fig. 4.

The amount of oil which flows through a cross section of the cable, $M$, is calculated by integrating the expression for $I$, given above.

$$M(x, t)=\int_0^t I(x, \lambda)d\lambda=S_0rcL^3\Bigg\{\frac{x}{L}\frac{t}{RC} -\frac{4}{\pi^4}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^4}\sin\frac{x}{L}(2n+1)\pi \times\left[1-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right]\Bigg\}. \tag{30}$$

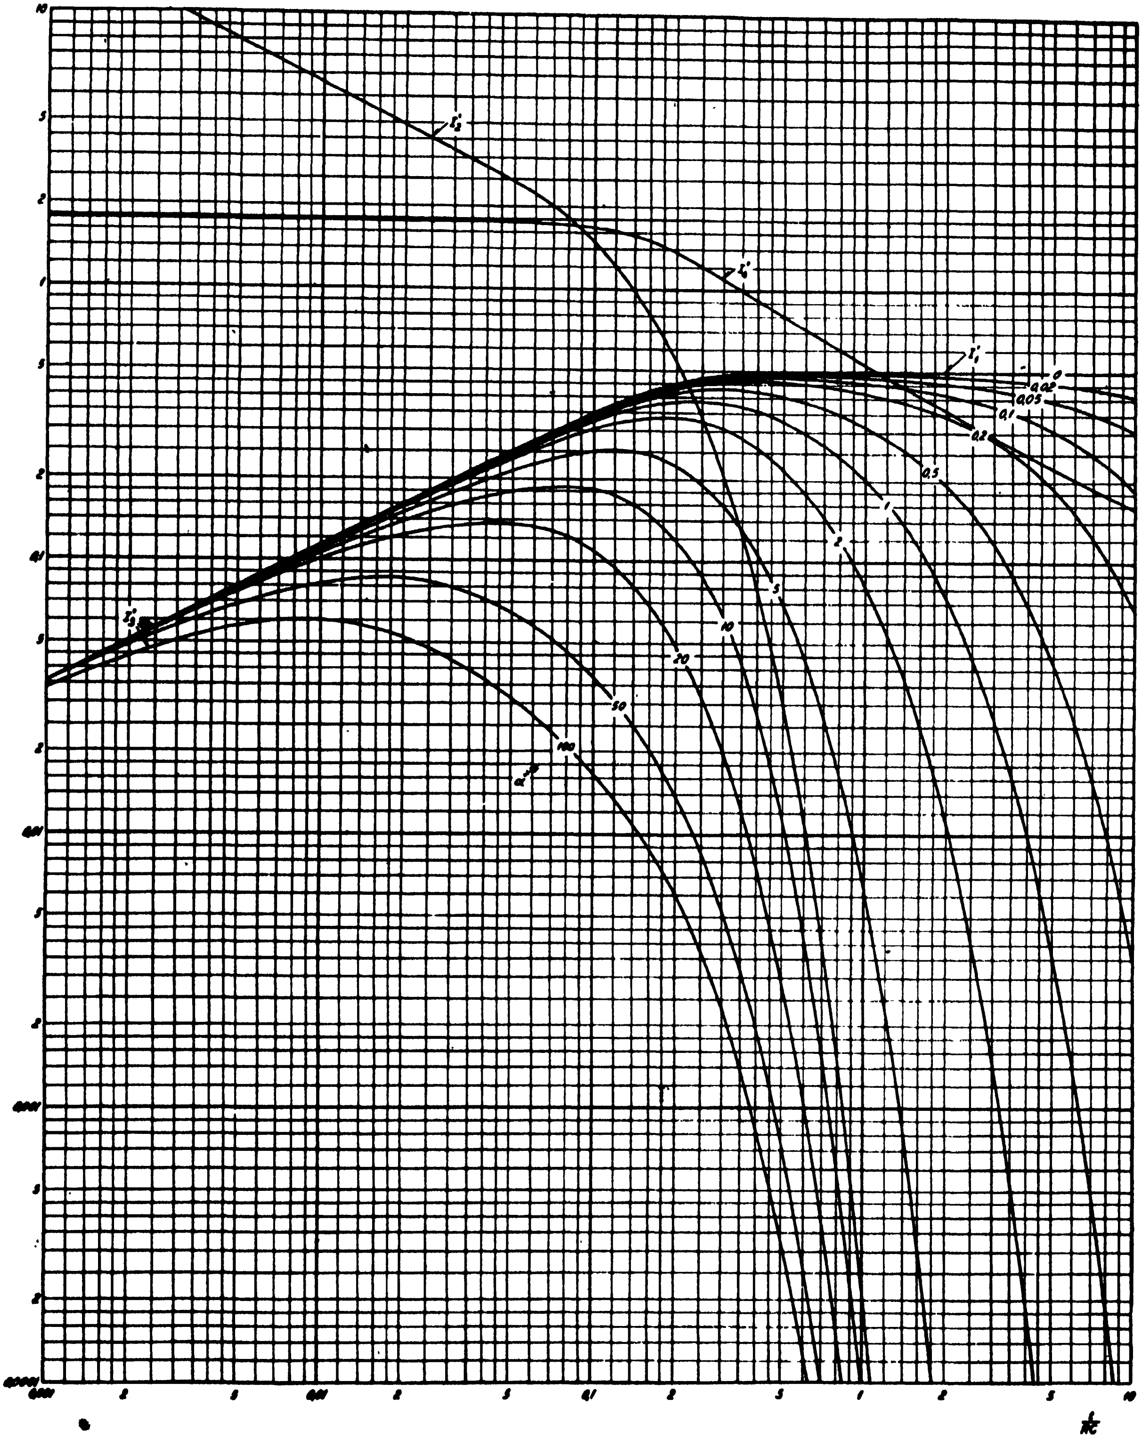

FIG. 4. Generalized functions used in the calculation of the oil current at the endpoints of a cable section with a time constant for the oil flow $RC$.

$I_1'(t/RC)$ applies in the case of an oil expansion $S(t)=1\cdot 1$.
$I_2'(t/RC)$ applies in the case of an oil expansion $S(t)=(d/dt)(1\cdot 1)$.
$I_3'(t/RC)$ applies in the case of an oil expansion $S(t)=e^{-\alpha t/RC}\cdot 1$.
$I_4'(t/RC)$ applies in the case of an oil expansion $S(t)=1/(t)^{\frac{1}{2}}\cdot 1$.

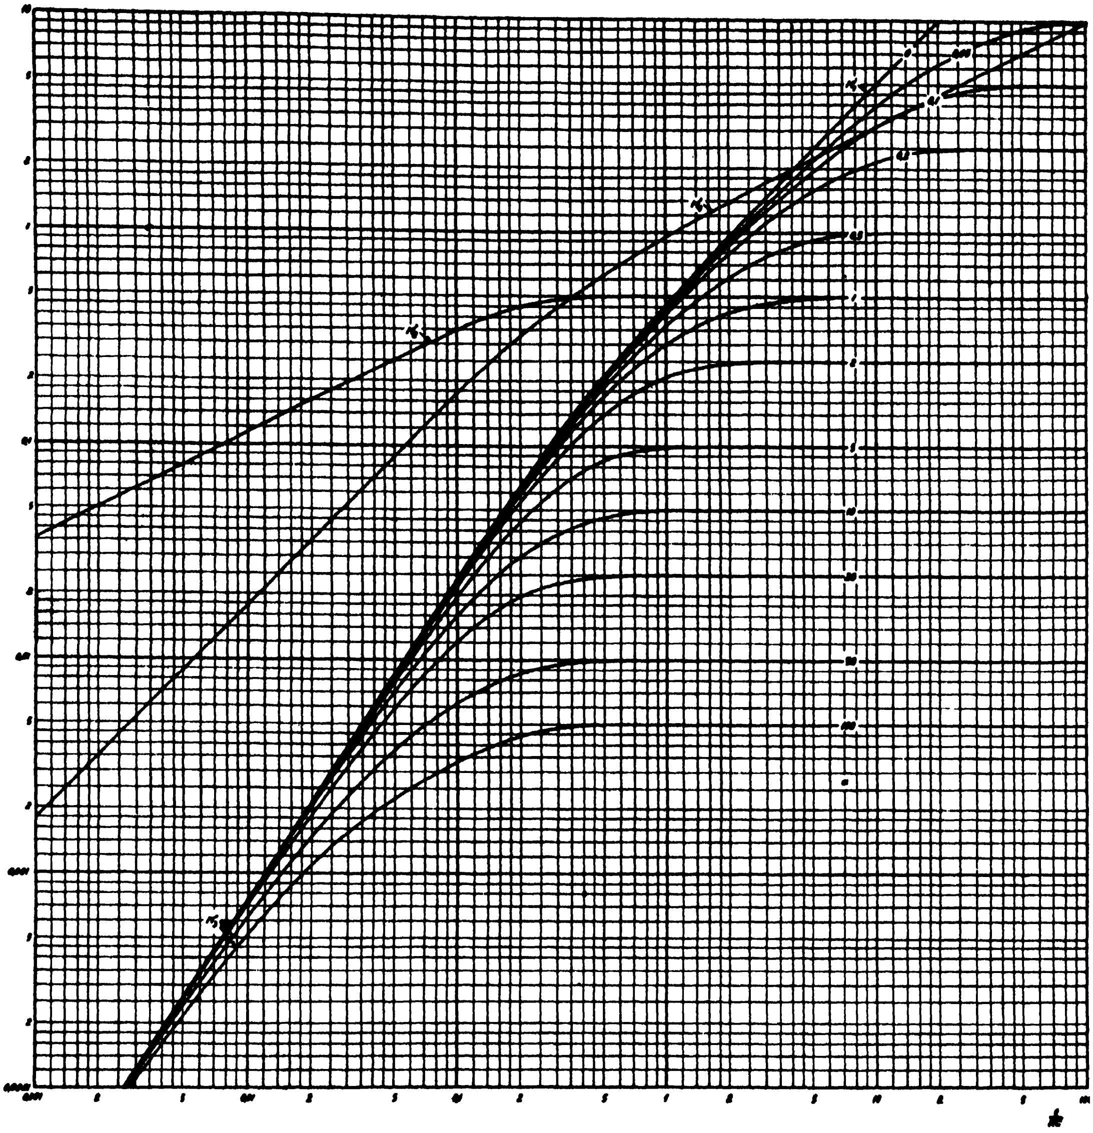

FIG. 5. Generalized functions used in the calculation of the amount of oil which passes the endpoints of a cable section with a time constant for the oil flow $RC$.

$M_1'(t/RC)$ applies in the case of an oil expansion $S(t)=1\cdot 1$.
$M_2'(t/RC)$ applies in the case of an oil expansion $S(t)=(d/dt)(1\cdot 1)$.
$M_3'(t/RC)$ applies in the case of an oil expansion $S(t)=e^{-\alpha t/RC}\cdot 1$.
$M_4'(t/RC)$ applies in the case of an oil expansion $S(t)=1/(t)^{\frac{1}{2}}\cdot 1$.

For $x=\pm L/2$ this leads to

$$M\left(\pm\frac{L}{2},t\right)=\pm S_0 rcL^3\left\{\frac{t}{2RC}-\frac{4}{\pi^4}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^4}\times\left[1-\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right]\right\}. \quad (31)$$

$[M(\pm(L/2),t)/\pm S_0 rcL^3]=M_1'$ has been plotted as a function of $t/RC$ in Fig. 5.

In consequence of the linearity of the partial differential equations for the flow, the pressure, current and amount of oil which flows through a cross section of the cable for an arbitrary oil expansion $S(t)\cdot 1$ can be calculated from the corresponding solutions, given above, valid for an oil expansion of the form $S_0\cdot 1$. The linearity of the differential equations also causes the action (the pressure, the current, or the amount of oil) of an oil expansion given as a sum of time functions, to be obtained as the sum of the actions of the individual terms of which the oil expansion consists.

First it is necessary to mention some methods described in the literature for calculating the oil expansion in oil-filled cables for different types of load variations. Then the pressure, current, and amount of oil which flows through a cross section of the cable will be calculated for some important time functions of the oil expansion.
